A man, aged forty-two, was admitted into Ward 17, Bellevue Hospital, October 29, 1877, who had been well and strong up to August 15, 1877, when he was seized with a sudden, severe pain in the epigastric region, accompanied by vomiting, the pain radiating toward the back and right shoulder. The pain lasted all night, but in the morning it passed away. No jaundice followed. On September 29th he had a second attack, similar to the first. Was not a steady vomitor of blood. On November 15th this tumor was only more severe in character. After this did not regain his former health; bowels constipated; and in about ten days noticed jaundice, which followed close upon a feeling he described as "something seemed to burst in his stomach, and he felt as if he was going to die." From this on jaundice steadily increased, with constant nausea. On admission the liver measured about 5 inches in the axillary line, and attached to liver in about the relation of the gall-bladder was a tumor, being in the epigastric and right hypochondriac regions, moving with the liver during forcible respiration and having a pulsation synchronous with the aorta. The tumor was tender on pressure, and about 4 inches in its transverse diameter. On November 13th this tumor was aspirated and four ounces of a reddish-yellow fluid drawn off, which, after standing, showed a well-marked clot in the centre.

The day following tumor was about one-third its former size. On the second day following the aspiration, the tumor was larger than ever before, measuring 4 1/2 inches transverse, 6 inches in length, and the patient vomits constantly, but vomited matter contains no blood-corpuscles. On December 6th it is noted that patient is very deeply jaundiced and very much emaciated. December 17th, was suddenly seized with a sharp pain, like that which he had before, and almost immediately afterward he became unconscious. On examination the tumor could not be found. He died at 3 P.M.
Autopsy.—The liver was about normal in size, showed some increase in connective tissue, was deeply stained with bile, the gall-bladder was full of bile, but not enlarged. The cystic and common ducts were pervious. The stomach was small and its walls thickened, the pyloric end being particularly so, and attached to the side of the larger pancreatic cyst. This pancreatic cyst had thick walls and was partly filled with a bright yellow mucus, the pancreatic duct was found to open into it. This cyst took the place of the head and part of the body of the gland, and would have contained about eight ounces. The small intestines were pushed to the left side. This cyst pressed upon the duodenum communis choleodochus and obliterated it. The tail of the pancreas had also degenerated into a small cyst.

In looking over the literature on these subjects the following points seem worthy of attention: Primary cancer of the head of the pancreas is relatively rare, according to Friedrich. Foerster only saw 6 cases of cancer of pancreas, and all these as secondary growths, in 639 autopsies in all kinds of disease (quoted by Friedrich in "Ziemsen"). Dr. Norman Moore, however, in "St. Bartholomew's Hospital Reports," vol. xvii., 1881, says that in 39 cases of cancer of pancreas the new growth was probably primary in 15 cases. Friedrich and Bartholow both speak of tumor being absent on physical examination and a portion of cases cancer of pancreas. Da Costa reported a tumor in only 13 out of 37 cases. Bigs found a tumor in only 4 out of 15 cases. Dr. Norman Moore does not speak of a tumor being felt in any of his cases. Jaundice is a common symptom of this trouble, and in Dr. Moore's cases where the cancer was primary jaundice was always present. In 14 cases of secondary growth, jaundice was reported. Dr. M. jaundice was present in only 7 of the cases. Murchison mentions persistent jaundice, pain in pancreatic region, and a sensible tumor as the symptoms of cancer of pancreas. In two of the cases described by Dr. Moore, the occlusion of this common duct was due to the pressure of the tumor at head of pancreas, as in the specimen before you. Friedrich and Bartholow speak of a tumor being often found in cystic degeneration of pancreas. In the specimen before you no tumor was felt during life, although carefully searched for, and vomiting did not occur until toward the close of life, whereas in the case of cystic degeneration a tumor was observed on admission and vomiting was an early symptom and would be observable in character. In both cases jaundice was intense.

TUBERCULOSIS TESTICULI.

Dr. John A. Wyeth presented the left testicle of a patient, twenty-seven years of age, who gave a history of a slowly developing inflammation during the last two years, but not the result of traumatism. There was no history of syphilis. There was a history of tubercular predisposition. There was a general broken-down condition of the testicle, and at two or three points ulceration had occurred, and there was pus in the tunica vaginalis, possibly extending into the substance of the testis. There were 14 cases of testicular growth tabulated by Dr. M., jaundice was present in only 7 of the cases. Murchison mentions persistent jaundice, pain in pancreatic region, and a sensible tumor as the symptoms of cancer of pancreas. In two of the cases described by Dr. Moore, the occlusion of this common duct was due to the pressure of the tumor at head of pancreas, as in the specimen before you. Friedrich and Bartholow speak of a tumor being often found in cystic degeneration of pancreas. In the specimen before you no tumor was felt during life, although carefully searched for, and vomiting did not occur until toward the close of life, whereas in the case of cystic degeneration a tumor was observed on admission and vomiting was an early symptom and would be observable in character. In both cases jaundice was intense.

Dr. F. N. Orts thought the history of the case was clear, and there seemed to be no doubt concerning the propriety of the operation. He had seen a number of cases of tuberculous testicle develop, apparently in consequence of great irritation of the genito-urinary apparatus. One case in particular developed in the course of several months, from pressure of local matter at its origin, and gave its first evidence through frequent, painless micturition. Finally cystitis developed. After a period of a year or more there was evidence of calculus material passing, but on examination of the bladder no stone was found, notwithstanding a perineal opening was made for the purpose of determining whether or not vesical calculus existed. Finally the testicle began to swell and suppuration took place at one or two points, and it soon became evident that the disease was tuberculous in character. The case went on and death afterward occurred from rupture of a spinal abscess, the disease of the spine being discovered only a few months before the fatal termination. The autopsy showed tuberculous condition of both testicles and also deposits in the kidney. There was no tubercular deposit in the lungs or other parts of the body.

Dr. Ripley asked Dr. Wyeth what he understood by the varying temperature of phthisis.

Dr. Wyeth replied such a temperature as ordinarily accompanies hectic, with an afternoon rise—in this case to 103° F.

Dr. Ripley thought 105° F. a high temperature for local disease of the testicle.

Dr. Gerster said he had observed quite a number of cases of tuberculosis testis, in some of which the temperature rose occasionally to 105° F., accompanied with severe chills and profuse sweating, and in one or two cases the lungs also were affected. But he had presented to the Society two cases of testicular tuberculosis in whom no pulmonary lesion could be made out by physical examination, and yet the temperature was high, and fell from the moment the operation was performed.

Dr. Wyeth said there was sufficient suppuration in his case to account for a temperature of 100° F., but, without the constitutional tendency, not sufficient to account for a temperature of 105° F. Another point to which he wished to draw attention was the advisability of early operation in these cases. Moreover, he regarded it as important to remove all of the scrotum which the man could spare, that is, all that part which has been involved in either the suppurative, tubercular, or inflammatory process.

Dr. Ripley said that in those cases in which the testicle is actually inflamed and swollen a comparatively high temperature was likely to occur, but where the disease has existed for some time, often with rupture and discharge of pus, he thought that 103° F. was an unusually high temperature, unless there is some other organ involved.

Dr. Gerster said one word of explanation in connection with his case was due to Dr. Ripley, and that was, he had observed the high temperature only in those cases of tuberculous testicle where actual breaking down of the tubercular deposit was going on, although there was no perforation. So long as the process of disintegration of the caseation takes place, the temperature changes incident to it were not present there was no high temperature.

Dr. Ripley remarked that absence of perforation gave rise to confined pus, and in that way might account for the rise of temperature.

Dr. Levi said the question of temperature was an important one, and referred to the conclusions of Dr. William Fox, who in his paper on fever at a temperature as one of the strongest features in these cases. Not so very high, but a rather low temperature, yet continued for a long time. He was rather surprised to hear of a temperature of 103° F. in Dr. Wyeth's case, and perhaps that might have been due, as Dr. Gerster had explained, to the fact that absorption was taking place. He asked Dr. Wyeth what the condition of the cord was above the epididymis.

Dr. Wyeth replied that it was intact.
The specimen was referred to the Committee on Microscopy.

**ANGIOMA OF THE LIP.**

**DR. A. G. GERSTER** presented a specimen removed from a man, thirty-one years of age, whose under lip Professor König, of Göttingen, excised for angioma thirteen years ago. The patient alleged that the tumor was about the size of a large hazel-nut, and that the cicatrix remained firm for ten years. The disease began to recur about three years ago, increased in size to that of an egg, and finally the patient came under Dr. Gerster's care in the German Hospital, where he performed an operation for its removal.

The specimen was of interest as showing the possible recurrence of this otherwise non-malignant disease after the lapse of ten years. As regards excision, it was sufficient to say that it was somewhat difficult on account of the hemorrhage, but the wound healed by first intention. To make up for the loss of the lower lip, an additional plastic procedure was resorted to.

Microscopically the tumor was a cavernoma, that is, had a stroma of connective tissue which was permeated by large irregularly shaped veins.

**DR. WYETH** regarded the specimen as unusually interesting from the fact that latterly he had performed some operations for the removal of these angiomata, whether arterial, cavernous, or capillary, which did not meet with general favor. He had removed three from the face; one from the forehead, one from the nose, and one from below the left eye, all being something more than one inch in length. All were of the capillary variety; that is, the intercircus aneurism and the cavernous tumor.

His mode of procedure was to cut directly down through the skin and tissues to the bone, holding a sponge on the parts, without stypic, and then pass silk ligatures directly through and bring the tumor together. In two cases he got union by first intention and in the third case partial union. The deformity was removed in all the cases and the cicatrix was almost imperceptible.

**DR. GERSTER** had seen recurrence only in cases where apparently the growth was not entirely destroyed, the operator using the galvano-cautery. He believed it to be essential to remove by some means every living belonging to the tumor. The growth in his case did not pulsate so as to be visible, although pulsations in the deeply seated arteries could be felt distinctly.

The Society then went into executive session.

---

**The Influence of Large Quantities of Water upon Fever.—Dr. Wilischin** (Centrallt. für die Med. Wiss., September 22, 1883), says that dogs, made feverish by the injection of putrefying desinfribled blood, were artificially fed with large quantities of warm water, their weight and bodily temperature being carefully noted. The following were the results obtained by Dr. Wilischin:

1. The temperature fell under the influence of the inhibition of large quantities of water.
2. The deprivation of water in the later stages of the fever had also the effect of lowering the temperature.
3. The animals became dull and sleepy under its effects.
4. The appetite increased under the administration of larger quantities of water.
5. The deprivation of water induced a diminution of bodily weight. In animals kept without water during the febrile state, granular degeneration of the kidneys, liver, and heart was found to a greater extent than in those supplied with excess of water. Of these organs, the liver most frequently had undergone this change. In some cases, the lesion was so far advanced as to have extended to the nuclei of the cells, which were themselves atrophied. The heart was least affected, the change having only effected an obliteration of transverse strie of the muscular fibres.

**Army and Navy News.**

**Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from March 2, 1884, to March 9, 1884.**

**PERIN, GLOVER,** Lieutenant-Colonel and Surgeon, Medical Director, Department of Dakota. Leave of absence extended twenty days. S. O. 23, Headquarters, Division of the Missouri, March 5, 1884.

**BACHE, DALLAS,** Major and Surgeon. Leave of absence extended seven days. S. O. 43, par. 1, Headquarters, Department of the East, March 5, 1884.

**BILL, J. H.,** Major and Surgeon. Granted leave of absence for one month. S. O. 20, par. 1, Headquarters, Department of the Platte, March 3, 1884.

**BAILY, J. C.,** Major and Surgeon. Granted leave of absence for one month, to take effect on or about March 1, 1884, with permission to apply to the Adjutant-General of the army, through Division Headquarters, for an extension of three months. S. O. 24, Headquarters, Department of Texas, February 26, 1884.

**STEPHENSON, WILLIAM,** First Lieutenant and Assistant-Surgeon, Ordered to Fort Niobrara, Neb., for temporary duty, on completion of which to return to his station, Fort Omaha, Neb. S. O. 20, par. 4, Headquarters, Department of the Platte, March 5, 1884.

**FISHER, WALTER W. R.,** and POLHEMUS, ADRIAN S., First Lieutenants and Assistant-Surgeons. Assigned to duty in Department of California. S. O. 55, par. 4, A. G. O., March 6, 1884.

**STEPHENSON, WILLIAM; BORDEN, WILLIAM C., and CHAPIN, ALONZO R.,** First Lieutenants and Assistant-Surgeons. Assigned to duty in the Department of the Platte. S. O. 55, par. 4, A. G. O., March 6, 1884.

**ROBERTSON, REUBEN L.,** and EDIE, GUY L., First Lieutenants and Assistant-Surgeons. Assigned to duty in Department of Texas. S. O. 55, par. 4, A. G. O., March 6, 1884.

**CROSBY, WILLIAM D.,** First Lieutenant and Assistant-Surgeon. Assigned to duty in Department of Arizona. S. O. 55, par. 4, A. G. O., March 6, 1884.

**GANDY, CHARLES M.,** First Lieutenant and Assistant-Surgeon. Assigned to duty in the Department of the East. S. O. 55, par. 4, A. G. O., March 6, 1884.

**PILCHER, JAMES E.,** First Lieutenant and Assistant-Surgeon. Assigned to duty in Department of Dakota. S. O. 55, par. 4, A. G. O., March 6, 1884.

**FISHER, WALTER W. N.,** First Lieutenant and Assistant-Surgeon. Assigned to duty at the Presidio of San Francisco, Cal., from 18th inst. S. O. 23, par. 1 and 2, Headquarters, Department of California, February 21, 1884.

**POLHEMUS, A. S.,** First Lieutenant and Assistant-Surgeon. Assigned to duty at Fort Winfield Scott, Cal., from 18th inst. S. O. 23, par. 1 and 2, Headquarters, Department of California, February 21, 1884.

**BENHAM, R. B.,** First Lieutenant and Assistant-Surgeon. Relieved from duty at Fort A. Lincoln, D. T., and ordered to Fort Sisseton, D. T., for duty. S. O. 22, par. 1, Headquarters, Department of Dakota, February 26, 1884.

---

**Changes in the Medical Corps, U.S.N., for the week ending March 8, 1884.**

**AMES, H. E.,** Passed Assistant Surgeon. From the Colorado, and ordered to the Grecile Relief Steamer, Bear.
Medical Items.

 CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 11, 1884:

AMERICAN VETERINARY COLLEGE.—Samuel Marsh, Esq., as President of the American Veterinary College, writes: "Dr. your issue of February 16, 1884, p. 99, appears an article under the title 'New York College of Veterinary Surgeons.' In said article 'Peter Peters, Veterinary Surgeon, writes,' etc. As we know your journal as one that always respects the rights of educational institutions, and of individuals, we desire through your columns, to correct certain misstatements and perversions of the truth made by your above-named correspondent. The Faculty of the New York College of Veterinary Surgeons, 'who organized the American Veterinary College in 1875,' resided in a body from the first named college in 1875; they were not 'discharged.' The several 'professors who organized the Columbia Veterinary College in 1875,' resided from the New York College of Veterinary Surgeons; they were not 'discharged' by the trustees of the latter college. That the New York College of Veterinary Surgeons is the only college in this State having the authority to grant the degree of Veterinary Surgeon is not gainsaid; the American Veterinary College is now the only college in this State having the authority to grant the degree of 'Doctor of Veterinary Surgery.' The American Veterinary College and the Columbia Veterinary College were chartered and incorporated under the general laws of the State of New York, viz., under an act of 1848, and the amendments of the same under an act of 1870; the latter has since been confirmed by an act of 1882. The general laws and the amendments thereof provide for the incorporation of 'scientific and literary colleges and universities.'"

INTESTINES IN THE CHEST.—Dr. C. G. Davis, of Milford, Mich., reports (Medical Age) the history of a man, aged thirty-seven, who, after suffering from ague and other troubles, finally died of septicaemia. A post-mortem made in the presence of Drs. Dallas Warren and Robert Johnson revealed a very distended stomach, enlarged liver and spleen.

Dr. Davis says: "The intestines were the next organs to look for, and by following the pyloric end of the stomach I found it turned upward against the diaphragm, through which I made an opening with the scalpel, and introducing my hand, found the intestines all in the left chest, under the lung and about the heart, resting upon the diaphragm, an opening of about one and a half inch in diameter through the diaphragm, near its left attachment, allowing a passage for the descending colon down to the rectum. The mesenteric glands were found enlarged and filled with deposits of pus, doubtless of pyogenic origin. The left lung was about one-third as large as the right, and divided into five irregular-shaped lobes. The right lungs appeared healthy as to their parenchyma. There were no adhesions of either intestines or the lung to the pleura in the left cavity; some were found on the right side, but they were not extensive.

Peritoneum healthy and continuous through the opening in the diaphragm where the colon passed out of the chest. The deformity of the lungs, the misplacement of the bowels and kidneys, must have existed from birth, and were not the result of hernia, as some may be inclined to believe."

A MODIFICATION OF RICORD'S METHOD OF OPERATING FOR VARICOCELE.—Dr. Deaderick, of Knoxville, Tenn., referring to a recent article in The Record, upon a method of operating for varicocele by ligating the veins subcutaneously, and fastening the ligatures to a metal plate, says: "It occurs to me that this method is open to more objections than a method which I follow. I make use of Ricord's operation, except that instead of fastening the two ends of the subcutaneous ligature to buttons or plates on each side of the scrotum, I fasten them to the ends of a U-shaped steel spring. This spring is made of small steel wire curled upon itself, and bent in the shape of a letter U. In this way the amount of tension on the ligature is under one's control, and there is nothing pressing against the scrotum, interfering with the exudation of serum from the needle punctures. With this improvement, it is hard to conceive of a more efficient or perfect mode of operating upon varicocele."

THE AMERICAN VETERINARY COLLEGE held its ninth annual commencement on March 4th. Samuel Marsh, President of the Board of Trustees, conferred the degree of D. V. S. upon the twenty-two members of the graduating class, and this ceremony was followed by the presentation of various valuable premiums to the members of the class. The President then delivered a discourse on the subject of study during the year. The valedictory was delivered by Hamilton Vreeland, and an address was delivered by the Rev. Dr. John P. Newman.

"LE MONITEUR DE LA POLICLINIQUE." (French, of course) calls the leading medical journal of this country a "red-skinned, Yankee cocaine, without education, without wit, without intelligence." How truly is a prophet not without honor save in his own country! Le Moniteur, etc., is educated, witty, and intelligent—doubtless as education, wit, and intelligence go in France.—Medical Age.

THE CONSTITUTIONALITY OF QUARANTINE FEES.—The Supreme Court of the State of Louisiana has decided that the State law requiring all vessels touching at New Orleans to pay certain quarantine fees is just, and that it does not infringe on the power of Congress to regulate commerce. The suit was entered by the "Morgan Company," to perpetually enjoin the collection of the fees now demanded by the resident physician at the Mississippi Quarantine Station from all vessels entering the port of New Orleans.

THE TREATMENT OF INSANITY AT HIGH ALTITUDES.—It is asserted by certain English physicians that the high, dry, and cold air of St. Moritz has remarkable curative powers as regards insanity. A movement is on foot to establish a sanitarium for mental invalids in that locality.

DRUG FARMS FOR YOUNG DOCTORS.—Dr. L. D. Morse, of San Mateo, Cal., writing upon the above subject says that in the San Francisco market there are many for young or old physicians, individually, to undertake the expense and special care necessary for raising medicinal herbs, etc. He thinks, however, that more of the drugs now imported should be raised in this country, and he states that an association has been formed in California to undertake the cultivation of a drug farm. He writes: "In many of the valley vallies of California, rhubarb may be grown, probably of as good quality as is produced anywhere else in the world. So also, ipecacuanha, ginger, and a score of other valuable drugs now imported. Vanilla beans can, undoubtedly, be grown here. Even if the best varieties should be grown under glass, artificial heat would probably double the output of such a farm. The demand would probably yield profitable results. Licorice is already quite successfully grown in at least one locality in this State. In the experimental grounds of the State
University, at Berkeley, cinchona trees are growing. They are not considered really successful, but there are other localities in the State with climate and soil quite different, where they may prove quite successful. The camphor tree at Berkeley, I believe, promises very well.

PLACE CEREBRUM.--FORCED DELIVERY.--LACERATION OF CERVIX.--SEPTIC FEVER.--RECOVERY.--Dr. G. F. Cleveland, of Le Roy, N. Y.; sends us the following in
structive history: "Mrs. P., aged twenty-five, mult
para (I delivered her of her first child about two years since), called on me, October 2d, to say that she was again six and a half months advanced in pregnancy, and that for the last six weeks she had been annoyed by spells of bleeding, but that she had not bled any for about a week. I advised her to return home (four and a half miles) in the morning, lying on her back, countenance as pallid as death, lips and tongue entirely bloodless, with but a faint flutter of pulse at the wrist, too feeble to be counted, everything about her saturated with blood; in fact she was lying in a pool of blood up to her shoulders. It was very evident that what was to be done must be quickly done, or my patient would be beyond the reach of any administration. A single dose of the fluid extract of ergot with half an ounce of brandy, and proceeded at once to examine the condition of the uterus. Found the os dilated to about the size of an ordinary door-knob, which is, I think, about seven inches in circumference; it was not rigid, but decidedly soft and flabby, and was entirely filled by placenta, which seemed to be hanging down, for it was unaverted, and I was not prepared for the os. I passed my finger through it, and by gentle pressure I was able to press my finger to gain an entrance to the womb I would tear up adherent placenta, and the hot blood would rush into my hand. I saw that my patient was rapidly sinking, and as the os was so dilatable I determined to force a delivery and rid the womb of its contents. Accordingly I let my patient inhale a little chloroform, and after an hour I ordered the after-pains and passed it into the vagina, and by gentle pressure worked it through the os, through the placenta, and into the cavity of the uterus, ruptured the membranes, found the head presenting, passed my hand further on and grasped the feet, turned the child and brought down the feet. But I met with an obstruction—my hand, which had been readily passed, was now grasped by holding the feet, so that the os refused to let it pass out. At this time I could not see that my patient was breathing, in fact, she had every appearance of being lifeless. On making a little more traction I felt the cervix give way and tear over the back of my hand, like wetted paper. I then brought into the world a living child, and turned my attention at once to the mother, ordered the husband to pour half an ounce of brandy between her teeth, and I began to manipulate the chest after the manner of Marshall Hall. In a short time she opened her eyes, swallowed the brandy, drew a long inspiration, and said she was "all right," a statement, by the way, which I at the time very much doubted. I then removed all the fragments of torn placenta, put firm pressure over the uterus, and gave another dose of ergot and brandy. All hemorrhage ceased, and a half-hour later patient was, as she said, "feeling quite comfortable." The patient subsequently had a septic fever, from which she made a satisfactory recovery.

TREATMENT OF CORNEAL OPACITIES.—Dr. Michel recommends sulphate of cadmium, of the strength of two and a half grains to the ounce of mucilage, as an application to opacities of the cornea. A camel's-hair brush, dipped in this wash, is applied to the centre of the spot and retained in contact with it for a few seconds. At first the application is made once a day, but after a while it is repeated two or three times in the twenty-four hours. When the pain grows less, the strength of the solution may be increased to five grains or even seven grains to the ounce. When the opacity is of recent formation it rapidly disappears under this treatment, but when it is of old date the applications must be long continued.—The Practitioner, January, 1884.

BUSINESS LIFE.—It is, unfortunately, one of the chief characteristics of modern business to be always in a hurry. In olden times it was different. Business of all kinds was carried on with much deliberation, and nothing was gained, or supposed to be gained, by that sort of high-pressure work which consists in being perpetually and impetuously hasty. The habit of haste—for it is a habit—is actively cultivated in the city of London, and in all places and circles which follow the fashion "the city" has set. The moment a lad takes his seat on a stool before the lowest desk of a house of business, he begins to make-believe to others, and too quickly to himself, that he is overwhelmed with work. Merchants and managers require this farce to be played by everyone in their establishments, from the heads of departments to the youngest clerk, on the supposed ground of a "habit of a mental habit" of hurrying, which before long becomes the keynote and motive of the whole life. It is the custom to write and speak as though commercial men were really as much pressed for time as they appear to be; and wholesome, but not very intelligent, counsel is offered to the effect that it would be better to get up a little earlier, and to work in the morning, with the view of preventing the physical dangers and evils which result from "running to catch trains," "eating hasty luncheons," and the like. Now the simple fact is, that all this haste and turmoil, prejudicial and often ruinous as it is, is artificial. If a "man of business" were to rise at five o'clock every morning, and "his train" left at 8.30, he would from habit avoid leaving his house until too late to enable him to "catch" it comfortably. It would discredit his position and look unbusiness-like not to be in a hurry. So, in the selection of a train by which to travel, he always chooses one that arrives with barely time for him to reach his place of business at the hour appointed. It would ruin him in the eyes of the public and be greatly opposed to his "standing" as an early man, and saunter to his office. The inference in business circles would be that he had little or nothing to do. The same habit runs through the life of the typical man of commerce. He likes to look and feel full of restrained yet bursting energy, and in his calmest moments to be so pressed that if he were less capable than he is he must be distraught. This affectation of suppressed force is the bane of city life. It is this that does so much harm to the nervous system. We sometimes see a locomotive standing waiting to start an express train; the steam is up to the highest pressure; the engineer must blow it off every few minutes, or the boiler would burst. This is a given thing of business as we see it in London, and as he tries to be, or appears, in the provinces. The old merchants of London, who, nevertheless, amassed large fortunes and founded great families, were wont to stand at their doors in Cheapside and the leading thoroughfares, and were never in a hurry. What would be thought of anyone who dared to seem leisurely to-day? If those who furnish the "city men" of to-day with medical counsel would go right down to the bottom of things and try to cure the evil of this mental habit, they would do far more to prevent the spread of nervous diseases, and to arrest the thousand-and-one troubles of body and mind which spring from work and high pressure, and hurrying, anxiety, and waste of energy, than by deeming in detail with particular forms and fruits of this evil, as is their wont.—London Lancet.

PRACTICAL HINTS REGARDING THE METHODS OF EXAMINATION EMPLOYED AS AIDS IN THE DIAGNOSIS OF NERVOUS DISEASES.

By A. L. Ranney, M.D.,
Professor of Applied Anatomy in the New York Post-Graduate Medical School and Hospital.

The advances which have been made within the past ten years in our knowledge of nervous affections probably exceed those made in any other department of medical science.

The more progressive practitioners are keenly alive to the importance of this branch, but they realize, as well, the difficulties which it presents to those not thoroughly acquainted with the anatomy and physiology of the nervous mechanism.

It is not uncommon with neurologists to hear expressions like the following from medical men of intelligence and candor on all sides: "I would like, doctor, to study the cases of nervous disease which I meet more scientifically than I now feel myself able to do; but I am ignorant of how to proceed in the examination, and more or less uncertain as to the basis of my conclusions."

Again, others say with equal candor: "I feel, doctor, that the text-books upon nervous affections abound in pictures of instruments employed in diagnosis, such as batteries, thermo-electric apparatus, galvanometers, aesthesiometers, dynamometers, dynamoscopes, etc., but they are scanty in the descriptions of the uses of these instruments and their value in diagnosis. I presume that it is impossible to correctly interpret the various phenomena of nervous affections without these costly appliances, so I am often forced to guess at the disease and let fate get out of the way."

Finally, the majority of practitioners apparently join in the feeling (which happily conduces largely to the pecuniary benefit of specialists in neurology) that nervous anatomy and physiology is "too complex a subject for them to master," and that they must be, therefore, given over to those who are devoting themselves particularly to the department of nervous diseases.

Now, I believe that it is not only possible but comparatively easy for any medical man (who is willing to make the effort) to grasp certain general principles which are applicable to the examination of cases afflicted with nervous diseases.

These can be carried out without expensive apparatus and with decided benefit both to himself and his patients. They will tend to render his diagnosis decidedly more scientific and certainly more accurate. They will aid him in properly directing his treatment. Finally, they will often save him the humiliation of seeing his patient seek advice from other hands.

The intelligence of laymen is always strongly impressed by evidences on the part of a physician of great care and marked skill, as shown in the first examination. The impressions left upon the patient's mind by the results of the first interview are of the greatest importance to both parties. While the doctor is studying the patient, the patient is, as a rule, studying the doctor with even greater interest.

Every step which is taken by the physician, as a means of forming a positive and final judgment, is watched with an earnestness on the part of the patient that invariably accompanies mental anxiety. Each question that is asked regarding the previous history of the patient, the possibility of similar troubles in his parents or blood-relations, the origin and course of the more important symptoms, etc., are even more indelibly impressed upon the mind of the patient than upon that of the physician, who keeps the written record.

When, later in the examination, the power or electrical reactions of the muscles and the sensibility of different regions of the body are being tested in various ways, and the results of such tests are being recorded in the case-book of the physician, the reasoning faculties of the patient are even more keenly alive and seek to penetrate (as far as his intelligence will permit him to do) into the mysteries of the science, and to draw conclusions regarding the clinical significance of certain symptoms, of which, perhaps, he was unconscious up to that time. It will often be necessary for the physician to quiet evidences of alarm on the part of the patient, from time to time, as the examination of the symptoms proceed, by judicious explanations or words of encouragement.

It should ever be remembered by the physician that any omission on his part to investigate the condition of the motor or sensory nerves, the pulse, the respiration, the temperature, the spinal reflexes, etc., in each and every case will sooner or later be remarked by some patient, who has either read extensively or had, from time to time, different medical advisers. Besides, interested friends (sometimes very intelligent from past experiences of their own) may often drop hints to the patient which will tend to prejudice his views that have previously been formed of the accuracy and care of the first examination of the symptoms.

There is, furthermore, a moral, as well as a personal view of the situation. This is well expressed by a quotation, employed as a text by a late author. It is as follows:

"When a patient places confidence in a member of the profession, puts his life, or his health, the prospects of himself, and may be those of his wife and children, in his hands, the least he, in turn, can do is to meet him with common honesty. If he is not entirely deserving of the confidence reposed in him, let him try to be worthy of it by doing his best. How much, however, does 'doing his best' involve? It involves all that lies in his power; each man to the very best of his ability. 'For unto whomsoever much is given, of him shall much be required.' 'Doing his best' is taking all possible pains, which includes such information as may be attainable. Avoidable ignorance is not a worthy return for confidence.'"

It is my object, in presenting this article before the medical profession, to give, with some detail, the description of the various steps that are commonly employed by specialists in neurology in the examination of their patients; and to suggest a simple method of recording symptoms, as a basis for the diagnosis and subsequent treatment of nervous affections.
I shall discuss the subject under the following heads:

First.—The clinical history of the patient, and how to record the chief symptoms of each case.

Second.—The symptoms revealed to the physician by his sense of sight.

Third.—The symptoms revealed to the physician by instruments of various kinds and other tests.

As the aim of the article is to interest and possibly instruct those members of the profession who are attracted toward but not thoroughly familiar with the department of neurology, the author need not apologize for the insertion of much that is old and little that is new to the specialist in this branch.

THE CLINICAL HISTORY OF THE PATIENT.

Every physician should be provided with a case-book. In it the main features of each patient’s case should be first recorded, and a memorandum of the treatment and modifications of the symptoms should be subsequently jotted down at each visit. In this way only can the results of an extended experience be made useful for scientific accuracy and the like đata. It will furthermore aid the doctor in utilizing his leisure hours by studying the cases which he meets during the busy routine of his office work. One case well studied is worth a hundred casually glanced at and hastily prescribed for.

It will help to economize time if the case-book is printed in such a way as to have the more important symptoms on the top of the page; spaces being left blank to allow of a record of any modifications of these that may exist. This plan adds to the legibility of the notes, and also admirably adapts them for comparison with those of previous or subsequent cases. Each physician may alter the arrangement of the pages of his case-book to suit his individual practice, but it is best for a general practitioner to keep it adapted for all classes of patients. Such a one is now published and offered for sale among the profession at large.

In a subsequent portion of this article I will suggest a form of case-book which seems to me to be well adapted to the requirements of a specialist in nervous diseases.

Let us now suppose that a patient enters the office of a physician for medical advice relating to a nervous malady. After the usual questions to the patient regarding the name, the age, the condition as to marriage, the nationality, and the occupation have been asked and the answers recorded, the patient should be brought rapidly to a concise statement of the more important symptoms for which he seeks medical relief. This can be usually accomplished by a short history; much valuable time is saved by so doing. These symptoms can then be recorded.

With these especially marked symptoms as a starting-point, questions may then be asked regarding certain of them which the physician deems the most important from a clinical aspect, seeking in each instance to learn all about the present and past history of one symptom at a time, and the modifications which have been observed concerning it, so far as the patient’s memory will prove of assistance.

Now, the ability on the part of the doctor to ask questions that are pertinent to each symptom will depend entirely upon the knowledge which he himself possesses of the subject. I have often tested medical students and young practitioners in this regard, and have been amused to see how rapidly their stock of pertinent inquiries became exhausted.

In order to intelligently ask about pain, for example, the physician must know all the axioms of nerve-distribution, which Ifington so ably advanced; he must be a master of the general, for a case, of the course of the separate nerves that enable definite regions to tell the doctor (by the presence of the sense of pain) of disease that is sometimes far remote from the painful area; again, he must be able to correctly trace the course of affected nerves, and thus to seek for abnormal conditions along the line of each nerve which might produce local pressure upon them; he must be familiar, in the fourth place, with the individual peculiarities of pain in special diseases, as, for example, the characteristic pains of rheumatism, neuralgia, locomotor ataxia, etc.; finally, he must be familiar with all the possible causes of pain in different regions of the body or extremities.

Then we shall have discussed the various symptoms revealed by inspection of the patient, as well as the tests employed to determine abnormal states of the motor or sensory nerves, and the reactions of muscles to different electric currents, many points will have been given that may prove of assistance in suggesting pertinent questions, to be employed in obtaining the clinical history of patients so affected; but it will require a constant practice, much study, and close observation to excel in the art of quickly and accurately gathering pertinent facts, from which conclusions can be drawn regarding the diagnosis and treatment of nervous diseases.

DURATION OF EXISTING SYMPTOMS.—It is important to ascertain the exact date of the commencement of the symptoms for which the patient seeks advice, as it is more certain that others with symptoms so detected by the physician at the first interview. This will often decide as to the acuteness of the attack, and also afford in some instances information respecting the seat of the disease. In the chronic varities of spinal disease (as, for example, progressive muscular atrophy, locomotor ataxia, disseminated sclerosis, etc.), the patient cannot give even an approximate idea of when the symptoms commenced, because the development has been extremely slow and gradual. On the other hand, a hysterical fit may be followed immediately by an attack of hysterical paralysis; a hemorrhage into the brain or spinal cord, that has ploughed up the substance of these organs, causes paralytic symptoms that develop insidiously; a traumatic sensory paralysis, or others a more gradual onset, although it may be comparatively rapid. As an illustration of the clinical bearing of the duration of symptoms, let us take the following illustration: Two patients present a deformed hand from atrophy of the muscles of the thumb and the interossei. The one has been slowly developed, and is probably the result of progressive muscular atrophy; the other has been very rapidly developed, and is probably due to some disease or local injury of the ulnar nerve. Should it have occurred in years past, and have shown no evidences of steady progression, the existence of progressive muscular atrophy could be then safely excluded.

THE EXCITING CAUSE OF EXISTING SYMPTOMS.—If there has been a definite history, it is important to ascertain the exact nature, seat, and severity of the injury. Concussion of the spine may cause severe and often fatal disease of the spinal cord. Violence to the head may depress the inner tablet of the skull without any evidence of depression upon the exterior. The brain may be seriously injured, when the bones that encase it may escape. Some of the spinal nerves may be impalpably in a wound or bruise, and thus paralysis may be induced independently of the nerve-centres.

THE AGE OF THE PATIENT.—Much may be suggested to the mind of the physician by the age of the patient, because some diseases are more common at one period of life than at another.

During early childhood we are particularly liable to encounter the symptoms of idiocy, epilepsy, and choreas, as well as those of an inflammation of the anterior horns of the gray matter of the spinal cord, the so-called "poliomyelitis anterior." The acute variety of the latter disease is most common between the ages of one and four, and it is seldom developed except in childhood. In the vast majority of cases, the condition termed "pseudohypertrophic paralysis," because the muscles are overgrown like those of an athlete, is developed during the first few years of life. Again, the tubercular form of inflammation of the meninges, both of the brain and spinal cord, occur in the young child. Among the rarer forms
of disease of the spinal cord, a congenital variety of the so-called "spastic paralysis," and also of "lcomotor ataxia," is encountered in young children. Reflex paraplegia is also occasionally seen in very young subjects. Cases of disseminated sclerosis of the spinal cord have been reported in the child.

Between the ages of puberty and the fully developed adult, Pott's disease of the vertebra may develop and create compression of the spinal cord; and attacks of rheumatism may render the development of embolic hemiplegia and aphasia possible. Meningitis of the brain and spinal cord are not uncommon during this interval. Hysterical paraplegia occurs in young females in connection with uterine disturbances. Between the ages of twenty and thirty cerebro-spinal sclerosis is commonly developed.

In the adult, progressive muscular atrophy, myelitis, menigitis of the cord, locomotor ataxia, the chronic form of poliomyelitis, and amyotrophic lateral paralysis are among the spinal diseases often encountered. Cerebral meningitis, and softening, tumors, and embolism of the brain, are frequently recognized. Shaking palsy seldom occurs except in advanced life. The symptoms of Duchenne's disease, and the paralysis of the insane are most commonly developed between the ages of thirty and sixty.

Linked with adult life comes, also, apoplexy associated with paralysis; and a late rigidity of the paralyzed muscles is developed if the injury excites a descending degeneration of the fibres that are torn across by escaping blood. Excessive indulgence in eating and drinking, coupled with the absence of proper physical exercise, and the possibility of acquired syphilis, render males more subject to paralysis than females.

The Sex.—Males suffer much more frequently from organic nervous affections than females. This fact is to be accounted for partly by the liability of that sex to injury, exposure to cold or dampness, and excessive mental or physical labor. But habits of indulgence in alcohol and venery, with its danger of syphilitic infection, are also far more common in males than in females, and are often prominent factors in the causation of morbid conditions of the nerve centres. Certain occupations, tending toward great muscular strain, or lead, arsenic, and mercurial poisoning, may be exciting causes of serious nervous affections. Prolonged exposure to compressed air (as in the case of divers) is often followed by paralysis. Many such cases have occurred among workmen in submarine excavations.

The Habitual.—Having exhausted the special lines of inquiry indicated by the prominent symptoms that each patient seeks relief for, questions should then be propounded to the patient touching upon the possibility of hereditary predisposition to nervous affections or of some hereditary "diathesis." Some nervous affections exhibit a marked dependence upon a hereditary predisposition, either to the disease actually present, or to some allied disorder. Epileptics, for example, are frequently offspring of tubercular or syphilitic parents or of epileptics. Again, chorea and hysteria may be developed from the most trivial excitement (even from imitation of others so affected) in subjects predisposed to nervous excitability or debility. Apoplectic subjects not infrequently begot offspring who manifest in adult life a decided tendency to vascular disease. Certain spinal affections seem to be particularly associated with heredity. Cancer and tuberculosis are unquestionably transmitted, and are not infrequently found in the brain and spinal cord or their envelopes.

A marked hereditary tendency toward some spinal affections seems to be well established. Pseudo-hypertrophic paralysis is transmitted through the mother. Locomotor ataxia occasionally runs in families, and progressive muscular atrophy is markedly hereditary. Some hysterical women can be shown to have sprung from ancestry in which epilepsy or insanity has existed; and idiotic children and epileptics sometimes owe their disease to a so-called "hysterical temperament" on the mother's side.

The Habits of the Patient should be the next subject of inquiry. Alcoholic subjects are always surrounded by dangerous possibilities. Inflammation, when once started in such patients, is liable to be of a severe and fatal kind. Trivial injuries often excite serious complications in such subjects, and old affections, which have been comparatively dormant for some time, may be kindled into activity by a "spree."

Again, the habitual use of drugs for nervousness, sleeplessness, and all the other ailments with which the laity often experiment at the suggestion of friends, but without the knowledge of their doctor, may be a factor in nervous symptoms that have become aggravated or actually developed by their injudicious use. Some patients can use tobacco without apparent injury, while it is a rank poison to others; tea and coffee are likewise injurious to many patients. The long-continued use of chloral, the bromides, opium, or other drugs may result in nervous affections of a serious character.

The Occupation of the Patient may be a possible factor in the development of nervous diseases. Sewing-girls frequently develop ulceration of the stomach from the pressure exerted upon that organ by stooping. Painters are peculiarly liable to lead-poisoning; and in certain arts, such as the mechanical, the metalsmith, in the external preparations are extensively employed, symptoms of these forms of poisoning may be developed. Exposure to cold or dampness is very often an exciting cause of spinal affections. Excessive exercise or occupations demanding an unusual strain upon the muscles may induce actual disease of the muscles, peripheral nerves, spinal cord, or brain. Extensive mental labor or anxiety is a frequent cause of brain inflammation and changes within the coats of the blood-vessels of that organ.

The Acquired Diseases.—Finally, the previous history of the patient in respect to acquired diseases is especially important as an aid in deciding as to the probable cause of existing symptoms. Financial attacks of illness which have been passed through should be carefully inquired into. The presence or absence of latent syphilis should always be investigated as per-
haps one of the most common causes of nervous affec-
tions. The presence or absence of tubercular deposits
in the lungs, or of cancer in the breast or viscera, should be
decided by a physical examination, because similar
defects may occur elsewhere. Diphtheria is frequently
followed by paralysis of the throat and limbs. Diabetes may itself
indicate an existing brain disease; or, as the result of
imperfect performance of the digestive processes, create,
in turn, symptoms referable to the nervous mechanism.
In point of fact, few, if any, of the more common diseases
are entirely exempt from a more or less direct association
with nervous phenomena.

There is a prevalent opinion among the laity (and, unhos-
fortunately, with some of the profession also) that the
nervous system is a distinct and separate part of the hu-
man organization, an entity entirely independent of the
other organs and having functions peculiarly its own.
They seem to forget that it is nourished by the same
source, the same blood, as other organs, e.g., the liver, the
heart, and that every part of the body is capable of sending
telegraphic communications to the brain and spinal cord by
means of the sensory nerves; and, finally, that these
organs are called into action rather as the servants of the
other parts of the body than as independent organisms,
by the various impressions which they receive from with-
out. All the mental processes are based, of necessity,
upon some impressions of the outer world gained by
means of the organs of sight, smell, hearing, touch, taste,
or the nerves of general sensibility.

The apparent disassociation which exists between the
nervous centres and the viscera often misleads the prac-
titioner of medicine, and causes him to disregard the
importance of a complete examination of the various
organs before a final judgment is expressed concerning
nervous phenomena that are brought to his notice.

Some of the more common forms of nervous affections
are purely functional. Text-books abound in cases where
some disease of the intestine, ovaries, uterus, kidneys,
bladder, and urethra have been the exciting cause of
paralysis. The manifestations of such paralysis upon the
nerve-centres are Hystericus, which is often associated with a
paralytic condition that is not easily differentiated from the
types of paralysis produced by destructive processes within the
brain and spinal cord. Epilepsy and St. Vitus' dance are purely
nervous diseases, and yet they may sometimes be the re-
sult of a defective assimilation of food, general debility,
some peculiarity of the blood, and many other such causes
that are not directly associated with the nervous system
proper.

On the other hand, diseases of the nervous centres may
induce so-called trophic changes, or changes of
nutrition, not only in the muscles—as is evidenced by
atrophy and other less complete kinds—but also in the
nerves, in the various organs, and even in the bones.
The peripheral nerves preside not only over the muscles,
to which they give the power of contraction, and the
tactile organs of the skin, to which they contribute the
ability to perceive all varieties of impressions, such as
the tactile sense, the sense of cold and of heat, the feel-
ings of pain, etc., but they have another equally im-
portant function, which they exercise chiefly by means of
the so-called vaso-motor filaments, viz., the regulation of
the blood-supply to the viscera, organs of special sense,
muscles, bones, joints, and skin. Now, when the nerve-
centres become involved by any form of destructive pro-
cess that cuts off these so-called "trophic fibres" from
contact with certain parts of spinal cord function,
important regions of the body may waste away without ex-
hibiting paralysis, the eye and ear may lose their marvel-
ous functions, and the skin may develop different forms of
eruptions, bed-sores, etc.

Finally, the spinal cord and the medulla oblongata
(which is its uppermost portion) contain certain collec-
tions of nervous columns that overlie the more
important functions, or those essential to life.

By means of an excitability which is present in these
collections of cells, the heart is kept pulsating; the res-
pirations go on, even in spite of any voluntary efforts
made to arrest them; the pupil dilates and contracts
when exposed to different degrees of light; and the blad-
der and bowels, and urethra, are regulated by the excre-
tions that pass within them. In the same way the sexual act is ren-
dered possible in the male; the stomach and intestine
keep up a perpetual worm-like movement; swallowing
is performed in such a way that the food does not enter
the air-passages or pass upward into the nose; the ca-
libre of the blood-vessels is constantly altered, so as to
meet the demands of different parts of the body when
active or at rest; and the acts of vomiting, hiccuping,
sneezing, sighing, laughing, etc., are rendered possible,
and often involuntary.

In closing this section of my article, I take the liberty
of presenting a sample page of my own case-book, spe-
cially designed for the recording of the results of the first
examinations of patients afflicted with any form of nervous
malady. Some of the headings will be discussed in sub-
sequent pages. Their bearings upon diagnosis will then be
made clear. The page which faces the printed one is left
blank to allow of subsequent record of the treat-
ment and any new symptoms that may arise.

SYMPTOMS OF NERVOUS DISEASES REVEALED TO THE PHYSICIAN BY HIS SENSE OF SIGHT.

When a patient and his medical adviser meet for the
first time there are many medical facts which may be de-
tected simply by a glance, without a question being asked.
Sometimes information thus gained is invaluable to the
doctor, and of the greatest importance in diagnosis. To
become skilful in this line, however, both study and prac-
tice are requisite.

Three years since I published, in the New York Med-ical
Journal, a contribution to the study of medical phy-
siognomy, and, in my late work on "Medical Anatomy"
(Wood's Library for 1882), I have devoted an entire
chapter to the subject. In this article, however, I shall only touch upon such points as are related to the diagnosis of nervous diseases.

This section of my article I shall discuss under the following heads: 1. The study of the features and general appearance of the patient. 2. The study of the gait and the attitude of the patient, when sitting, standing, or reclining.

The Features and General Appearance of the Patient.—One glance at a face affected with such striking alterations as those produced by Bell's paralysis, Du- chenne's palsy in its advanced state, marked atrophy of its muscles, and some other nervous conditions which are associated with extreme facial deformity, would be sufficient, with even an inexperienced practitioner, for a diagnosis. But all diseases of the nervous centres, or of the cranial nerves themselves independently of the brain, are not so forcibly evidenced in the face. Something of value, however, usually be learned by a careful study of each of its parts, especially the forehead, eye, lips, tongue, and ears.

A prominent and tortuous artery upon the temple may catch the eye of the doctor. It is well to know that such a condition often accompanies kidney disease. A scanning of the face will show whether the complexion is redder, as in health, or pale from some cachexia; clear and free from eruptions, or sallow and dingy; waxy and transparent, as in Bright's disease, or tinged with blue from imperfect circulation. The skin may show fine or wrinkles may possibly exist that point strongly to some complicating disease of the brain, lungs, heart, or digestive organs, the presence of persistent pain, and other valuable data. In adults or the aged these lines are of less clinical importance. I have discussed them in other articles, previously referred to.

A jaw that is long may suggest some difficulty in breathing. An unlined shoe may cover a dropslip foot; a slit in the region of the "great-toe joint" may have been made as a relief to gouty inflammation; one shoe badly worn at the toe may tell of an existing hemiplegia. Patients with enfeebled mental powers and drunkards are particularly liable to have their clothing wrongly or incompletely buttoned; the pants imperfectly closed or open; the shoe down at the heel; the hair uncombed, and to present other evidences of indifference to neatness of appearance.

Good strong hair in abundance, and teeth that are free from defects, are evidences, in the adult, of a naturally vigorous constitution. Broad shoulders and deep chest are indications of inherited strength both of the organs and muscles.

The Diathesis.—The general appearance of the patient may afford some valuable information respecting an hereditary diathesis. Laycock has admirably described them. Patients of the "gouty" diathesis usually have a heavy frame, well-developed muscles, a large head and jaw, strong hair and teeth, a robust appearance, and an erect carriage. They are peculiarly susceptible, in adult life, to diseases of the blood-vessels, apoplexy, aneurism, and heart troubles.

In contrast to this type, those of the well-marked "strumous" diathesis have a light bony framework, which is often characterized by an enlargement of the ends of the long bones. The hand is sometimes unshapely from this peculiar defect, or the rings which pass the joints are too large for the finger. The chest of such subjects is also small. The glands of the neck tend to become enlarged at about the age of puberty.

The hair of strumous subjects is liable to be thin and fragile. The eyelashes are usually long and silken, although the lid margins tend to be thickened, or less disfigured. As children, they are liable to be unusually precocious. The teeth are crowded into a narrow arch and are liable to decay early. The under jaw is light. Evidences of rickets in childhood may exist during adult life. Scrofulous children inherit either a velvety skin, dark-brown complexion, dark hair, dark brilliant eyes, and long lashes, with the lineaments of a face finely drawn and expressive; or a fair complexion, thick and swollen nose, broad chin, teeth irregular and developed late, inflammation of the Meibomian glands, scrofulous ophthalmitis, eruptions of the head, nose, and lips, and enlarged cervical glands. These subjects are often "chicken-breasted," and "bow-legged." The "strumous diathesis" entails a peculiar liability to defective nutrition, glandular enlargements, and "consumptive" changes within the lungs during early manhood. Epilepsy and hydrocephalus often develop in such subjects during infancy or childhood.

The so-called "nervous" diathesis is commonly associated with small but perfect bones, an absence of fat, a well-formed cranium, small features, quick intelligence, and an active frame. They usually have a bright eye and small abdominal organs. They bear fatigue well, but are peculiarly susceptible to nervous excitability and depression. In adult life they become the more common victims to neuralgia, epilepsy, hysteria, dyspnoea, and many other nervous diseases.

Dark-haired and swarthy subjects are often of the "bilious" temperament. They commonly possess large frames, strong muscles, and a tendency to moderate obesity. They are active rather than lethargic. The digestive organs are often disturbed by habits of over-indulgence at the table or excessive mental efforts. Such subjects commonly suffer from "scurvy" during early childhood, and often develop gouty symptoms in early adult life. They are not infrequently victims to vascular changes, kidney disease, and apoplexy, after the age of fifty years.

The "lymphatic" diathesis is generally met with in sluggish, lazy, and large subjects. They are commonly addicted to all kinds of venereal diseases; they suffer from epilepsy, and to excessive eating. They have heavy bones, but soft and flabby muscles. They are often pale. They usually thrive best in invigorating climates.

Now, it must be remembered that it is seldom that the physician meets either of these types unadulterated. A man of the gouty diathesis, with a wife of the "nervous" type, will probably have children that exhibit certain characteristics of both. Hence it is often desirable, before making a diagnosis, to inquire into the peculiarities of build and temperament of the ancestors of patients afflicted with nervous diseases, as well as to their duration of life and the causes of their deaths.

The Cachexia.—These are diseased conditions. The one which are really chiefly familiar to the neurologist are those of syphilis, cancer, goit, mercurial or lead-poisoning, and malaria. In all of these there is a poverty of the blood, because the red corpuscles are more or less destroyed and the constituents of the blood-plasma are altered. If a cachexia is superimposed upon some special form of diathesis, a double danger to the patient is the result. A strumous subject, for example, may have his tubercular tendencies materially hastened, if not actually developed, by malaria, syphilis, and mercurial or lead-poisoning.

Special Physiognomy.—As the physician scans the features of his patient, it is best to inspect different parts of the face separately, as it were. Let us note what he should particularly observe.

The forehead. If the forehead be well developed, the "nervous diathesis" is liable to be present. If protuberant and overhanging a small and imperfectly developed face, rickets, hereditary syphilis, or hydrocephalus have probably existed in childhood. If hereditary syphilis has conduced toward the cranial deformity, the teeth will be found to be defective. Ulceration upon the forehead, unless it be due to a wound, is invariably syphilitic. Scars of this region or copper-colored spots are equally significant and suggestive. Depressed fractures over the frontal region are not necessarily associated in the adult with injury to the brain, even if extensive, be-
cause the frontal sinuses are developed after puberty, and the front wall of the sinus may be then crushed in without disturbing the back wall or the underlying brain. A very small cranium and a retreating forehead are often present in imbeciles.

The eye. In the aged, if the cornea be cloudy, it is well to lift the upper eyelid and seek for an arc of a little pigmented tissue called "aging of the eye," or "sclerosis," as it is called, of the spinal cord. It occurs only when this disease has involved the "cilio-spinal centre" of the cord. This condition is indicated in the eye by preternaturally small pupils that do not respond to light, but which still move when efforts to accommodate the vision to near objects (within the space of twenty feet) are demanded. To test this fact, place the patient at a window and instruct him to look fixedly at some object more than twenty feet off whenever his eyes are open, so that the pupil need not contract in order to focus the vision. Now tell him to close the eyes and keep them closed until instructed to open them. After the patient has kept his eyes closed for a few minutes, tell him to open his eyes. Watch carefully at this moment for a response in the pupils, as they will contract instantly in health. If they fail to do so, the existence of spinal sclerosis is almost positively indicated.

Abnormalities of the pupils may afford the practitioner material aid in diagnosis. The pupils are found to be dilated during attacks of disease, and after excessive muscular exertion, in the later stages of anæsthesia, and in cases of poisoning from belladonna and other drugs of similar action. A contracted state of the pupils exists during alcoholic excitement, in the early stages of anæsthesia from chloroform, and in poisoning by morphia or other preparations of opium, physostigmine, chloral, and some other drugs. Paralysis of the third cranial nerve decreases the area of the pupil of the same side, since that nerve controls the circular fibres of the iris.

Again, one pupil may dilate irregularly in a weak light. This suggests the existence of adhesions of the iris, as a result of past inflammation. Irisitis is often syphilitic, and this symptom may tell of past infection. The inner surface of the eyelid is a valuable guide to detect the presence of anæsthesia, as it shows a pallor that is in marked contrast to the redness of health. Alcoholic subjects are apt to have a vascular redness of the eyeball. Bright's disease often causes a drop of fluid beneath the conjunctiva that might be mistaken for a tear. It can be moved, however, while a tear cannot without causing its disappearance.

The movements of the eye should be the next subject of inquiry. Brain diseases sometimes manifest their existence very early by some form of paralysis of the ocular muscles. Strabismus or cross-eye may exist when the third or sixth cranial nerves are impaired. We meet it chiefly in connection with hydrocephalus, apoplectic clots, brain-tumours, cerebral meningitis, growths within the orbit, and as a congenital or acquired deformity.

It is a fact well known among oculists, and one which often helps them materially in diagnosis, that the defects of vision occasioned by impairment in the power of some of the muscles which control the eyeball, cause the patients unconsciously to assume a position of the head which tends to assist them in the use of the affected eye. So diagnostic are some of the attitudes assumed by this class of afflicted people, that the condition which exists may be told at a glance, as the patient enters a room, by one thoroughly familiar with the diseases of this important organ. The explanation of this tendency on the part of this class of patients lies in the fact that any loss of power in the ocular muscles immediately shows itself in the perception of every object, as it were, doubled; and it is to overcome these double images that patients almost instantaneously discover their ability to get rid of the annoyance by some special attitude, which, of course, depends upon the muscle that is weakened or paralyzed.

It will be necessary, in order to clearly understand the mechanism of this peculiarity, that the separate action of the six muscles which directly act upon the globe of the eye be considered.

The action of each of the ocular muscles may be given, there follows, with the proviso that many of the motions of the eye are not the result of the contraction of any single muscle, but often of a number acting either in unison or successively.

The superior oblique muscle turns the eye downward and outward; the inferior oblique muscle turns the eye upward and outward; the superior rectus muscle turns the eye upward and inward; the inferior rectus muscle turns the eye downward and inward; the internal rectus muscle turns the eye directly inward; the external rectus muscle turns the eye directly outward.

This statement as to the above muscles reveals nothing which would not be immediately suggested by the insertion of each, with the exception of the superior and inferior rectus muscles, which, if inserted alone, this situation would naturally suggest, tend also to draw the eyeball inward, on account of the obliquity of the axis of the orbit, and the same obliquity of the muscles, since they arise at the apex of the orbit. The action of the oblique muscles is, as any one familiar with their origin and insertion would naturally suppose, to control the oblique movements of the eyeball.

Now, as soon as any one of these six muscles becomes pressed upon and weakened by the presence of tumors, inflammatory exudation, syphilis, or other causes, the patient at once perceives double images, and, in order to get his eye into such a relative position with that of the healthy side as to enable them both to focus upon the same object in a natural manner, the patient soon learns to so move his head as to compel the two eyes to look in parallel directions.

A very simple rule can be suggested by which the physician may be enabled, not only to tell in what direction a patient would move his head in case any special muscle be rendered weak or utterly useless, but also to diagnose the muscle affected, when he looks at the patient, without any knowledge of his history. The rule may be thus stated: In paresis of any of the ocular muscles, the head is so deflected from its normal position that the chin is carried in a direction corresponding to the action of the affected muscle.

Thus, in paresis of the external rectus, the chin would

1 While this statement would be absolutely true in theory in all cases, we must acknowledge, as a clinical fact, that patients learn to utterly disregard the image in the affected eye when the internal or external rectus is the rest of paresis, and to use the normal eye only for the purposes of vision, thus rendering this attitude of the head less diagnostic than when the oblique muscles are affected.
March 22, 1884.]  THE MEDICAL RECORD.

be carried outward toward the injured muscle; while in paresis of the internal rectus muscle the head would be turned away from the side on which the muscle fails to act. In case the superior oblique muscle is impaired, the chin would be carried downward and outward; while in the case of the inferior oblique muscle, the chin would have to be moved upward and outward to benefit the vision of the patient. The superior and inferior recti muscles, when impaired by disease or other causes, would likewise create a deflection of the head in a line corresponding to that of their respective actions.

Paresis of the external and internal recti muscles causes, in addition to the facts already described, another point of very great value in diagnosis, viz., an alteration in the apparent size of the objects seen from what they would be in health. The condition of vision termed by oculists "megalopsia" or "macropsia," signifies paresis of the external rectus; while the opposite condition, called "micropsia," indicates loss of power in the internal rectus muscle.

In the former of these conditions, the objects seen by the patient seem to be greater in point of size than the intelligence of the patient assures him is the case; while in the latter, objects seem smaller to the patient than they really are.

I take the liberty of quoting, in this connection, an extract respecting the eye from my brochure on medical physiognomy:

"The intimate communications between the fifth, the seventh, and the sympathetic nerves, through the media of the ciliary, optic, and Meckel's ganglia, would lead us to expect that the eye should exhibit in its altered appearance the derangement of internal structures. When a glance of this organ is caught, what a field of mute expression is open to the mind! This silent and instructive index of the whole man may be bright or dull, heavy or clear, half-shut or unnaturally open, sunken or protruded, fixed or oscillating, straight or distorted, staring or twinkling, fiery or lethargic, anxious or distressed; again, it may be watery or dry, of a pale blue, or its white turned to yellow."  

"The pupils may be contracted or widely dilated, insensible to or intolerant of light, oscillating or otherwise, unequal in size, or changed from their natural clearness of outline. "The noble arch of the brow speaks its varied language in every face of suffering humanity. It may be creased, wrinkled, raised or depressed, while the lid of the eye, an important part of this vault, exhibits alternations of puffiness or hollowness, of smoothness or unevenness, of darkness or paleness, of sallowness or brown discoloration, of white or purple. Lines intersect this region, and the varied tints are perpetually giving new color, new feature, new expression, by their shadows. If the frontal muscle acts in connection with the corrugator supercili, an acute deflection upward is given to the inner part of the eyebrow, very different from the general action of the muscle, and decidedly expressive of debilitating pain, or of discontent, according to the prevailing cast of the rest of the countenance. An irregularity of the pupils of the two eyes indicates, as a rule, pressure upon nerve-centres or upon the optic nerve itself. In adynamic fevers the eyes are heavy and extremely sluggish, and are, as a rule, partially covered by the drooping eyelid; while in certain forms of mania they are seldom motionless. This latter peculiarity is also often noticed in idiocy."

"In the so-called "Bell's paralisis," due to failure of the facial nerve, the eyelids stand wide open and cannot be voluntarily closed, since the orbicularis palpebrarum muscle is paralyzed. This condition may be further recognized, if unilateral, by a smoothness of the affected side, since the antagonistic muscles tend to draw the face toward the side opposite to the one in which the muscular movement is impaired; an inability to place the mouth in the position of whistling, since for this act the two sides of the face must act in unison; loss of control of saliva, which dribbles from the corner of the mouth; and a tendency to accumulation of food in the cheek, since the buccinator muscle no longer acts.

When the third pair of nerves are affected upon either side the upper eyelid cannot be voluntarily raised, for

the levator palpebrae muscle fails to act; and the eye is caused to diverge outward, since the external rectus muscle, not being supplied by the third pair, and having no counterbalancing muscle, draws the eye from its line of parallelism with its fellow. In photophobia, attempts to open the eye create resistance on the part of the patient, since the entrance of light causes pain; while, as death approaches, or in the state of coma (save in a few exceptions), the eyes are usually open. In cardiac hypertrophy an unusual brilliancy of the eye is perceived, since the arterial system is overfilled from the additional power of the heart. A peculiar glinting stare exists during the course of scarlet fever, which is in marked contrast with the liquid, tender, and watery eye of measles. Many diseases of the eye itself tend to greatly alter the normal expression of the face. Prominently among these may be mentioned cataract, glaucoma, cancer, staphyloma, exophthalmus, iritis, conjunctivitis, amaurosis, etc., but the special peculiarities of each need not be here described." Finally, the ophthalmoscope is an important and valuable aid to those who are skilled in its use in detecting changes in the deep parts of the eye, chiefly those of the optic nerve and the vessels of the retina, by means of the sense of sight.

Dr. William C. Ayres has lately published in The American Journal of the Medical Sciences an exceedingly valuable and complete article upon this branch of diagnosis. By means of the ophthalmoscope the neurologist determines the presence or absence of a neuro-cutinitis, or a "choked disk" as it is called, which is peculiarly suggestive of some brain lesion that is creating a gradually increasing pressure within the cavity of the skull. Again, the vessels of the retina are derived from the same source as those of the brain; hence changes in the one are liable to be associated with similar changes in the other."

(To be continued.)
ON THE USE OF FORCE IN THE TREATMENT OF RESISTANT CLUB-FOOT.

By E. H. BRADFORD, M.D.,
SUSCHEM TO CHILDREN'S HOSPITAL, BOSTON, MASS.

It is certainly desirable to place in the hands of the general surgeon a method by which obstinate, relapsed, or half-treated cases of congenital talipes equino-varus may be cured without the expenditure of a great amount of time or the trouble of a great amount of special detail. This is particularly needed in the service of a large general hospital, and in the work of a country practitioner. The operation of excision of the tarsus has probably come into vogue on account of this need; but although this mode of procedure is apparently attended by slight risk and followed by excellent results, if equally good results can be obtained by less severe surgical interference the method is certainly to be discarded. Personal experience* in tarsotomy has led me to this conclusion, for although excellent results were obtained it appeared that the resistance to correction was not due so much to the deformity of the tarsal bones as to the tissues (presumably ligamentous) binding the displaced bones together, and that theoretically it was better surgery to attack the latter than the former structures. Simple tenotomy is not sufficient to divide the ligaments which lie close to the tarsal bones. Therefore, permission was obtained to carry out by Dr. Phelps, of Chateaugay, is objectionable on the ground that correction would leave a gaping wound, and also because, on general principles, a deep incision is to be avoided if equally good results can be obtained without. Gradual stretching, the method most in vogue, demands in the most obstinate cases a great deal of time and a daily attention not always at command. The method of forcibly rectifying a club-foot is not a new one, but it has not found favor because of the mechanical difficulties encountered, and also because a practicable means of fixation after such correction had not been in use, consequently not enough has been gained to sanction the procedure. Furthermore, tradition has deterred many surgeons from immediate correction in the fear of subsequent non-union of tendons. The first mechanical means of value for the purpose of immediately correcting obstinate club-foot was reported by Dr. Morton, of Philadelphia. In two cases in which I had the opportunity of testing this method its results were highly satisfactory, and perfect success was not gained from the fact that perfect fixation through lack of experience in the method and in the mode of after-treatment was not effected. The appliance seemed to be defective, in that it lacked precision, relying as it did for the correcting force upon straps, which are liable to stretch and slip. The accompanying drawing illustrates an appliance which appeared to remedy this difficulty.

The object of the appliance is to exert pressure under control of the operator in three directions, and also to enable him to twist and raise the front of the foot.

The apparatus consists:
1. Of a plate large enough for any foot.
2. Of three steel buffers or padded plates, which are attached at the ends to steel screw-rods playing through sockets with a female screw thread at the sides of the large plate. By turning the screws, which is done by the handles, the plates or buffers are pushed forward. They should be placed so as to press (1) upon the side of the first metatarsal; (2) on the side of the os calcis just beneath the malleolus; (3) on the outer side of the foot over the projecting head of the astragalus. The female screw through which the male screw plays is adjustable upon an arm curved so that pressure can be applied when it may be found necessary. The sockets and arms are arranged so that they can be shifted and placed at any point along the side of the large plate, or can be shifted from side to side, so that the appliance can be used for either foot.

3. A straight rod, extended in the plane of the plate, gives increased power in raising the front of the foot. This is not always needed, and can be removed.

In operating upon obstinate cases of club-foot (the only cases for which this method is designed) the method of procedure is as follows: Tenotomy is performed in the usual way, the planter fascia divided first, the tibiales tendons (if contraction is present) and the teno Achilles last (after the deformity at the arch of the foot has been in a degree corrected); the foot is then forcibly manipulated with the hands, pressure being exercised upon the projecting head of the astragalus by the thumbs, and force applied in a counter-direction by the hands grasping the ankle and forepart of the foot. It will be found in certain cases that complete correction of the deformity cannot be accomplished by the hands alone, and the hindrance will be seen to be not a shortened tendon or an insertion accessible to the tenotonem.

The instrument just described is then to be applied, and the screws turned and adjusted so that the plates will press upon the os calcis, the head of the astragalus, and the side of the first metatarsal as far as its articulation with the tarsus. The foot will now be firmly held, and by additional turns of the screw force can be applied in the desired directions. Rotation upward and outward can be effected by twisting the plate and the equinus deformity of the foot can be corrected by pressing the end of the plate upward. In case it is desired to increase the power in this direction this can be done by increasing the length of the handle. If the screw plates are properly adjusted and it has been ascertained that there is no danger of a fracture, as the pressure can be so directed that the ligaments will yield before any of the bones of the tarsus can be broken. An anesthetic is of course required, and correction will be done gradually rather than by any sudden tear. The extent to which force can with safety be applied is with difficulty defined; it may be said, however, that experience shows that a much greater pressure can be used than would at first be thought feasible—in a majority of cases enough force can be used to convert the foot from the position of varus to that of valgus, and to correct the equinus position. In the simpler cases this is always possible; in the severer cases some minutes should be given to gradually stretch the foot. Sometimes complete correction is not possible at one sitting, and something will have to be left for after-treatment or for a second sitting.

After the foot has been brought into a position which is nearly normal, and the contracted tissues so stretched that the foot can be held without a great amount of force, the foot should be fixed in the corrected position. For this purpose nothing has been found so useful or comfortable as a plaster-of-Paris bandage properly applied. The foot should be held in as nearly a normal position as is possible, grasped by one hand at the toes while counter-pressure is exerted on the leg. Roller plaster bandages prepared in the way that is customary for plaster jackets are wound around the foot and leg.

* Boston Medical and Surgical Journal, 1881, p. 241.
which are first to be covered with one layer of sheet-wadding. The bandages are to be applied without loosening the hold upon the foot, which is to be kept in the corrected position until the bandages have become suf- ciently hard as not to yield when the hold on the foot is loosened, and additional turns are then applied around the toes. The bandage should be carried above the knee and half way up the thigh, and the leg should be flexed at the knee, thus preventing any subsequent rolling of the limb within the plaster bandage. After the dressing has become stiff, and before it is absolutely hard, it can be cut through by two cuts along the dorsum of the leg and foot, and cross cuts over the foot and thigh, so that the lid of the plaster-box may be lifted and the parts inspected subsequently, when necessary, without destroying the bandage.

There should be no wrinkles in the bandage, and no pressure should be made upon the dorsum of the foot while the gypsum dressing is hardening. After ten days to three weeks the stiff bandage may be removed, and if the foot is sufficiently corrected, a walking-shoe applied.¹

The chief objection which will be urged against this method will be the supposed risk incurred. It would seem, however, danger is not so great as would be thought. Experience, with the above method, conclusively that the temporary pressure upon the skin necessary to break a bone does not cause sloughing, or even an abrasion; the same is true of the pressure required to rectify a club-foot. Experience has also proved that it is safe to fix a limb immediately after osteosclerosis with plaster of Paris bandage. The same applies to be the case in club-foot, if ordinary care is used in applying the bandages. Sloughs may occur on the inside of the ball of the toe, on the outer and under side of the sole, and on the dorsum of the foot; but these sloughs are no more troublesome than those sometimes occurring in the use of Scarpa's shoes or appliances, held by straps, and therefore liable to occur from the fact that in a foot held in a well-applied plaster-of-Paris bandage, the pressure is not confined to a few points but is nearly uniform over the whole foot. In case a slough appears (a fact to be determined by lifting the lip of the plaster-of-Paris box which holds the foot), the following an operation can be performed. The skin has recovered so that a plaster bandage can again be applied if a second one is necessary.

A plaster bandage is applied in the ordinary way from the lower part of the leg above the malleoli to above the knee, which should be bent; a strip of strong iron rod is placed on the first layer of the bandage, bent at the top so as to half encircle the thigh, to pass along the outer side of the leg, and to project slightly above and to the outer side of the outer edge of the foot. At the lower end of this rod a buckle is attached, and the portion lying upon the plaster bandage is thoroughly incor- porated by the successive turns of the bandage. A strip of rubber adhesive plaster is wound around the foot (which can be protected in the sole by card-board if necessary), and to the free end of the plaster at the level of the terminal end of the fifth metacarpal a piece of webbing is sewed. This is to be buckled to the buckle at- tached to the iron rod. Other strips of webbing and other buckles can, if needed, be put at any desired point, and by a wrench the iron can be bent in any direction, so that the point from which the pull is to proceed can be placed at any desired direction; additional strips of iron rod can also, when necessary, be applied. It is of course desirable to prevent the whole appliance from slipping down, and this can be done by placing a long strip of adhesive plaster on the skin of the leg before the gypsum bandage is applied, and a buckle on the outside of the bandage; if the free end of the plaster is not held in the buckle, slipping down in which the appliance is prevented. A stocking and slipper can be worn on the foot if a hole is cut in the side for the strip of webbing to pass through, and the patient can bear weight upon the foot.

As an objection to the method of applying a fixed dressing, it has been said that the plaster dressing being a fixed one and not allowing motion, gradual gain cannot be made by the foot in position in which the appliance has been placed. This is of course true, but almost complete correction can be gained in the majority of cases immediately, and the further gradual gain is only such as can be secured by a walking-shoe. A fixed dressing secures the indicated rest after the force required to gain the correction, and enables the stretched tissues to adapt themselves to the new position. The foot is forcibly put in a new position, and may be said to have suffered a "sprain," the indications for the treatment of which are fixation, which is most readily secured by a plaster bandage.

The danger of non-union and tendons after correction immediately following tetany may occur, but resistant cases can practically be cured, although it is mentioned by many authorities. In this, as in many other particulars, experience appears to disprove tradition.

After complete correction—and by that term is meant that the plane of the sole of the foot can be brought to a right angle with the axis of the leg, and that a line of the inner edge of the foot turns to the plane of the outer edge of the leg—and after pain and swelling have subsided, a walking-shoe is applied. This is to be worn until the muscles have recovered the usual balance of power, the object being to prevent the possibility of incorrect walking.

The requisites of a walking-shoe are that it should be usually small at first, without the supervision of the surgeon or a skilled nurse; that it should allow motion in all di- rections except those toward the position of former dis- tortion; that it should not be cumbersome, heavy, or unsightly, and that it can be readily worn for some time. Various appliances have been in use for this purpose, but the one which has seemed to me the most efficient is the one used by Doctor De Graeff of New York, which has devised and used, and for an explanation of which I am indebted to him. A published description of this useful appliance had best be left to the originator.

All of the foregoing cases were of the congenital de- formity of an aggravated type; those of acquired variety were not included in the list.

By a perfect result is meant that the patient stands and walks on the whole of the sole of the foot; can when standing on the heel flex the front of the foot above the floor, and that the patient's foot presents no projection of the head of the astragalus or any of the tarsal bones on the outer and upper surface of the foot.

By an imperfect result is meant that the foot falling short of this standard. By nearly perfect is meant that the heel can be brought to the floor without twisting the foot, but that the front of the foot cannot be raised without lifting the heel. This is true of the left foot in Cases 8 to 11. The patients are still under treatment.

Nos. 9, 10, and 11 were treated for forcible manual straightening without mechanical assistance. Nos. 14, 15, and 16 were experimental cases in a measure; they were the first ones treated in this way, and were but partly successful, for the reason that the method was not per- fected, and chiefly because the feet were not fixed after operation from fear of injury following the use of plaster-of-Paris bandages, and because the bandages were not applied above the knee. The patient was bent in the foot to the point of the bandages occurred. The deform- ities were not more resistant and were less severe than the other children who were successfully treated, were all benefited, and walk with slight noti-

¹ Halun, Brit. Med., March 19, 1889, describes a new method of holding the foot while a plaster bandage is applied.
formity, except when the feet are bared. Case 16 is instructive from the fact that an aneurism of the posterior tibial followed a month after tenotomy. The tenotomy was fierer than was needed, but at the time it was thought advisable to cut very freely, as the appliance for stretching was not perfected. The aneurism, was

![Image](https://via.placeholder.com/150)

month later, cut down on, and found to proceed from a pin-hole opening in the artery. This was tied, as any bleeding-point would be, and the patient recovered promptly, and at present, three years later, walks without appliances. An equinus deformity remains, the patient being unable to bring the heel to within one inch of the ground without twisting the front of the foot, and walk on three-fourths of the sole.

![Image](https://via.placeholder.com/150)

Case 17 has been the longest under observation, and would indicate that there is little danger of a recurrence of the deformity. At the present time he walks perfectly well, without appliance, and with perfect feet. For a year and a half after his discharge from the hospital he has been seen professionally but five times. He wore for a year light walking supports, which his mother has been able to adjust herself without medical supervision.

![Image](https://via.placeholder.com/150)

Case 2 has not been seen since his discharge from the hospital. Letters from the parents report that at the present time, eighteen months after discharge, the child is "walking perfectly."

"The same is true of Case 3.

Case 4 was one of equally severe deformity. The patient is now, eight months after discharge, able to walk perfectly. The amount of flexibility at the ankle-joint is indicated by the accompanying tracing, taken by placing a piece of paper at the side of the leg, the sole of the foot being flat on the floor.

In Case 6 the patient suffered a good deal of pain for a week, and on the removal of the plaster a slough was found on the side of the ball of the toe and also on the dorsum of the foot. The appliance as indicated in Fig. 2 was used, and the patient went about with crutches. He began to use a walking-shoe in six weeks, and was discharged from the hospital, and three months later was in the position indicated in the photograph, and able to walk about freely without appliance, crutch, or cane, having taken care of his foot himself during that time, he being seen medically but six times, chiefly for observation. The treatment was perhaps hurried unnecessarily, and an earlier removal of the plaster would have prevented the sloughs appearing. These, however, did not in any way prevent the continuance of treatment.

The patient's foot was very resistant, and at the time of operation all possible force was required after tenotomy to press it into a normal position. The patient was fifteen years old, and had been walking on a deformed foot all his life.

Case 8 was the most resistant of the series, partly because the foot was small and force was therefore with difficulty applied. Three sittings were necessary to straighten the left foot: a small slough appeared, and the spur appliance was used. The right foot was straightened in one sitting.

The length of time required in the treatment of the above cases varied. In the cases where the feet were the least resistant the plaster bandage was removed in from three to four weeks, and walking-shoes applied immediately. In Cases 2, 5, and 13 the whole active treatment occupied but a month, after which time the patients were left to the parent's care and the care of the physician, although directed to wear the walking-shoes for a year. Case 13 was seen a year afterward, and the feet found to be in a perfectly satisfactory condition. The same may be said of Case 5, seen three months after discharge from the hospital. Where greater resistance was encountered longer time was needed. Case 6 was seven weeks under active treatment; Case 8, the most resistant of the cases collected, was four months under constant observation. In both the plaster bandages were removed on account of sloughs, and the spur appliance used until the feet were in a condition for a walking-shoe.

It should be borne in mind that the method of treatment by extreme mechanical force is not to be used except in extreme cases, and in cases were a speedy result is
desirable. It is not claimed that equally good results cannot be obtained by other more gradual methods. The writer, however, believes the method to be safe, to save time and trouble, and to give perfect results.

Hydrops Amnii and Change in Presentation.—Dr. N. O. D. Parks, L.R.C.S.I., etc., of Ashton, R. I., writes that he was called to attend a woman who had been in labor for over twelve hours. The pains were feeble, but after some hours improved. Examination showed a head presentation, as well dilated. The pains then ceased again, and the patient got up and walked around. There was evidently a very large amount of liquor amnii, though the membranes were not ruptured. When the pains returned, examination showed that the foot was presenting instead of the head. Dr. Parks quickly ruptured the membranes and seized the foot, but found it hooked over the head. He finally disengaged it and completed the delivery. "The points of interest in this case," continues Dr. Parks, "are the rapid and alarming change of presentation and the difficulty in delivery arising from the foot becoming hooked around the child's neck. The fetus had evidently been floating about in more than a gallon of liquor amnii, and constantly changing its position, and the lesson I would derive is in every case of hydrops amnii to rupture the membranes the moment you get a favorable presentation without waiting for a pain, irrespective of the condition of the os."

A CASE OF FRACTURE OF THE PELVIS.

By Edward S. Dwight, M.D., New York.

I was called on September 12, 1883, to treat a young German fresco-painter, nineteen years of age, who, while working in a store in this city, had fallen from a scaffold for a distance of about fifteen feet, the back part of his right hip striking diagonally against a projecting shelf a little above the floor, and the ilium of that side being fractured from a point a little to the outer side of the upper extremity of the sacro-iliac symphysis, downward and outward into the great sacro-acetabular notch.

The patient was unable to stand, although there was marked crepitation along the line of fracture; efforts to rise caused a sensation of falling in pieces; and the thigh could not be flexed to an angle of less than 120° without great pain over the line of injury, and also over the tuberosity of the ischium. Severe pain was also felt in the groin. There was, however, no ecchymosis.

The treatment adopted was as follows: A roller bandage was first applied around the pelvis and was replaced on the following day by a thick plaster-dressing, enclosing both the pelvis and the upper half of the right thigh. The latter was slightly flexed, the front and outer side of the hip-joint being reinforced by moulded plaster splints. To prevent traction upon the ilium by the dorsal and laterial muscles of the trunk, I also added a few turns of roller bandage, which were carried over the right shoulder and under the perineum. These were tightly drawn, so as to depress the shoulder as much as possible, and were kept from slipping by means of a transverse band sewn to them in front and behind and passing around the left side of the chest. This contrivance diminished the greatest extent of the shrinking in the injured part which, together with numbness and tingling along the course of the great sciatic nerve, had been experienced, particularly at night.

At the end of six days, the plaster bandage having become very much loosened by the subsidence of the swelling, it was replaced by another, and tighter. This was applied over a layer of wadding and inclosed the pelvis only, the thigh being slung at an angle of 140° by a series of turns of roller which passed around, and were sewn to, the upper rim of this plaster-dressing, and which crossed each other above the thigh, where they were also sewn together, as well as to the plaster.

The rim of this second plaster bandage, being very thick and firm, prevented upward muscular traction, and the whole apparatus being constantly pulled downward and forward by the weight of the limb, was in consequence kept closely applied against the seat of injury.

Two weeks after the accident I slung the thigh from the neck also, carrying too a loop of strong cord from the bottom of the sling down below the instep, and allowed the patient to get out of bed and walk into the next room, which, with the aid of a crutch, he was able to do without pain.

Three weeks later this dressing was also removed, and replaced by the following apparatus in leather.

(This represents the back of the apparatus. The central pad rests on the sacrum; the six straps (right side) are all freely movable at their insertion, and are thus susceptible of being placed at any angle, so as to adapt themselves to the outline of the hip; the upper two are applied high up, so as to exert downward pressure upon
the crest of the ilium; the next two pass over the great trochanter; and the two lower ones are applied low down, so as to exert upward traction upon the tuberosity of the ischium. The three broad straps upon the left side are firmly sewn to the sacral pad, so as to afford efficient counter-pressure. The strap hanging from the lowest, on the right side, passes under the perineum, and is intended to aid in keeping the whole in place. A broad band of canton flannel was applied around the body before the belt was put on.

The patient was now allowed, after a day or two, to walk about the rooms without a crutch, which he was able to do without pain, the belt acting as a moulded splint, and its lower straps preventing him from unduly raising his thigh. As the belt had a tendency to work upward, another perineal strap, upon the left side, was added with advantage.

Eight weeks after the accident the patient was able to go out of doors, and could flex his thigh to an angle of 85° without pain. Rheumatic tenderness and twinging pains, at changes of the weather, persisted up to the end of October.

The upper part of the fracture consolidated first. There was no effusion of callus perceptible to the touch, but the iliac border of the sacro-iliac symphysis seems much more prominent upon the injured than upon the opposite side.

Progress of Medical Science.

TUBERCULOSIS AGAIN.—At the recent meeting of the German Naturalists and Physicians, Professor Bollinger brought forward the results of some of his investigations on this subject (Wieder Altem. Med. Zeit., No. 40). Direct inoculation was performed on guinea-pigs, and the guinea-pig failed to induce the disease even when the animals were placed under the worst hygienic conditions. Similar injections, however, made with milk derived from cows affected with bovine tuberculosis, resulted, in every case, in the reproduction of the disease. No result followed the injection of the same milk after it had been boiled, and hence the obvious deduction is insisted upon that precautionary boiling should be universally adopted. Professor Bollinger professes complete faith in the theory of infection from micro-organisms, and especially in the specific nature of the tubercle-bacillus, and in the identity of human tuberculosis with that form of the disease affecting the bovine animals. These views were strongly combatted by discussion by Professor von Recklinghausen, who maintained that in the face of the fact that pathological changes, not distinguishable from those produced by tubercle, could be set up by the injection of indifferent or even crystalline substances, the discovery post mortem of this or that form of micro-organism could not be held to be conclusive as to the parasitic origin of such changes. That many varieties of micro-organism may make their way into the tissues and there develop and increase is undoubtedly true, but that they have any direct causal relation to all the pathological changes with which they are associated is denied. A familiar example is furnished by the small-pox pustule, in which certain bacteria are constantly found to be developed; but they certainly cannot be held to be the originators of the disease.

Professor Germain Sée, at the opening of his winter course at the Hôtel Dieu, gave an exposition of the different phases of phthisis, and took the opportunity of expressing his opinion on the reality of the bacillus of tuberculosis, and on its value in relation to diagnosis, prognosis, and the preventive treatment of the disease. Professor Sée considered that the discovery of the bacillus in this affection was of the utmost importance, as whenever its presence was detected in the matter expectorated, pulmonary tuberculosis might with certainty be diagnosed, even before the disclosure of any other physical sign, for this micro-organism is not discoverable in any other pulmonary affection, whatever be its nature or origin. M. Sée dwelt upon the importance of this sign, as by a knowledge of this fact the physician might, by early treatment, be enabled to prevent the development of the disease, not by attacking the bacillus, which is unassailably when once in the organism, but by placing the patient in such a condition as would enable him to effect the destruction of the parasite, or at any rate to resist its baneful influence on the system.

Three distinct points in reference to tuberculosis in birds came out from facts explained at a recent meeting of the London Pathological Society by Mr. Sutton and Dr. Gibbes. The first is that although in grosser anatomical features the lesions differ markedly from those of human tuberculosis, yet historically, the resemblance is close, and in the universal presence of the bacillus apparently complete. Precisely the same may be said of the relation between bovine tuberculosis and the human disease; and, granting Koch's assumption that the bacillus is the test of tubercle—a postulate which is not yet universally accepted—signs and the veritable resemblance is apparent. Another fact is the singular limitation to the granivorous species of birds, associated with the almost general starting-point of the disease being in the alimentary canal. Dr. Ribbert's testimony here also comes in confirmation; and the suggestion is unavoidable that there is some connection between the intestina and the morbid change. The next step, in other words, enters the body with the food. Lastly, and in striking parallelism with the foregoing, is the evidence obtained of the transmission of the disease to animals fed on the tuberculous tissues of the bird. It is obvious, then, that several points are raised in connection with this subject which have a very wide bearing indeed, not to speak of the pathology of tuberculosis, and the very great significance of Koch's discovery, but upon the far more important matter of the transmission of disease through food.

In the Bayerisches ärztliches Intelligenz-Blatt, Dr. Herzerich reports the history of two girls, sisters, aged respectively fifteen and three moons, who, after being nursed by an undoubtedly phthisical mother—the first for five months, the second for three—were reared and fed on soup, milk, and pap. The mother adopted the following disgusting method of feeding: She first chewed the food herself, then spat it out into a spoon, and gave it to the children. So long as she had little expectation the children bore this feeding well; but so soon as her expectoration became profuse, though the children continued to take their food with appetite, they both rapidly emaciated; ulcers formed in the throat and sides of the cheeks, some large and of irregular shape, others small and round, both with infiltrated edges; and extensive swelling of the lymphatic glands occurred. Severe fever, purulent diarrhoea, and progressive atrophy caused the death of both children within a month of one another. The post-mortem appearances were the same in both. All the mediastinal lymphatic glands were swollen and caseated; caseous nodules occurred under the pleura and scattered throughout the lungs, also in the liver, spleen, and of smaller size in the kidneys. The mother survived the children for some months, and died after extensive destruction of the lungs had occurred. It is worthy of remark that her children by a former marriage showed no sign of phthisis; also that the two children in question, so long as they were suckled by a comparatively healthy mother, remained themselves healthy.

BLOOD-LETTING IN THE TREATMENT OF SEXUAL DISORDERS.—In The Practitioner for February, 1884, Dr. Alexander Harkin claims to have obtained immediate and permanent results from blood-letting, or cupping, over the occipital region, in various functional disturbances of the generative apparatus. In spinal neurasthenia fol-
lowing masturbation, in seminal losses due to other causes, in irritability of the bladder without actual catarrh, and in similar disorders, he extols the salutary influence of this topical remedy. He argues that most of these pathological states are to be regarded as true nerves, depending largely upon a hyperemic condition of the medulla oblongata. In the milder cases he relies very much on the effects of bromide of potassium and the extract of belladonna, with cold douches to the nape. Before proceeding to wet cups, which in every other case it is not convenient to adopt, he tries the effects of dry cupping, frequently repeated, or of a blister "nuche collis."

The Use of Collodion in Acute Orchitis and Other Conditions.—Collodion is not adequately appreciated and utilized, according to Dr. Ganggee (Birmingham Medical Review, January, 1884). Its ready evaporation and contraction give it the dual antiphlogistic power of reduction and compression to the benedictus, for example, Dr. Ganggee knows of no plan of treatment so simple, rapid, and satisfactory as coating the cord and scrotum with layers of collodion by the aid of a camel's-hair brush. The sensation is momentarily sharp, the shrinkage rapid, and so is the subsidence of the phenomenon. To swollen parts which cannot well be bandaged, collodion is especially applicable for the compression attending its contraction.

When the nasal bones are fractured, a very effective mould for keeping them immovable, after adjusting them with the fingers, may be thus made: place over the nose a thin layer of absorbent cotton soaked in collodion; as it dries, another layer of cotton and more collodion, taking care that the application extends sufficiently on each side to give buttress-like support. The patient compares the feeling to the application of a firm bandage on the nose, and the bones consolidate effectively under the shield, which may be renewed as it cracks and peels off.

The Prolonged Use of Jaborandi in Bright's Disease.—Dr. F. A. O'Brien, of Atlanta, Ga., sends us a communication, in which he calls attention to the beneficial action of jaborandi, given in small or moderate doses, for a long time, in the various forms of albuminuria classed under the head of Bright's disease. He has found that the drug is better borne when combined with nux vomica than if exhibited alone. In his opinion the action of jaborandi is not to be explained solely from its diuretic and purgative effects. It has been observed, also, that it has a specific influence on the kidneys, permitting the tubules to relieve themselves of the inflammatory products that block up their lumina.

Non-Medicinal Treatment of Habitual Constipation.—There is scarcely a derangement that physicians are more frequently called upon to treat than habitual constipation. It is notorious that drugs often result in temporary benefit only. Besides, the appetite suffers as frequently as the frequency of their repeated employment. It is as owing to the derangement of the bowels, Dr. Atkinson recommends a simple plan, from which he has generally obtained good results. Although it is neither original nor new, its systematic employment is not generally insisted upon to the exclusion of salts, pills, and the like. In order to get the bowels relieved in the first instance, it is well (The Practitioner, January, 1884) to give five grains of both compound colocynth and compound rhubarb pill at bedtime (this rarely requires to be repeated), then to take a tumblerful of cold water the next morning on waking, and repeat it regularly at the same time each day. Should the bowels remain sluggish, some time, the same quantity of water may be taken daily between meals. If there be no increase in place on rising or shortly after, a small injection of warm water may be resorted to. After each movement of the bowels a small hand-ball syringeful of cold water should be thrown into the rectum and retained. A soup-plateful of coarse oatmeal porridge (made with water and taken according to the Scotch method, viz., by filing half the spoon with the hot porridge and the other with cold milk) each night at bedtime, or even every night and morning for a time, is often a very great help. But above all things it is necessary for the patient to try and get relief at a certain fixed time regularly every day. If these directions are strictly carried out in their entirety, the evil, even if it has been of long standing, will generally be corrected, and the patient will improve in health and appearance.

Epileptiform Fits Caused by Prolapus Recti.—Dr. Shnigiro reports the interesting case of a gentleman, aged thirty-three, who for three years suffered from epileptiform fits of gradually increasing severity and frequency. Of late the seizures began to come several times a day, and were followed by general weakness, irritability, mental depression, giddiness, headache, and failing of sight. Examination gave entirely negative results as far as the nervous system was concerned, but a constantly occurring prolapus recti was found. As the patient stated, he had suffered from occasional prolapus since his childhood, but during the last few years the intestine fell out more frequently, and bled more profusely than any time. Vigorous effort to reposition the rectum had been made, but had remained successful, the patient underwent an operation for prolapus. The fits disappeared.—London Medical Record, December 15, 1883.

Explosive Marginal Glossitis.—This is the name given by M. Fournier (Jour. de Med. Prat.) to a peculiar and relatively rare inflammation of the tongue, well described in a monograph recently published by M. G. Lansoniant. It is found most frequently in children, but is observed also at an advanced age. The cause of the condition are obscure. It has been considered as a syphilis (Parrot); but the relation is far from constant, and the same may be said of dyspepsia and malnutrition. Some of M. Lansoniant's patients indulged in excessive use of tobacco or of alcohol; others had suffered from nervous diseases, rheumatism, or herpes. The three characteristic symptoms of the affection are: an irregular and sinuous patch of superficial inflammation and desquamation; a raised margin of whitish or grayish color surrounding the diseased part; a tendency to migration, causing the lesion to change its form and seat very rapidly. It is either unilateral or bilateral, and is never accompanied by pain, so that it may remain for a long time without any symptom. It is characterized with glossitis of smokers, cachectic glossitis, and some forms of mucous tubercle. Cauterizations have no beneficial effect. The best treatment consists in the avoidance of irritating food and drink and in the use of soothing applications or pulverizations.

Affectations of the Pleura in Diseases of the Female Organs.—Acute pleurisy has for a long time been recognized as a complication in certain acute inflammatory affections of the female pelvic viscera. Dr. H. Haeckel, of Potsdam, has recently made some observations on pleuritic effusion occurring as an undoubted result of chronic ovarian and uterine disease. In all the cases which could be accurately examined by Dr. Haeckel, the inflammatory process had extended into the pleura from the peritoneum, and doubtless through the well-known communication of the cavities of those serous membranes through the lymphatics of the diaphragm. As in such cases, when an ordinary ovarian tumor exists, the pleural effusion is a result, the removal of its cause—namely, the tumor—is directly indicated, and in cases where this has been done the effusion has disappeared. But if there be good reason to believe that the tumor is malignant, then "the existence of the tumor persists; the carinomatos elements are possibly to be recognized, implies that cancer has already scattered its deadly germs far and wide, so that it is no longer possible to extirpate the tumor radically."
THE MEDICAL RECORD:

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY
WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, March 22, 1884.

THE STATE OF THE QUESTION REGARDING AN INDEPENDENT LICENSING BOARD.

The Committee on Public Health has reported back unfavorably the bill to establish a medical faculty of the State University.

This is what has been expected. It does not signify that the Legislature is opposed to such a bill, but it is a recognition of the fact that the medical profession of the State is not yet ready to say what kind of a law it wishes.

Nothing will now be done upon the subject of medical legislation for a year. But it is the duty of the profession, meanwhile, to ponder over the subject, and to be prepared to act intelligently and decisively at the end of that time.

It will be proper for us to present now some of the points bearing upon the matter.

It is almost universally conceded by the thoughtful men of the profession that some kind of State legislation is needed, and is proper. The reasoning of those who claim that medical legislation always has been and must be futile has been abundantly answered, and need not be discussed here.

We have in the State fourteen chartered medical schools, which graduate annually between eleven and twelve hundred students. The proportion of graduates to matriculates ranges from twelve to forty-nine per cent. The duration of study, the arrangements of courses, the preliminary requirements, all differ very widely. The stringency of the final examinations also varies extremely. The result is that students who fail at one place can succeed at another, and that any young man, no matter how deficient his education, poor his morals, or meagre his intellect, can probably get into the medical profession through some one of its fourteen portals.

We have been accused of "poisoning the minds of the profession" as regards the medical colleges, but it can hardly be said that in the above anything but the truth has been stated. And we can, perhaps, safely add that every one of the State's fourteen colleges is a business institution, run in the interests, primarily and above all, not of the public and profession, but of its faculty and owners.

The logical result of all this is, first, that a great many persons are induced to take up the study of medicine who are not fitted for it, and secondly, that a great many persons are graduated in medicine who have not had the training or character that would make them, as physicians, safe members of society. Finally, owing to the business necessity under which the colleges lie, of having plenty of students, an extraordinary surplusage of physicians is forced upon the community.

It can be urged that doctors have no right to be protected by the State against over-competition. This may be true, but doctors do have the right to try and prevent the ambition of a certain small proportion of their guild from injuring the rest; and the State has a right, and is in duty bound to see that the medical men who assist in its executive and judicial functions are competent for their work.

It may be still further urged that such reforms as we need can come from action by the regular profession itself, without State help. But most decidedly this is impossible, because the worst evils are the result of the activity of men outside of the regular ranks. Nothing is more silly than to suppose, for example, that our State Society, by appointing committees to visit around and listen to examinations, can do any radical good. And no proposition could better show the absolute ignorance or insincerity of certain college men, who speciously argued for such a measure. Such visitors could only attend the regular schools, and their visits, if really inquisitorial, would simply give an impetus to institutions not visited. On much the same footing would be the establishment of a State Faculty with simple advisory and visiting powers.

Those who conscientiously wish reform, then, will oppose any attempt to compromise on visiting committees from the State Society or from a State Faculty.

Let us have no reform rather than any farcical pretences to it.

Again and again the profession has returned to the opinion that the best single measure which we can now adopt to improve the status of medical affairs is to take away the licensing power from the medical colleges, and entrust it to a separate and independent Board. The arguments against this proposition, which The Record has consistently advocated for many years, are all of them directed, not to the principle, but to the details.

Such a licensing board, it is said, will get under political influence; it will have to be mixed in character; a competent board cannot be selected; they cannot judge of the students' capacity or qualifications; they will be under the same (money) temptation, to give licenses too freely, as are the college faculties. All these arguments were presented with great force to the Legislative committee by the joint body representing the World's Dispensary, the United States Medical College, and Distinguished Institutions in this city.

But, on the other hand, it is said that the function of the colleges is to teach, not to license, and harm has come because they have done both; a separate licensing body would compel the weaker colleges to adopt a better standard. Furthermore, the existence of such a board would deter uneducated and unscrupulous men from rushing into medical colleges, thinking (as is the fact) that they can get a license to practice in eighteen months; if it did not at first raise the educational standard in the best colleges, it would certainly raise the average, giving to the State one licensing body with strict requirements, rather than fourteen of the present most variable and
elastische kind; it would also keep out from the State in
future the unskilled products of Western and foreign diplo-
ma-mills.

The advantages that would thus accrue would un-
doubtedly outweigh certain objections and defects in-
vitable to a new system. No bill can be drawn up
which will prove entirely acceptable.

We urge upon the profession of the State to accept no
visiting-board compromises, or any similar delusions of
reform, and to ponder well whether a single independent,
non-teaching licensing board would not be an advantage
to the State and profession.

THE MODERN SURGEON IN SEARCH OF NEW ORGANS.

In the march of time and the progress of science it has
come to pass that the human body has been pretty
thoroughly explored. One after another its different or-
gans have been discovered by the indefatigable anato-
mist, and have in turn had various functions assigned
them by his hypothetical friend the physiologist. Indeed
the modern anatomist must be content to enumerate and
describe the findings of his enterprising ancestors. Of
course the physiologist will continue to invent functions
until the human species shall have become extinct. He
being a man of genius, and as such subject to imagina-
tive inspirations, nobody will attempt to dispute this ex-
cercise of a proud prerogative.

Of late years, however, the new surgeon has come to
the van of professional enterprise. And his daring ex-
ploris already threaten to eclipse the fame of the phy-
siologist. But here is this difference between their re-
spective methods. Whereas, the latter was content to
supply an organ with a pleasant outfit of functions, that
had no perturbing effects upon the economy, the new
surgeon only feels happy when he has radically removed
an organ, leaving the distressed function, now made
homeless, to wander at large. Of course this has given
an immense stimulus to the propagation of knowledge
concerning vicarious action. So that, all things consid-
ered, surgeon and physiologist may continue to live at
peace for several years to come.

It is the pedantic anatomist, however, who is becom-
ing alarmed at recent surgical triumphs. For how can
he hope to give a satisfactory demonstration of visceral
topography, in the old sense, when a person's internal
arrangements have been radically altered, or successfully
operated away by the perfected apparatus of the new-
time surgeon.

Yes, the quite modern surgeon is a bold, bold man,
thoughly imbued with the spirit of iconoclastic radi-
calism; and this fundamental truth would appear to
hold good all the world over. But among all his breth-
ren the palm for boldness may be readily conceded to
the German variety of novel operators. It would cer-
tainly seem as if no tissue, organ, or system were quite
safe from his predations. His chief regret is that there
is such a paucity of extirpable material within the comp-
pass of a single body. Nature has turned out of her
mysterious workshop an apparently satisfactory creature
called man. Superficial contemplation is content to pro-
nounce him a success. In fact, even in his present shape
he has been admired by certain shallow, old-fashioned
people. But the new surgeon can improve upon this im-
perfect being. What with a judicious and prolonged
course of cutting, stitching, pruning, and extirpating, we
may presently hope to be able to supply the world with
a better race of men and women than unaided nature
can ever furnish.

Among the radicals, then, the chirurgical problem of
the hour is to determine exactly with how few organs,
and with what minimum remnant of these, the vital func-
tions may continue to be performed, long enough for the
publication of the individual case as illustrating a new
triumph of operative skill. And to be sure a patient with
any sense of the decencies and proprieties of civilized
life will survive until his case has been duly chronicled.
After that, he is of course at liberty to join the shadowy
army recruited from the ranks of victims of successful
operations.

In view of this pleasant condition of things we may in-
quire, what has the surgical revival of the past few years
mainly taught us? To begin with, it has been demon-
strated that one kidney is amply sufficient for the elimin-
tion of a satisfactory quantity of urine. Therefore, take
out the other emunctory. Doubtless the bladder is at
times a quite convenient receptacle. But it is a luxury
rather than a necessity. A rubber bag will do just as
well. Hence substitute rubber bags for your bladders,
and you will not be troubled with catarrh and stone.
The womb, it must be admitted, seems a rather essential
contrivance, especially when offspring is desired. Yet
surely we can manage to get along without it. Neither
it nor the ovaries should be allowed to forget that they
are mere tenants in a body landlord- ed over by the
advanced surgeon.

Evidently the occasional removal of such appendages
can only have a purifying effect upon the moral tone
of life below the diaphragm.

As for the spleen, since it has no particular office to
fulfil in the economy, the sooner we dispense with it
altogether, the better. Let the spleen be taken away
immediately after birth. And then the stomach. As
we grow more familiar with this puffed-up cesophageal
diverticulum, we can no longer hide our contempt for its
unpardonable intrusion into a cavity already overcrowded
and replete with bloated ballast. To be sure the stom-
ach is the pet of the gluton, of the man whose god is his
belly. But what of that? Think of the rectum. Is that
delightful portion of the alimentary canal to be a mere
channel for the extrusion of effete rubbish. Not at all.
Its powerfuly absorptive mucous membrane brooks no
neglect. Therefore feed by the rectum, and take out the
stomach. You need not after that pay the doctor for
curing its aches.

The extravagant length of the intestine is an intoler-
able reflection on the department of the human interior.
Exsect it and avoid colic. The bulky liver is an ever-
galling weight in the right hypochondrium. Cut it early
and often, if you wish to prevent jaundice.

Gallstones or no gallstones, all must admit that, cho-
lecystotomy is more necessary than vaccination. The
wasteful superfluity of lung-tissue has already been de-
monstrated by the German pulmonic exsector. Breathing
is much easier with one lung in alcohol.

Our multitudinous nerves, it is almost needless to say,
require frequent neurotomy and neurectomy. Let us hasten to take away altogether at least half of them. The others can be stretched to suit individual tastes. Nervalgia will thus speedily become obsolete.

And the brain, finally. Of all compound lobular inventions the most useless, as your very modern surgeon endeavors to show. He can devise new operations with his lobus Spigelli. What need, then, of a bone-encased labyrinth of lobes and fissures, that even the neurologist vainly endeavors to assay, label, and memorize, all in purest Greek?

These brief suggestions suffice to indicate the scope of advanced surgery. The prophylactic era of medicine is everywhere upon us. Shall there be no further dawn of new light for the operator? Shall his keen blade rust until a tumor actually forms? By no means. Let him rather be the destiny that shapes our ends to suit modern requirements. We may then hope to soon attain that degree of perfection which the evolutionist says is in store for us.

THE ANTIPYRETIC TREATMENT OF TYPHOID FEVER IN PRIVATE PRACTICE.

The antipyretic treatment of typhoid fever has been the subject of discussion at two recent sessions of the London Medical Society. Many interesting facts were brought out, but no definite conclusions were reached. Dr. Bristow made the severest attack upon the antipyretic method. It had, he said, been abandoned at St. Thomas’ had failed at Guy’s and other London hospitals, and had been given up largely also in Germany, except by those whose reputations were bound up in sustaining it. Dr. Samuel West brought forward objections to this method also, and Dr. F. Taylor showed that in Guy’s Hospital the mortality among 440 cases not treated antipyretically was 17.7 per cent., while that among 100 cases treated with cold sponging, baths, or Leiter’s coils, was 27 per cent. It was shown also that the mortality statistics varied greatly in different years, without respect to treatment.

On the other hand, Drs. Coupland, Cayley, and Broadbent brought forward some very convincing arguments in favor of antipyretics. The following figures were given:

<table>

</table>

These figures do not of themselves make a decisive showing, but on the whole tend in favor of antipyretic measures in hospital practice.

The important question arises, however, as to the practicability of using these measures in private practice. It is claimed that Brandt’s army statistics are really those of private cases, and show how favorably his method works in this class of patients.

It is to be regretted that our learned professors and servants have so far paid such little attention to what is, after all, the question of main interest to the general practitioner and the public. Are antipyretic measures applicable and successful in private practice?

So far as we can learn, one of the first to obtain facts and statistics upon this point is Dr. G. C. Smythe, of Indianapolis, Ind. In an article published in the Canada Medical Record, he states that he has collected one hundred and fifty-seven cases in the practice of himself, Drs. J. R. Featherstone, W. H. Vanzant, and S. E. Earp, all Indiana physicians. The patients were treated with cold sponging, the pads, and baths. Only three deaths occurred, or 1.9 per cent. Hemorrhages occurred in six cases and relapses in eight.

Dr. Smythe’s statistics are very striking and contrast strongly with those of Guy’s Hospital, where the mortality was 27 per cent. under more or less similar methods.

It is claimed by some that no serious obstacles exist to the employment of external antipyretics in private practice. This, however, is not the case. In order to have the cold sponging effective there must be one or two intelligent and conscientious nurses. For the baths, large bath-tubs, and strong and careful assistants are needed. In very many cases, therefore, these measures for reducing temperature cannot be employed, and we fear that the antipyretic method in many cases means simply large doses of quinine and some desultory sponging. It may be, however, that with Leiter’s coils or cold air, the object can be accomplished.

In conclusion, there is no object better worthy of collective investigation than the one we have discussed. There are plenty of hospital statistics, but we need more facts from private practice.

THE FOOT-AND-MOUTH DISEASE—CONTAGIOUS ECZEMA.

Despite some contrary statements it appears probable that the disease which has appeared among the herds of Kansas is contagious eczema, or the foot-and-mouth disease. The latest opinion is that it was imported from England by means of the stable clothing of two Scotchmen. Foot-and-mouth disease has been several times imported from England, and once from Canada, during the past few years. It has, however, never before got among the cattle in the unfenced ranges of the West. Hence, as it is perhaps the most highly contagious of all cattle diseases, the condition of affairs is a serious one.

Foot-and-mouth disease is defined by Williams and by Steele as a highly contagious and infectious febrile disease, associated with a vesicular eruption in the mouth, between the pedal digits, and around the coronets. It affects cattle chiefly, but also sheep, pigs, dogs, poultry, and even human beings.

After an incubation of one to four days the animal is attacked with fever, there is a constant moving of the mouth, salivation, and lameness. Large vesicles appear, from which the cuticle may be thrown off, leaving raw and even suppurating spots. Sometimes the suppuration becomes deep, and the hoofs are lost.

Ordinarily foot-and-mouth disease is not a severe malady, and the animal recovers in about a week.
During this time, the milk secretion is diminished and rendered unhealthful, if not positively contagious. The flesh is also made poorer, but is not believed to be injurious.

The cause of the disease is thought to be in some minute organism, but this has not yet been satisfactorily demonstrated.

DEATH FROM THE RUGBY GAME OF FOOT-BALL.

The British Medical Journal quotes our editorial upon foot-ball casualties and adds, "Of the very great danger which attaches to the Rugby game, we have often had sad proof."

It then refers to the case of a young man who was recently fatally injured during the game, dying either from a fractured skull or a ruptured artery. This is by no means the only case of the kind.

The Rugby game of foot-ball may answer for small boys who cannot kill each other, and for trained athletes who can take care of themselves. But as a game for amateurs and students it is brutal and dangerous, and does not furnish proper physical exercise, to those who need it.

It is proposed that the athletic training and general physical education of college students be put under the charge of a medical man. If this is done, we trust that efforts will be made to substitute a more rational game for the "Rugby" one—which is fascinating because it is a kind of free fight, not because it is an exhibition of skill.

THE ATTEMPTS TO FIND NEW FORMS OF PROTECTIVE VIRUS.

Germany has earned the credit of instituting the most careful methods of examining the minutest organisms and of studying their life-history. The French savants are, on the other hand, using their energies in trying to modify these organisms so as to obtain protective virus. The methods adopted already are various, and it seems probable that a process which succeeds with one organism will fail with another. Pasteur's original method of cultivating germs at a constant heat, and exposing them to the action of oxygen, though scientifically successful, has proved a practical failure outside of France. The dilution method suggested by Chauveau, followed by Peuch and others, and perfected by Salmon of this country, has apparently been abandoned in France. Recently the method of modifying anthrax virus by subjecting it for a short time to a certain temperature has been tried again. The method of passing the virus through animals of a different species to that usually affected by it, has been tried both in France and England.

At the last meeting of the Académie de Médecine, M. Pasteur announced some important results of the application of this method to the virus of hydrophobia.

M. Pasteur has found:
1. That the spinal cord and medulla, as well as the nerves of dogs dying of rabies, contain the virus.
2. That this virus cannot be cultivated in any liquids so far tried.
3. That the inoculation of small quantities of the virus prolongs the incubation, and if the amount inoculated is very small, the dogs are not affected. This seems to show that in hydrophobia the dilution-method will not furnish a protective vaccine.
4. The action of cold does not modify the strength of the virus.
5. The virus is absorbed by the blood.
6. That the passage of the virus through different kinds of animals causes a modification in its virulence.

M. Pasteur stated that he had in his laboratory twenty-three dogs whom he had rendered insusceptible to the hydrophobic poison, by inoculating them with the modified virus.

DELEGATES TO THE AMERICAN MEDICAL ASSOCIATION.

An opinion prevails somewhat, that, by reason of the action of the Medical Society of the State of New York, the medical profession of this State has been cut off entirely from the privilege of sending delegates to the American Medical Association.

This opinion is erroneous. It has been used, however, as an argument in favor of establishing new medical societies in various parts of the State, although it is a fallacy. The necessity has not yet arisen, nor is it probable that it will arise, for the organization of independent medical societies, in order to have the power to send delegates to the American Medical Association, except in those counties where the medical societies herefore existing have declared their adherence to the Code of Ethics adopted by the Medical Society of the State of New York.

This view we have already expressed, and it has been sustained by the action of the American Medical Association, and now its Journal, in an editorial, March 8, 1884, announces that, "as a large proportion of the county societies in other parts of the State" (speaking of New York), "have adhered to the national code, and thereby preserved their right to representation in the national organisation, it is probable," etc.

Those county medical societies, therefore, throughout the State, which have adhered to the national code, have not been cut off from the right of representation in the American Medical Association, as has been so frequently stated.

The editor also says: "We learn from a reliable source that the new State and County Medical Associations in New York are prospering beyond the anticipations of their warmest friends." Just how warm that is cannot be estimated readily; but certainly a very high temperature will be required to transform a glittering generality into a sure foundation.

THE LOST MEDICAL WORK.—Dr. J. H. Aveling writes to the British Medical Journal that a copy of Wolfebridge's Speculum Matricis, 1671, of which it was supposed that Dr. Fordyce Barker had the only copy, exists in the Radford Library of St. Mary's Hospital, London. The book was the first English treatise on midwifery. Dr. Barker loaned his book to a French copyist, who has disappeared and may be dead. It is not thought that he was dishonest, however, and the book may yet be found.
**News of the Week.**

**National Medical College, Washington, D. C.—** The sixty-second annual commencement exercises of the National Medical College (the Medical Department of Columbia University, Washington, D.C.) took place on Thursday evening, the 20th inst., graduating fourteen M.D.’s. It was announced that thirteen gentlemen had also passed a satisfactory examination on the primary branches.

**Medical Department, University of Georgetown, D. C.—** At a meeting of the Faculty of the Medical Department of the University of Georgetown, D.C., on the 13th inst., a committee of three was appointed to report a plan for the procurement of a suitable building for college purposes.

**Death of Dr. Lunsford P. Yandell.—** We learn with the most profound sorrow that Dr. L. P. Yandell, editor of the *Louisville Medical News*, died suddenly on March 16th, in the forty-seventh year of his age, from paralysis of the heart. Although in poor health for several years past he kept bravely at his work, up to almost the hour of his death, passing away, honored, beloved, and mourned by all who knew him. He graduated in medicine from the University of Louisville, Ky., in 1857, and subsequently served in the Confederate Army as surgeon—became professor of clinical medicine in the University of Louisville in 1869, and afterward of theory and practice and diseases of the skin in the same institution. Dr. Yandell was a man of fine culture, a graceful and forcible writer, and a most accomplished physician. His death is a serious loss to the medical profession as well as to medical journalism.

**Proposed New Hospital in Baltimore.—** A bill entitled an act to appropriate a sum of money to enable the Baltimore Medical College to equip and maintain a hospital, to be known as the “Maryland Infirmary and Lying-In Hospital for Indigent Women,” has been introduced into the Senate of Maryland.

**Another Death from Ether is reported in the British Medical Journal, the victim being a laboring man, fifty years of age, who was being operated on at the Gloucester Infirmary for cancer of the gums and throat.**

**The Centennial Anniversary of the General Hospital at Vienna is to be celebrated in June next.**

**A Sect of Child Murderers.—** The *Allgemeine Medicinsche Central-Zeitung* states that a sect of persons has been discovered to exist at Rostov, in Southern Russia, who kill children by narcotic poisons, in order to keep them from earthly suffering and secure them at once heavenly joys. The people are the victims of a religious madness.

**A Kindly Act.—** Our valuable contemporary, the *Journal of the American Medical Association*, has taken the trouble to fill up two columns with a full translation of a scurrilous and personal attack upon *The Medical Record*, printed in an obscure and obscure French journal.

**The Medical College of Ohio held its annual commencement on March 7th, graduating a class of one hundred.**

**The Miami Medical College held its annual commencement at Cincinnati on March 6th, graduating a class of twenty-seven.**

**The Medical College of South Carolina held its annual commencement on March 1st, graduating twenty students in medicine, and three in pharmacy. The College has established a graded course of three years.**

**The Medical Department of the University of Buffalo held its annual commencement on February 26th. Degrees were conferred upon sixty-two graduates. The address to the graduating class was delivered by Dr. Roswell Park.**

**The Detroit Medical College held its annual commencement on February 29th, graduating a class of twenty-five.**

**The Michigan College of Medicine, of Detroit, held its annual commencement on March 3d, graduating a class of twenty-seven.**

**The International Congress.—** President Panum says that the International Congress has its success already assured. More than four hundred physicians have sent in titles of papers to be read.

**Medical Berlin.—** The Society of Internal Medicine, at its meetings February 11th and 18th, continued the discussion upon “Arsenic in Phthisis.” The general tenor of criticism was decidedly against the drug’s having any special effect. Dr. Karwalski told of a case in which a patient developed acute phthisis while taking large quantities of arsenic. Dr. Thilenius, as the result of long experience, had found it entirely useless in checking the course of the phthisical process, though it improved the general condition. Dr. Leyden had had a similar experience. Dr. Croner reported a case of *nephritis after mumps*. He considered the kidney disease a sequel of metastasis. At the meeting of the Berlin Medical Society, Dr. Zadeck exhibited a case of *pericardial tumor*. Dr. Pohl-Pincus read a curious essay upon the method of obtaining immunity from infectious diseases. In an unprotected person the inoculated poison irritates the lining cells of the lymph-paths, which contract, delay the passage of the virus, and lead to induration. When immunity has been conferred, it is because there is something in the virus (anthracin, cholerin, tuberculin, etc.) which modifies the lymph-channel cells; they do not contract, but widen and the poison flows freely along. Dr. Pincus believes that if we can obtain the "tuberculin" from phthisis, immunity can be conferred from that disease.

**Medical Vienna.—** The Royal Society of Physicians met on February 15th, under the presidency of Billroth. Professor Neumann related the histories of two cases of syphilitic inflammation of muscle. He referred to the rarity of the disease, and the two forms in which it appears, diffuse and circumscribed. Dr. Kassowitz described the so-called pseudo-paralyses in children suffering from hereditary syphilis. He ascribed the symptoms chiefly to bone disease. Professor Billroth asked if the two symptoms of syphilitic myositis, viz., pain and contraction, might not be due to bone disease. Professor Billroth made an address in which he described the formation of cysts in bone.
A NEW MEDICAL COLLEGE IN CINCINNATI.—It is reported that a new medical college has been organized in Cincinnati, under the title of the Medical University of Ohio. This will make the fourteenth medical college in the State of Ohio.

MEDICAL PARIS.—At a meeting of the Académie de Médecine, February 26th, M. Pasteur read an important paper relative to the virus of hydrophobia. This is referred to elsewhere. After a discussion upon the lunacy law, Dr. Albert Robin read a paper upon carbolic acid in typhoid fever, and Dr. Gouguenheim a paper entitled “Anatomy and Pathology of the Peri-tracheo-laryngeal Glands.” These glands lie, he said, behind the larynx, trachea, and oesophagus, in the immediate neighborhood of the recurrent laryngeals. As a result of twenty discussions, he had found that they lay in three groups forming a chain. These glands are liable to become hypertrophied in the tuberculous, the cancerous, and the syphilitic, causing symptoms from pressure. At a meeting, February 24th, of the Société Médicale des Hôpitaux, M. Martineau stated that his syphilitic moulsey had developed symptomatic epilepsy.

THE BUFFALO (N. Y.) OBSTETRICAL SOCIETY has been organized. The following are the officers elected for its first year: Dr. W. W. Potter, President, Dr. R. L. Banta, Vice-President, and Dr. S. T. Howell, Secretary and Treasurer. It holds meetings monthly.

NEW YORK POST-GRADUATE MEDICAL SCHOOL.—Dr. Edward Kershner, U.S.N., has been appointed Professor of Naval, Military, and State Hygiene. Dr. G. F. Whiting has been elected Professor of Laryngology, and Dr. W. D. McMik, Professor of Operative Surgery.

OUR IRRITATED CONTEMPORARY Le Moniteur de la Policlinique has returned to the attack, and gives another editorial, entitled “La deuxième aux Yankees,” which means that he plays the deuce with the Yankees. This time, however, he devotes himself to our esteemed and irreproachable contemporary The Philadelphia Medical Times, and more especially to its “rédacteur, Dr. Thornton Parker.” This bad and bold man has written an article upon epilepsy, which, says the Moniteur, is nothing but a parenthesis from a work written by the editor of said Moniteur in 1875. “Have we not reason to say to THE MEDICAL RECORD: You do not read us, and vous nous pillez sans vergogne!” concludes the Moniteur. We trust that the new “rédacteur” of the Medical Times will explain.

DR. CHARLES F. STILLSMAN, of this city, at the last meeting of the Hudson County Medical Society (N.J.) delivered by invitation a lecture on “Backward Traction in the Treatment of Caries of the Spine.” The points made were, first, fixation, secondly, symmetrical traction, and thirdly, backward traction.

PROPOSED MEDICAL LEGISLATION IN MARYLAND.—A bill has been introduced into the Maryland Legislature providing for the regulation of medical practice. The bill is based upon the law of West Virginia, and makes the State Board of Health an Examining Board.

A committee of citizens have also memorialized the Legislature to act upon the following, according to the Maryland Medical Journal. 1. The enactment of a comprehensive law for the registration of vital statistics in the State. 2. The enactment of a general law to prevent the pollution of watercourses, etc. 3. The enactment of a law for efficient Boards of Health. 4. The enactment of a law providing for a sanitary survey of the State. The State Society has petitioned the Legislature to establish an institution for the care and training of the feeble-minded and idiotic.

HONORS OF MEDICAL MEN.—Dr. Vidal, of Hyères, France, has been made Knight of the Legion of Honor; Surgeon-General William G. Hunter has been made Knight of the Order of St. Michael and St. George.

BELLEVUE HOSPITAL MEDICAL COLLEGE COMMENCEMENT.—The Annual Commencement of Bellevue Hospital Medical College was held on March 13th, at Steinway Hall. Dr. Isaac E. Taylor, the President of the Faculty, conducted the exercises, and upon the stage were the Trustees and Faculty of the college, Commissioner Brennan, Algernon S. Sullivan, Dr. Lewis H. Sayre, Professor Charles A. Doremus, the Rev. Dr. Alfred Beach, and other prominent gentlemen. Diplomas were bestowed upon one hundred and forty-nine graduates. The four leading scholars were given appointments in Bellevue Hospital. Mr. Algernon S. Sullivan delivered the address to the graduates.

DISTRIBUTION OF MEDICAL STUDENTS.—Of the 9,700 medical students in 1882-83, in regular medical colleges, 1,146 were in New York colleges. After New York comes Pennsylvania, with about half the number (1,088), then follow Illinois, 900, Ohio, 800, Missouri and Kentucky, each about 600. In homœopathic schools Illinois is far ahead of any other State, having 422 matriculates. Then follow Ohio, 197; New York, 187; Pennsylvania, 147; Massachusetts, 109.

PROFESSOR SCHIFF AND AN ANTI-VIVISECTOR.—One Madame Kingsford, who signs herself a doctor of the Faculty of Medicine of Paris, published in Geneva an article against vivisection, which among other things contained the following: “M. Professor Schiff, who has been a vivisector for thirty years, said he never used anesthetics, properly speaking, but only stupefactors and narcotics, which he injects into the circulation.” In reply to this Professor Schiff wrote to the Journal de Genève. He says that “Madame Kingsford made a short visit to his laboratory and asked him, among other things, if he chloroformed his subjects.” Schiff replied, “No, madame, I etherize them, for I believe that ether is the most perfect anesthetic, and ought to be used upon animals as well as men.” He concludes: “Madame Kingsford cannot have forgotten this conversation; and there is but one alternative—either she has uttered a calumny or else she does not know that ether is an anesthetic.” In reply to this Madame Kingsford has published another statement reiterating her first charge.

ADVERTISING DOCTORS.—We are glad to find a Philadelphia contemporary joining warmly in the condemnation of the present tendency by medical men to advertise improperly. We only wish that the following sentiments were felt more keenly elsewhere. The Medical News says: “In this eager striving for notoriety rather than the just honors of the medical profession, do we not discern the need of maintaining a high standard of ethical requirements? Abate in any respect our regard for the
THE MEDICAL RECORD.

[March 22, 1884.

proprieties of professional life, and see the consequences. Remove one stone, and the whole edifice tumbles about our ears. Allow these forms of advertising to obtain a footing of the slightest tolerance, and the newspapers will not have space enough to accommodate the multitudes eager to display their wares. What, then, will be the position of the medical profession? Yet the American Medical Association says, as interpreted by its editor, that "a doctor can publish and circulate his professional cards as freely as he likes!" We have already been asked whether a physician could not have his professional card and "limitation" neatly posted in the advertising spaces of the street and elevated railroad cars. There is no American code against this. Certainly the permissive sentences carelessly emitted by the American Association "abate in some respect a regard for the proprieties."

Dr. J. H. Douglass, of Utica, N. Y., one of the oldest practitioners in Central New York, died on March 13th, aged seventy-five. He was born in New York City, but during the greater part of his life was a resident of Utica.

THE SIMS MEMORIAL FUND.

To the Medical Profession and Others throughout the World:

The great achievements of Dr. J. Marion Sims call for some more lasting testimonial than obituaries and eulogies. To him medical science is indebted for much brilliant and original work, especially in gynecological surgery. Those who have been benefited by his teaching and new operations, and such as have had the direct advantage of his personal skill are among the first to recognize and acknowledge this debt.

To him is due the honor of giving the first strong impulse to the study of gynecological surgery in America. It is believed that the medical profession everywhere, the vast number of women who owe their relief from suffering directly to him, and those who realize the benefits he first made possible, will gladly unite thus to honor the man through whose original and inventive genius such blessings have been conferred upon humanity. At the suggestion of many friends, therefore, the subjoined committee has been organized, and it is proposed that a suitable monument be erected to his memory in the city of New York.

To this end the active co-operation of the medical profession and the many other friends of Dr. Sims throughout the world is respectfully solicited. Contributions of one dollar and upward may be forwarded to the journal which has been constituted the treasury of this fund—The Medical Record, New York.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE ANTIPYRETIC TREATMENT OF TYPHOID FEVER—THE HOUSING OF THE POOR—THE PROFESSION AND INTERFERENCE.

LONDON, March 1, 1884.

The discussion at the Medical Society of London, on the cold-bath treatment of typhoid fever, terminated on Monday evening last. The result of the discussion has been the distinct enunciation of an opinion practically unanimous that the results of this mode of treatment are satisfactory. The doubts which have been entertained in the strict sense have been few, and their arguments feeble. The plain truth is, that most of the opponents to the antipyretic treatment are to be found amongst those who have either never tried it, or who, having resolved to make trial of it, have carried it out imperfectly and carelessly. Having used it inefficiently in a few cases without good results, they discard a remedy they have not properly tried, and proceed to argue against it. The antiseptic system has been treated in the same way. It is, in fact, only within the last few years that surgeons are beginning to realize that if good results are to be expected from Listerism, it must be carried out in all its details with scientific precision. I have seen the word "antiseptic operations" done which were not antiseptic at all. The remedies tried are those which ought to have been tried.

With regard to the cold-bath treatment of typhoid fever, there are, doubtless, cases in which its use is to be deprecated, as even Liebermeister admits. As, however, regards its beneficial action in the majority of cases, I should have thought a careful perusal of the statistics brought forward by Liebermeister, Brand, and others, years ago, would have convinced even the sceptics. Drs. Galley and Coupland now bring an array of statistics founded on British cases, and their conclusions point in the same direction as those reached by German and French observers years ago. The fact is that British hospital patients will not submit themselves unquestioning to any strange mode of treatment, and British physicians do not ape the abrupt methods of the Vienna school. The trouble, too, is considerable, even in well-appointed hospitals, and where many patients are undergoing the antipyretic treatment extra attendants are needed, which means increased expenditure. All things considered, the obstacles to the efficient carrying out of the treatment are numerous, and doubtless this accounts in some measure for the comparatively small result which it has been tried. Many English physicians who have fairly tried it, have long been convinced of its value, and all that the recent debate can be said to have done is to give a sort of official seal to an opinion which has long been held by independent and trustworthy isolated workers.

A Royal Commission is to be held on the "Housing of the Poor." They might, with advantage, extend their sphere of operations to the houses of the rich. I have seen sanitary defects as rife in the latter as in the former. Some houses are built as if the chief design of the builders had been to lay on a never-failing supply of sewer-gas. In some cases, though, the builders have never taken the trouble to connect the house drains with the sewer at all.

It is proposed to introduce a bill into Parliament prohibiting the sale of intoxicating liquors by grocers. It is clear that the "Grocers' Bill," as it is called, has proved a failure, and wrought unmitigated evil. The profession of this country will give their earnest support to any measure calculated to lessen an evil of which they see so much. The days of Todd are past, and I believe that no section of the community is more in earnest than the medical profession in trying to stem the tide of intemperance. Certainly no profession has furnished so large a number of scientific advocates for temperance.

OUR PARIS LETTER.

(From our Special Correspondent.)

THE TREATMENT OF DISEASE IN GENERAL AS WELL AS LOCAL PRINCIPLES—SOME POINTS IN REGARD TO THE THERAPEUTICS OF GONORRHEA—CONCERNING KAIRIN—DANGERS ASSOCIATED WITH THE USE OF SALICYLIC ACID AS A FOOD PRESERVATIVE—THE TOO FREE USE OF CARBOLIC ACID.

Paris, February 29, 1884.

"That the local manifestations of disease should be treated on general as well as local principles, is a verity that is now recognized by surgeons, and by even the most confirmed specialists. Dr. Guyon, Professor of Surgical Pathology at the Paris School of Medicine, and Surgeon to the Necker Hospital, and who is besides well known as a specialist for diseases of the urinary organs, lately delivered a chemical lecture on the treatment of chronic urethritis and gonorrhoeal cystitis, in which he strongly insisted on this point. Before entering into the therapeutics of these affections, he recalled the attention of his hearers to the anatomy of the urethra, of which he said there were two distinct portions: the one anterior and the other posterior. The posterior is the seat of the ligament of Carcassonne, by a veritable sphincter, which divides the canal into two organs, as it were, as they are distinct from each other in their anatomy, physiology, pathology, and even in their embryogeny. In referring to the etiology of chronic urethritis, Professor Guyon stated that excesses in diet and the intemperate treatment of the digestive system are frequently the causes of the chronicity of the latter. But, at the same time, one should not lose sight of the considerable influence that certain diatheses have upon the progress and duration of the disease, in which case the latter is generally confined to the posterior or membrano-prostatic portion of the urethra. Professor Guyon refutes the opinion that stricture is a frequent result of this disease, and also the theory of a discharge in the urethra—which opinion is at least exaggerated. He equally refuted the generally received notion that chronic urethritis and deep urethritis were synonymous, as he found in three-fourths of the cases of chronic discharges the secretion was performed in the anterior portion of the urethra, and it was in one-fourth of the cases that the posterior portion was affected. Moreover, anterior urethritis is, generally speaking, manifested only by a discharge which is noticed only in the morning, whereas in posterior urethritis frequent micturition is a constant symptom. Under these considerations it is evident that the indications of treatment must depend upon the precise seat of the lesion, its duration, its intensity, and also the relation of the disease to the health of the patient, hereditary or acquired. Professor Guyon insisted strongly on the importance of general treatment, according to the constitutional cause originating and keeping up the discharge. Local treatment should also be resorted to, but he condemned injections, as, when employed in the ordinary way, they rarely reached the spot affected. He therefore recommended the direct application of remedies in the form of instillations, cauterezations, and catheterism; but the latter should be resorted to only in obstructive cases, for which purpose he prefers large metallic sounds. Medicated bougies, he found useless.

If injections were prejudicial it was because they were frequently employed without discrimination, as it was the fashion to adopt them whenever there was a discharge from the urethra, without any reference to the cause or stage of the disease. It is in this way that M. Guyon accounts for a great number of cases of cystitis, particularly that accompanied with gonorrhoea, which results not only by extension of the urethral inflammation but by the earliest use of injections, which should never be employed in gonorrhoea before the thirteenth day of the disease, and even then they should not be resorted to but with the greatest precaution. In cases of gonorrhoeal cystitis M. Guyon advises the daily instillation into the bladder.
of ten to fifteen drops of a solution of nitrate of silver (five to ten grains to the ounce), which arrests the bleeding and gives very rapid relief. This treatment is applicable both to recent and chronic cases.

A great sensation has been caused in the medical world by the recent discovery by Professor Fischer, of Munich, that he extracted from the hair of Kairin, which he gave the name of kairin. From its resemblance to quinine, M. Fischer imagined that its therapeutic properties would be analogous to the time-honored antipyretic par excellence. Considering the continued high price of quinine, it is certainly desirable that some other substance could be found to replace it. Several experiments with kairin have been made in Italy and Germany, and according to the reports published this new substance is the most efficacious, trustworthy, and safest antipyretic that could be employed. It is said to be more powerful and rapid in action than even quinine or salicylic acid. Notwithstanding these advantages, kairin has not yet found much favor in France, although Dr. Hallopeau recently published a very interesting paper on the subject, in which he corroborates the experience of the Italian and German authors just referred to.

Since the introduction of salicylic acid in medicine, and from its known preservative properties, it has been freely adopted in commerce for the purpose of preserving such substances, particularly those concerned in food and drink. Kairin is reported, however, by the Council of Hygiene, that salicylic acid could not be used daily for any length of time with impunity, the Minister of Commerce has instructed the Prefect of Police to forbid its sale as an ordinary article, and that it should be considered as a pharmaceutical substance only. Articles of food and drink containing salicylic acid will be seized, and the guilty parties will be tried before the tribunal. Alimentary substances imported from foreign parts and which may contain salicylic acid, will also be amenable to the same restrictions.

Carbolic acid is another substance that has been too freely employed in various ways, particularly in medicine and surgery. Dr. Albert Robin lately read a paper at the Academy of Medicine, in which he pointed out the disastrous effects of this medicine in the treatment of typhoid fever. His argument was that a patient suffering from this fever loses more sulphur and potass from a person in health; the quantity of mineral in the system is consequently reduced to a dangerous extent for the proper functioning of the muscles of the body, particularly those of the nervous and muscular systems, and as carbolic acid increases the excretion of these two substances it ought to be proscribed from the treatment of typhoid fever. Dr. Robin believes that a great portion of the nervous and cachectic phenomena that are observed in certain cases of typhoid fever may be attributed to the use of carbolic acid. The same considerations, he added, are applicable to the whole group of medicinal substances which are eliminated in the same way as carbolic acid, such as thymol, nephol, resorcin, benzol, anilin, etc.

TYPHOID FEVER AND THE SOLAR Plexus.—Dr. Leven says that the clinicians who speak of abdominal symptoms in typhoid fever have deceived themselves. As a rule such symptoms do not exist, and if they make their appearance they are due to irritation of the solar plexus by purgatives. The influence of such irritation is easily shown. It suffices to press on the median region of the stomach and the medullary ganglia of the great sympathetic placed on a line with the navel, about two inches around, will give evidence of pain. Pain on palpation of the iliac fossa has also been erroneously spoken of. Most frequently it is only hyperesthesia of the abdominal parietes, resulting from irritation of the right sympathetic ganglion. These phenomena furnish one of the numerous contra-indications of purgatives in typhoid fever.—

Prog. Med.

REMARKABLE HISTORY ILLUSTRATING THE CONTAGIOUSNESS OF DIPHTHERIA.

To the Editor of The Medical Record.

Some facts which have recently come to my knowledge illustrating the contagiousness of diphtheria, will, I think, interest your readers.

In October last, a child recently brought to the town of Royalton, Vermont, was attacked with this disease. There was no other case in town at the time. A homoeopathic physician from the village of South Royalton attended it. The child died. Its mother took the disease and recovered. The doctor’s family consisted of himself, his wife, and three children. He took it, and his youngest child, five months old, was also taken sick. His wife came down with typhoid fever at about the same time, and it was necessary to put the baby in other hands. It had no appreciable throat symptoms, but a bad sore on its toe. He did not regard this as diphtheritic, and when a neighbor offered to take it home he allowed her to do so. The family of this neighbor, Mrs. H——, consisted of herself, her husband, two boys of seven and nine years, and a nursing baby. In a few days after the doctor’s baby was taken in, her baby had diphtheria and died. Her husband, herself, and one boy also had it, the other boy escaped. The child died and was handed over to Mrs. S——, who with her husband lived on a hilltop, two miles out of the village where the cases last mentioned occurred. She engaged a young woman, Miss L. S——, to take care of the child. In a few days Miss L. S—— had diphtheria and went home. She lived also out of the village, in another direction. The family consisted of her father and mother, herself and three brothers. Her mother and one of her brothers were taken. She also gave it to another person of whom I will speak later. To return to the little bearer of contagion, the doctor’s baby. Mrs. S—— having lost her nurse, handed it over to Mrs. D——, in the village. In Mrs. D——’s family of husband, herself and one child, the eldest a boy of eighteen, then a girl of sixteen, and a boy of eight. These three children sickened, within a day or two of each other, soon after the arrival of the baby, and all three died within four or five days. The baby was then taken to another town, where it recovered. These events occurred in October and November. Miss L. S——, previously referred to, had sore throat and diphtheritic symptoms. They were mild, and a week later, as she felt well, with the exception of some remaining soreness of the throat, she went to the adjoining town of Tunbridge, to the home of Mr. C. L——. In this family were four, the father and mother, a girl of sixteen, and a boy of eleven. In four or five days after Miss H——’s arrival, the girl was attacked with a malignant form of diphtheria and lived only one day. The boy came down next, and then the father and mother. These all recovered.

Royalton is a healthy farming town. There was not another case of any description besides those mentioned, which followed a line of direct communication from the original case through the doctor to his family, through his baby to every family it entered, and finally through a visitor of one of the convalescents to the family in Tunbridge.

Yours truly,

William T. Smith, M.D.

Hanover, N. H., February 23, 1844.

TREATMENT OF LUPUS BY INJECTIONS OF ETHER.—

Dr. Lermoyez, of the St. Louis Hospital, Paris, recommends the hypodermic injections of ether for the cure of lupus, and reports successful results.
MEDICAL LEGISLATION AND ITS BEARING UPON STATE EXAMINATIONS FOR THE MEDICAL DEGREE.

To the Editor of The Medical Record.

Sir: I take it for granted that the object of medical legislation is to secure, for the use of the people, the best possible medical service. Medical laws benefit the people just as they tend to increase the knowledge and skill of the profession. To obtain the legal right to practise medicine we must pass certain examinations and conform to certain rules and regulations imposed by the State. We seldom hear a voice raised in praise or defence of the present methods by which candidates gain admission to the profession. Distasteful murmurs of its imperfections come to us from every quarter.

To us its imperfections are: the want of some proper standard of preliminary education; insufficient legal time of study; the want of a higher, common, uniform examination for all who enter the profession, conducted independent of interested teaching bodies, with authority to require college charters, and license to practise, for sufficient cause.

Two bills were introduced and discussed at the recent meeting of the Medical Society of the State of New York. They were presented to the Society by the committee on legislation, and dealt only with final examinations and the granting of revoking powers; both bills were finally referred to the charged committee for reconsideration. We hope this reconstructed committee will see fit to report a bill at the next meeting of the State Society, proposing some standard of preliminary education that students are known to possess before they enter on their professional studies, and that all medical students shall register themselves as such in the County Clerk's office of every county, their legal time of study dating from such registration.

We all know that three years is too short a time for ordinary minds to master the various branches of medical science. In Europe the legal time of study varies from four to six years. Would it not be well to make the time four years in the State of New York, with a graded course of study? From the animus of the discussion I have been led to think of the two bills as the committee's bill and the college bill. From the eloquence and sophistry evoked in the discussion of these bills, it is evident that the great colleges of New York aim to keep things substantially as they are. For appearance sake, and the more effectually to kill real reform, they have arrayed themselves on the side of reform, but they want little of it.

He was a man
Who stole the livery of the court of heaven
To serve the devil's will.

By parliamentary rules the college bill, to us a bill of magnificent shadows in the totality of its provisions, was forced into the report of the committee against its will— at all events, to the report of the committee to be fogged and hoodwinked the Society into the belief that its shadows were substance, to postpone and procrastinate all action of the Society, to overrule and set aside a bill of real reform. The college bill provides for the appointment by the Governor of the medical faculty of the University of the State of New York, consisting of nine legal practitioners, not connected with any medical school or college. The committee's bill provides for a like medical faculty, the first nine to be appointed by the Governor, six to be chosen from the regular, three from the homoeopathic, and one from the eclectic profession. As their terms of office expire, the different State medical societies are to nominate candidates qualified according to the statutes; the regents of the University are to select the new members of the medical faculty. This takes the appointing power out of politics. The other bill gives the appointing power for ever to the Governor. Both bills give power to revoke license to practise, the college bill gives power to revoke a college charter; common law now provides for the same for sufficient cause. The bills provide and give power to this medical faculty, much in the same manner, to examine students for a license to practise. In the committee's bill this is the only gate of entrance to the legal ranks of the profession in the State. If the college bill stopped here it would be of value, but it closes no old gates, it simply opens a new gate, through which no one would be likely to enter while the old ones remain open. To stop these many gates of uncertain, unknown height and width, that we know not what may squeeze through, is the special object of reform. Equity and justice demand a common examination for all who enter the profession. The medical faculty, as an examining board in the college bill, seems introduced simply as an ornament; an image of the form without expected worshippers, for it allows the colleges to go on conferring degrees with license to practise just as they have done, with this slight exception—a minimum of reform, if it is worthy the name—three members of this State examining board are to be present at the college examination. The questions to be asked to candidates for degree at the college examination shall be submitted to the members of the medical faculty attending such examination, and all answers thereto shall be open to their inspection.' Thus, the duties of the visiting board are simply to look on, while the college faculty conduct and manipulate the examination—figure heads playing third or fourth fiddle to the faculty, without power or responsibility of the first or second. It is not even required to make a report of their observations.

This sort of censorship is nothing new, it has been in vogue for years and years in some of our colleges, and as heretofore conducted amounts to nothing as a test of medical scholarship. It has never assumed any real tangible form, and has never had a committee of its own, but an independent way. It has amounted to nothing in the past and nothing is to be expected from it in the future, while trammeled by college influence. Make censors independent and responsible, then they may do their duty.

Fred Loonis, in the discussion before the State Medical Society, objected to the appointment of homoeopathic and eclectic physicians on the State board of examiners. The college bill, of which he was the special champion, and the special disector of the committee's bill, permits the board to be composed wholly of homoeopaths or eclectic physicians, at the pleasure of the Governor—a fine chance for political favoritism. He is a new phi lambda man, and would fellowship these with men in an independent way. It has amounted to nothing in the past and nothing is to be expected from it in the future, while trammeled by college influence. Make censors independent and responsible, then they may do their duty.

A knowledge of anatomy, physiology, histology, chemistry, general, special, and histological pathology; etiology, symptoms, diagnosis, and prognosis of medical and surgical diseases; the same of diseases of women and children, operative surgery and midwifery, toxicology, a knowledge of these and their physiological action, hygiene and preventive medicine, and perhaps pharmacy and medical history might be added. A reasonable acquaintance with all these branches of medical science is a necessity to the educated physician. There is nothing ho-
meropathic nor eclectic in any of these branches of study, and they are of the utmost importance to all pathies and all isms. If a State examining board knew candidates only by numbers, knowing nothing from whence they came or whither they go, a mixed board could examine and pass upon the candidates in common on all these subjects, after which they could be examined in therapeutics, each after his kind, regular, homoeopathic or eclectic. There need be no jarring in this arrangement. This would give assurance to the world, and the profession, that all licentiates had attained more or less proficiency in the various branches of medical learning. After acquiring all this primary knowledge as a basis, every one has a right to be examined in his branch of practice, as his reason, judgment, and conscience may dictate. To secure the foregoing good, we can most cheerfully endorse a mixed board or any board of State medical examiners. No matter what flag the practitioner may sail under, if he has a heart in him, when the pinch of disease comes he will bring all his knowledge to bear to curative ends, without any regard to any pathy or ism.

But Prof. Loomis said it was not safe to separate the examining from the teaching bodies. England tried it, and it failed. When did England try it, and it failed? I am unable to find when. At present there are nineteen examining boards in Great Britain, more or less mixed in their appointments. And these are not always appointed by the crown, the universities, and her hereditary list. No change has been made in these laws and regulations since 1838. At the present time England is more agitated on the subject of medical reform than we are. A bill is now before Parliament reducing her nineteen licensing bodies to three, one each for England, Scotland, and Ireland. And all independent of the teaching body, but under the direction and control of a General Medical Council of eighteen members, appointed jointly by the crown, the universities, the Royal Colleges of Physicians and Surgeons, etc. There is no comfort for the college bill in the history, or present aspect of medical legislation in England. Her bane is the number of her licensing bodies with uncertain examinations, which she is trying to correct.

In France, the professor said, the examining body is taken from the teaching body; but the teacher there is paid a fixed salary, students or no students, graduates or no graduates, and is amenable to a sharp, criticizing government and profession for the proper discharge of his duties set above him. Where are they above them do American medical colleges serve? To whom are they responsible? To whom do they give an account of their doings? They are imperial in their authority. The committee's bill proposes to scan their doings and make them, in a certain sense, responsible to a higher power; and this is where the shoe pinches, and why the colleges rebel.

Prof. Loomis also said it had been tried in other States and had failed. He did not name the States, nor give the causes of failure. It has not failed in Illinois, Virginia, Alabama, Canada, and some other States where it has been tried. He thinks the non-teaching members of the profession would make poor examiners compared with college professors; that it is an art that teachers have learned; that they, the non-teaching members, are really incompetent to stand guard at the portals of the profession. What, five thousand medical graduates in the State and not one in five hundred fit for such duty! What stuff, then, do our colleges turn out? The strongest possible argument, if true, that something should be done to college professors; that it is an art that teachers have learned. But it is not true. If it is true, how about the medical examining boards for the army and navy? They are not composed of college professors, but they play the very mischief with the better class, the cream of college graduates; only about one in three being able to pass these examining boards. Should not the State see to it that she provides equal medical knowledge and skill for her common citizens that she deems necessary to provide for her soldiers and sailors? Are not our family ties as tender and dear to us as the ties of the army and navy to the State? Shall we be put off with an inferior medical profession? Give the non-teaching members of the profession a trial; it can do no harm—a valuable element in all professions. The colleges will go on doing their work conscientiously as they have done, perhaps better, for, at least, there will be a small, wee power behind, or rather in front of them. We can see nothing but good to come from the establishment of an independent State board of medical examiners. Everything pertaining to medical education and medical colleges will remain as they be, as long as they like, but other colleges will go on as to time of study, etc., etc. It simply provides an additional screen to try to sift out the chaff that may have escaped a first winnowing. What honorable, high-minded college can object to this? We believe its influence will be to make the student a better student, the teacher a better teacher, and thus secure for the people a better profession.

To dull and idle students, who fail in class examinations, the good professor would be very apt to say, "Gentlemen, these answers will not serve you before the State board of medical examiners. Your must do better than this, or it will be useless for you to try that examination. You will disgrace yourselves and your teachers; try and do better." What a stimulant, to both student and teacher, to double their diligence! The teacher as well as the student would have something to fear, something to work for, a power to serve beyond the college walls. College work would be open to sunlight. The more thorough, and the higher the standard of education in a college, the more students would be able to pass the State board of medical examiners, the more popular the college—whatever reversing the present order of college popularity.

Other points have been criticised in both bills. A bill cannot well be drawn to please everybody. For a name Medical Council has been suggested, with good reason, in place of Medical Faculty, and the compensation has been thought to be too low, etc., etc. These are all minor points that time and experience will serve to correct, over which real reformers will not be obstinate or particular, so long as the bill embodies the cardinal thought—one single door of entrance to the profession, by or through a common, uniform examination, independent of college influence, and that directly done."—ALFRED MERGER, M.D.

SYRACUSE, N. Y.

MEDICAL LEGISLATION FROM ANOTHER POINT OF VIEW.

TO THE EDITOR OF THE MEDICAL RECORD.

Sir: It must have ere this become sensibly pregnant in the minds of every reasoning medical man that doctors of medicine are meddling too much with doctors of medicine, and that inefficient health boards are doing likewise. There are already too many conflicting medical laws, too many medical organizations, and too much medical law-making. Should this state of things continue much longer, especially as it has in the State of New York during the past few years, the best part of the fabric will crumble to atoms. During the more ancient period of the American people there was but little interference with medical men, nor medical men with each other. But it is not so now. A physician in those days was known by his intelligence, education, reputation, and refinement, when now the majority are but known by their certificate or diploma. It would be much better did some of our learned medical dignitaries devote time to the investigation of medical matters than to be concocting conflicting medical laws which the courts will eventually be compelled to declare void, as in a quite recent case in the city of New York.

Respectfully,

S. J. W. LEE, M.D.

BRIDGEPORT, CONN.
THE MEDICAL RECORD.

March 22, 1884.

THE ADVICE GRATIS SYSTEM AND THE CHANCES OF THE YOUNG PRACTITIONER.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: If you will give my letter a place in your journal, I would like to say a word in respect to Dr. Roosevelt's letter published in The Medical Record of February 2, 1884, concerning "The Advice Gravis System." Dr. Roosevelt says: "We need some practical method of sitting the undeserving from the deserving applicants for relief. Can any one suggest such a means?"
The Illinois State Eye and Ear Infirmary, in Chicago, required each one to make a sort of oath that he was unable to pay for medical services or his medicine, or both, before he could be admitted to the dispensary. The Assistant Superintendent was a notary for this purpose, and the individual was given to understand that if he perjured himself he might be prosecuted. So, though his conscience might be benumbed, dread of the law would probably prevent his doing what he knew would expose him to its tender mercies.
The infirmary is an old, well-established institution, and this rule may be said to work well, inasmuch as it is very unusual to find among the patients any but the very poor. Of course there are exceptions, but until laws can be devised to protect society entirely from evil-doers, we cannot expect our charitable institutions to escape occasional impositions. Any one who could frame laws to save us from the wiles of the wicked would undoubtedly be a great benefactor to the human race, as well as to those physicians who regard free dispensaries as one cause of their misfortunes. Yet it is quite possible that that class of doctors might find struggling their portion still, for the fate of physicians, like the fate of all else in this world, seems to be written in that law which reads, "The survival of the fittest." We cannot establish a soup-house, that the same complaint might not arise from striving, hard-working butchers and bakers, and in our present state of civilization there seems always to be more or less pain to individuals in the very wisest courses open to us. "So inevitably diffusive is human suffering that even justice makes its victims," and we can only hope that both our justice and our charities may benefit the many though they sacrifice the few.

A LAYMAN.

ATTENUATING VIRUS BY DILUTION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In your editorial note on "Attenuation of Virus by Dilution," on page 269 of The Medical Record of March 8, 1884, you have given a wrong impression in regard to the justice of my claims for having originated a new method of attenuating virus. This, I believe, can be made very apparent to you, and I have no doubt you will take pleasure in making the proper corrections.

In the first line on page 270 you say: "This method of attenuating virus can, however, hardly be considered original."

"In the Archives Générales de Médecine, a year ago, Dr. Leblanc gave an account of the experiments of Professor Peuch, of Toulouse, with the virus of ovin variola (Typhus variola). This he inoculated in various dilutions. The protective influence, however, was not found to be great, and we very much doubt whether by a simple process of dilution a trustworthy protective virus can be obtained."

No doubt you were led to these remarks by the publication of an article of mine in the number of the "Proceedings of the Kings County Medical Society." If you will look at that paper again, however, you will see that the address in question was made in November, 1882, or considerably more than a year ago. Its publication was delayed by circumstances over which I had no control; but the manuscript has been in the hands of members of that society since the time the address was delivered.

Again, if you will have the kindness to refer to The Medical Record of April 7, 1883, you will find an article written by me, entitled "On the Production of Immunity from Contagious Fevers by Inoculation with Diluted Viruses," in which Professor Peuch receives due credit for his experiments. My own experiments were made a full year in advance of those of Professor Peuch, and an account of them was read at the meeting of the Society for the Promotion of Agricultural Science at Montreal, in August, 1882. The only question of priority that can be raised is in regard to the experiments of M. Chauveau, which were referred to at sufficient length in my article in The Medical Record.

In regard to the degree of protection, I think you are also mistaken. If I have always found it very complete M. Peuch stated that the sheep which he inoculated with diluted virus acquired immunity. Since then Arloing, Cornevin, and Thomas have made experiments with the diluted viruses of charbon symphomatique, and have confirmed both the principle and the fact that immunity is conferred by this method; but they were unable to secure uniform results because, as they admitted, they could not by their manner of preparing the virus obtain this of uniform strength. You will see, therefore, that the European scientists have not yet reached the cardinal principle of my method, viz., the use of a virus of standard strength which alone can produce safe and certain results.

Another point in which my experiments lead M. Chauveau and all others is the demonstration that a virus which ordinarily penetrates to every part of the body may be compelled by dilution to multiply locally at the point of inoculation, and thus showing it to be a constitutional disease. That a knowledge of this fact is essential to the practical application of the method to the greater part of the contagious diseases is apparent without discussion.

I am sorry to trouble you by writing at such length, but I have so frequently heard the remark by members of the medical profession, that our journals keep them well informed of everything being done in Europe and leave them in complete ignorance of what our own investigators are accomplishing that I have concluded to, at least, do my part toward changing this condition of things.

Very truly yours,

D. E. SALMON.

WASHINGTON CITY, D. C.

WASHINGTON, March 10, 1884.

[We take pleasure in publishing Dr. Salmon's letter, while the idea of obtaining protective vaccine by dilution is, as we stated, not original with our correspondent, he is entitled to the great credit of devising a most ingenious method of obtaining standard dilutions.

We must adhere to the opinion that the practical value of dilute protective virus is very doubtful, and has not yet been demonstrated by Chauveau with anthrax or charbon symphomatique, by Peuch with ovin variola, or by Salmon with chicken cholera.

We seriously doubt, also, if it has been, or can be shown that a purely local process confers immunity from a constitutional disease. The inoculations of pleuro-pneumonic virus, long before Dr. Salmon's experiments, apparently showed this, but only apparently.—Ed.]

THE SUSCEPTIBILITY TO HYPNOTISM.—M. Brémont has made, on sailors, soldiers, and officers, from fourteen to twenty-six years of age, a large number of experiments, showing that lethargy, catalepsy, and somnambulism can be produced in healthy, non-hysterical people, and that these phenomena are preceded by a peculiar state of fascination. The period of fascination is characterized by a sudden increase in the frequency of the pulse. One-third of the young men experimented upon manifested one or more of the above-mentioned symptoms,
THE MEDICAL TITLES BILL.

To the Editor of The Medical Record.

Six: The Senate bill (S. 1599) to "change the titles of medical officers of the army" is a direct blow at the military status of the Medical Department. The title of "Surgeon-General" (in place of Medical Inspector-General), forced upon medical officers of the British army a few years ago, has given great dissatisfaction, and the animus of the "Home Guards" was clearly shown in making the list of Medical Inspector-Generals Surgeons-General—i.e., general Surgeons—instead of Surgeon-Generals—i.e., Generals of Surgeons. Now a similar trick is to be played with our officers, probably with the same object. The title of "Surgeon" carries with it the sole idea of a bone-setter, an operator—a sort of human butcher. It is a misnomer in this country, where every medical man graduates as a physician. It is productive of much confusion, conveys no idea of a military status in either branch of the service, and gives a false impression of the duties of a medical officer of the present day. The duties of the latter are largely sanitary, and are (both in peace and war) far more medical than surgical in their nature. The terms medical department, medical corps, and medical officer are clearly understood. As the title of "Surgeon" has no definite meaning in the United States (as it has in Europe), it is seldom used here, and it may be confounded with veterinary-surgeon, surgeon-dentist, police-surgeon, etc.

The titles of "Passed Assistant Surgeon" and "Assistant Surgeon" are also meaningless, and are calculated to inspire but little respect and confidence for the younger members of the profession in a military community. The title "Medical Officer" is clearly indicative of professional duty; but a military title should be used officially to denote the military status of an officer in every branch of the service. If it be necessary to add the word "medical," it should be added to the title, as follows: A Medical Director-General of the Army, with the rank of Brigadier-General; a Medical Director-General of the Navy, with the rank of Commodore; Medical Inspector-Generals for medical officers with the rank of Colonel, and Captain in the navy; Medical Directors for medical officers with the rank of Lieutenant-Colonel, and Commander in the navy; Medical Inspectors for medical officers with the rank of Majors, and Lieutenant-Commanders; Medical Officers for all medical officers of the army and navy below Major and Lieutenant-Commander. These titles are indicative of professional duty, are in use in other services, and would do away with the term "Surgeon," which is unsatisfactory, misleading, and confusing.

I sincerely hope that the medical officers of our army will oppose the Senate bill, or have it so changed that the titles will convey a better idea of their medico-military duties.

NEURALGIA PENCILS.—So-called neuralgia pencils, "Migraine Stift," are now being offered by a number of German pharmacists, especially in Berlin. They are said to consist essentially of a mixture of menthol, thymol, and eucalyptol, fused and cast in small conic pellets, which are fitted in a suitable handle. The forehead and temples are touched with the pencil. A slight impression of burning is at first produced, which soon gives way to a pleasant, cool sensation. Several pharmacists claim priority in this invention. Friedlaender exhibited neuralgia pencils at the late Vienna Exhibition, and a year ago nerve-crystals were offered by Blaser, which were described in the Pharmaceutische Zeitung as consisting of a mixture of crystallized Japanese peppermint oil and camphor. The pencils, under the name of the "menthol cone," were exhibited by Dr. E. C. Wendt at a meeting of the New York Neurological Society recently.

NEW PORTABLE FARADIC BATTERY.

By C. L. Dana, M.D.,

NEW YORK.

The faradic battery, of which the accompanying is a cut, consists of a cell B (and D), and a small box A, containing a faradlic coil. The cell D is an extra one and not used in running the coil. The large box with the open lid holds one cell and the coil, with their connecting wires and electrodes.

The cell is different from that ordinarily used to run induction coils. It is known as the "Bergmann & Haid Cell," and resembles the Leclanché, but is considerably stronger, does not run down so easily, and can be used for a longer time. One of these cells will run a coil for three hours continuously, and will then recover nearly its full strength. A single Leclanché cell will not ordinarily run an induction coil. This "Bergmann & Haid Cell" consists of a glass jar, in which is placed a porous cup containing manganese and other materials, and the carbon pole. In the part outside of the cup is a saturated solution of chloride of ammonium and the zinc pole. The cell is of the "open-circuit" variety, and generates no electrical current until the connections are made. In order to start the battery it is only necessary, having filled the outer part with water, to make the connections with the coil.

The coil itself is of the ordinary kind, with arrangements for a fine smooth interruption, and for giving a primary, secondary, and mixed current. More extra currents are not needed, neither is it necessary to have slow interruptions.

The advantages of this battery are:

First.—Its cheapness; a box with coil-wire connections and electrodes can be had for $5. The cell costs $1.20. The large box holding coil and cell is not absolutely necessary, but one can be made for seventy-five cents or a dollar. I advise the purchase of two additional cells, which will make the total cost about ten dollars. I do not know of any really good faradic battery that does not cost half as much again.

Second.—Its portability and convenience. If one wishes to use a battery for some time on a patient at his home, the physician can take one of the cells and leave it at the house. He has then only to carry about the coil, which he can easily do in his pocket. If one has a second out-sick patient, he can leave another cell with this case also, and he has only to attach his portable coil to the different cells.

Third.—It does not get out of order. This at least has been my experience. The zincs cannot be suddenly destroyed by being accidentally left in the acid. The cell requires no care except to occasionally add water. Of
course, in time it wears out, but one cell will last one or two years or longer, according to the amount of use. And it does not cost much to get new ones.

The portable coils are made by Mr. H. E. Stammers, 1443 Broadway, New York, who also supplies the cells. These, however, may be obtained also of electricians elsewhere.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from March 9, 1884, to March 15, 1884.

BILLINGS, John S., Major and Surgeon. Granted leave of absence for one month, with permission to go beyond sea, to take effect April 1, 1884. S. O. 61, par. 6, A. G. O., March 13, 1884.

HEIZMANN, Charles L., Captain and Assistant Surgeon. Leave of absence extended three months. S. O. 57, par. 9, A. G. O., March 8, 1884.

WALLES, Philip G. Appointed to be Assistant Surgeon with the rank of First Lieutenant, to date from February 7, 1884, vice Brewster, resigned. A. G. O., March 10, 1884.

Official List of Changes in the Medical Corps of the Navy, during the week ending March 15, 1884.

TERRILL, F. H., Passed Assistant Surgeon. To Coast Survey Steamer Hasler.

McCarthy, R. H., Passed Assistant Surgeon. From the Coast Survey Steamer Hasler, and wait orders.

Antiseptics and the Prevention of Perforal Fever.—As far as we can judge from letters received from all parts of the country, the current of professional opinion sets strongly against the views recently advocated by Dr. Thomas at the Academy. The following letter may be considered a sample of these. Dr. F. A. Tuttle, of Jefferson, Ohio, writes: "Many of us in the rural districts were much surprised by the paper of Dr. Thomas. I have practised medicine for twenty-five years, and in looking over my cases for cause of death, I find but one that I attribute to septicaemia. How much is such a statement worth? All the strong convictions of your life are founded on antecedent and sequence—the oft-recurring and coherent have produced the profound convictions on which you trust and act, and you have a right to trust them. I am aware that exact data are more reliable, but the great map of our experience is acquired and organized without exact statistics—pigeon-holed by the brain for future reference. We teach our patients to look forward to their parturition cheerfully and hopefully; that nature will not be tawdry in this physiological process; that we have a right to trust her here as elsewhere. The cow retires from the herd and brings forth in safety; the savage woman follows the same instinct with the same results; and we still hope in the country that our civilization has not converted a physiological into a pathological process. I have learned to fear uremic poison before birth toximes more than septic poison after birth. Rate your great centres of population are advancing, how long will it be before the conditions necessary for fertilizing the ovum (rupture of the hymen) will be equal to a capital operation? How long, with nursing bottles and fixtures, before the mammae gland will be a rudimentary organ? I see your death-rate far exceeds your birth-rate, and were it not for the bone and muscle poured in from the country, the vine would clamber in your halls and the fox look out of your windows." In the country we plant and mature our crops rejoicing in the coming harvest. We are glad to come to you as teachers, for you have unlimited clinical material, but we will continue to raise up our posterity in the old way. No book on my table looks more worn than Dr. Thomas's. His directions to an expert may be all well, but in the hands of the average M.D. and the midwife I should prefer Dr. Barker's discreet criticism as a working formula. The standpoint from which this question is viewed, the hospital and city or the country, must make our deductions vary greatly.

The Action of Disinfectants on Tubercular Material.—Dr. Vallin (Tribune Méd., et jour. de Pharm., 1885, p. 211) has endeavored to determine in what degree the tubercle bacillus was affected by the previous exposure of the tubercular material to reputed disinfectants. Fragments of tubercle from a patient who had died of phthisis were found to yield an infusion powerfully infective. The infusion, dried upon blotting paper, was also infective. Similar strips of prepared paper, after being subjected to sulphur fumigation, were found to be entirely inert when the straws were of 30 or 40 grains to 50 cubic metres of air; but with 20 grammes of sulphur the results were not constant; and with 15 grammes of sulphur the strips still yielded specific infectable material. Experiments were also made with other disinfectants. One part of corrosive sublimate in one thousand parts of water was effective, as were also nitrous vapoors. Water appeared to have the property of destroying germs; for, if the strip of paper on which the tubercular infusion had dried was disinfected with water, the inoculated animal retained its health.

A Scrap of History of Perkins's Tractors.—The publication of a new edition of Dr. Holmes's "Classical Essays on Homeopathy and Kindred Delusions" revives a temporary interest in Perkinism. The following note to unpublished extract may give a faint idea of the state of mind that prevailed in this country at the time this delusion prevailed. It is kindly contributed by Dr. W. Thornton Parker, and is an extract from a letter from Dr. Benjamin Parker to his son, Dr. W. Thornton Parker, Sr., dated November 11, 1842: "I am much pleased with Holmes in the most part; but I have not had time to read him through. All about Perkinism is perfectly correct and true. I lived in those times, and was in the midst of the excitement. A gentleman in Virginia sold a plantation and took the pay for it in tractors, which tractors died on his hands. Nothing was more common than to buy horses and carriages with Perkins's tractors. But the worst effects of the delusion Holmes has silently passed over. The yellow fever pre-
valled in New York to a great degree, and proved fatal to thousands. Perkins thought he could cure the fever with his tractors, and went into the city while it was raging; and, as might be expected, he immediately fell a victim of his own folly. —Philad. Times.

THE PREPUCHE OF THE NEW-BORN.—Dr. C. M. B. Kidd, of Vergennes, Vt., writes: "In the early part of my practice I was not a little amused by a young unsophisti-
cicated mother calling upon me with her infant, in a somewhat excited, or rather anxious state of mind, and confidentially informing me that her baby—a bright healthy boy—she feared, was not altogether right, and after a few preliminary explications she proceeded to re-
mainly with a story of troubles from the North and West with this class of troubles, and have become strong and well without any medication, and still remain here in business. This climate must be adapted to the relief at least of granular kidney, as the almost constant action of the skin will relieve the kidneys much by eliminating urea from the blood, and thus aid the physician greatly in treating Bright's disease. This climate, in short, has all the advantages of other semi-
tropical climates which I have visited, and, in my opinion, is superior to many of them in many respects. The tables of the first-class hotels here are second to none in the country—fresh shad every day, caught during the night in the St. John's, and other fish of the finest quality and flavor, oysters coming from the Cape Cod, fine poultry and eggs, abundant oranges and sweet pota-
toes the year round, green turtle and venison always at hand, bread and pastry of best quality, milk not abun-
dant, but good. The New York markets supply the hotels with beef, mutton, butter, and all other good things that can't be found here, and no mortal man or woman can ever take the place of the best Florida hotels. Palatka is a pretty little town, and growing rapidly, with seven hotels—two of them large and first class, while the others are good—and thousand of visitors come here each winter to spend a few weeks or a few months. There are also several good boarding-houses here where hundreds of invalids come for the benefit of the climate and to be restored to health. There are several excellent resident physicians here, and my own ill health at home obliges me to add 'one more to their number as a 'winter resident,' and I need not say we will all do the best we can, socially and professionally, for all who come down here, either for pleasure or for health. This season is larger than the seasons of the Southern, North and West, and wherever your popular journal circulates, in order that all medical men may understand what the Florida climate has done and is doing for the sick. And I want to say right here to all my professional brethren, of all medical schools, that they can send their patients who require a mild winter climate to any of the live and growing towns of Florida, and they will always find good hotels to feed them, and good physicians to take care of them if they should need medical aid."

RECEIVED REMEDIES FOR BURNS.—Dr. J. H. Finrock, of Laramie City, Wyoming, writes: "Dr. Prettyman's new Remedy for Burns," published in The Record of January 12, 1884, prompts me to send you the following, which was first made known to the profession by Dr. Binkerd, of Delaware. During the past twenty years I have had to treat an unusual number of cases of burns, and have tried many remedies; but this has given the best satisfaction of all. I first apply soda bicarb., in powder or solution, to relieve the pain, and then dress the part with the ointment, changing the dressings only when the discharge renders it absolutely necessary.

REMARKS ON Rupture of the Bladder, WITH a SUCCESSFUL CASE of this Injury TREATED BY PERINEAL URETHROTOMY AND PELVIC DRAINAGE.¹

BY ROBERT F. WEIR, M.D., SURGEON TO THE NEW YORK HOSPITAL.

The cases of recovery from a ruptured bladder can, in common phrase, be almost numbered on the fingers and toes. In exact numbers, they are given as 26 cases by Rivington,² in his elaborate paper on this subject, out of a total of 226 instances collected by this surgeon. On analyzing these fortunate examples, however, it is found that one case, Keal's,³ is briefly and unsatisfactorily stated as a partial or subperitoneal rupture; in five⁴ others the rupture, occurring during parturition, had safely torn through the vagina three times and into the rectum twice, and in four⁵ other cases the discharge of bone from the bladder, or its detection in that organ some time subsequently, was the only evidence of the previous rupture or rather ulceration of the bladder. Finally, in another case of Rivington's, the late discharge of urine from an abscess in the groin, which in its turn had followed an injury, was the scanty proof of a late, partial case, and these cases, aside as of but little aid in determining the proper surgical procedure in rupture of the bladder, we have only fifteen recoveries from this severe injury to consider. Seven⁶ of these recoveries occurred in ruptures that were extra-peritoneal, or in parts of the bladder not covered by peritoneum, i.e., near its outlet and generally in front, where it was found in 32 cases. Again, in 32 cases these cases aside, there remain eight cases were said to have involved the peritoneum, which would indicate that the upper or posterior part of the bladder (in 73 cases 39 had the laceration behind) had been torn. In truth, however, these latter and more serious cases detailed by Walters,⁷ Le Gros Clark,⁸ plank, Mason,⁹ Thorp,¹⁰ McDougall (2 cases),¹¹ Morris,¹² and Chaldecott,¹³ have been subjected to a close scrutiny by Bartels,¹⁴ Rivington, and others, and only one (Walters') passes unquestionably as a successful case of an intra-peritoneal rupture, the others being relegated to the extra-peritoneal variety of the injury. In other words, the mortality of the extra-peritoneal rupture is most discouraging. In 15 cases only one survived, i.e., 8½ per cent. The mortality of the extra-peritoneal form is much less; in 74 cases, 14 recovered, or 18½ per cent.¹⁴ This is a high figure, perhaps too high, for Maltreit,¹⁵ following Bartels, gives the mortality of extra-peritoneal ruptures as 65 per cent., or 29 cures out of 76 cases.

The point developed by this examination of the cases, that the intra-peritoneal cases are almost invariably fatal, is to be kept in mind when discussing the diagnosis and treatment. Much of this mortality is due, doubtless, to the other injuries sustained at the time, such as fractures of the pelvis, which occurred 109 times in Bartels' 169 cases (or rather 163 cases, as 6 of them have been found to be duplicates). Other serious injuries were also present in many cases. But in the 15 successful extra-peritoneal cases there were 9 cases of fracture of the pelvis, in 5 of which this complication was early appreciated. Hence a recognized fracture of the pelvis associated with a rupture of the bladder should not contraindicate surgical interference.

Seeing, then, the great difference in the mortality between the two varieties of the injury under question, is it possible to make not only a diagnosis of rupture of the bladder, but also to diagnose the locality of the injury; that is to say, whether the extravasation is above or below the peritoneal line?

The symptoms given in our usual works on surgery are somewhat vague and obscure; the collapse, the abdominal pain and muscular tension, with more or less meteorism, conjoined with bloody urine, which may pass by the patient himself (for it is an injury more likely to occur to males, since in 181 cases only 22 were in females), is often a warning for its avoidance the use of the catheter, point strongly in themselves to this injury. But only one symptom of real value beyond the existence of bloody urine can be elicited by the use of the catheter. When this instrument, after entering the bladder (to be determined positively by the finger in the rectum) and evacuating its contents (sometimes none are present), the passages in further, giving eisit, in an ebb and flow movement corresponding to the respiration, to an additional quantity of urine, and this possibly of a different depth of color from that first drawn, the pathognomonic symptom of a ruptured bladder is reached, and if the passage of the catheter-point is through the back and upper part of the bladder it is certainly an intra-peritoneal rupture. Once the confirmation of injecting very cold water was resorted to, the patient feeling the current in his bowels. Unfortunately in but very few cases has it been possible to achieve accuracy by means of the catheter. The rupture may be too small, or the timidity of the surgeon may be too great, or the opening may be plugged up by overlapping of the mucous membrane, or by an intruding mass of intestine, as happened in one instance.

Failing this important symptom there is another of considerable value, and noted in many of the cases; it is the existence of dulness on percussion in the hypogastrium or in one or both iliac fossae. I have in one instance seen it show itself in the left lumbar region. This dulness is due generally to extravasated urine and more or less rapidly increases, and does not change its position on turning the patient on his side, if this be possible. The rectum should also be carefully explored for the more rare lateral and posterior extravasations. I believe this extravasation to be not only an important indication of a rupture of the bladder, but also to point strongly to the extra-peritoneal state of the laceration and will be clearly appreciated by a glance at this diagram taken from Tillaux. It shows plainly how much of the bladder

¹⁵ This is according to the figures of Rivington, i.e., Simple intra-peritoneal ruptures, 106; extra-peritoneal ruptures, simple and complicated, 66; intra-peritoneal ruptures in the form of sub-rupture of uncertain position, 6; reported cases of recovery, 60.
¹⁶ Contribution to l'Etude des traumatismes de la vessie. 1881.
is subperitoneal, and one would at first expect that ruptures would as frequently occur here as above this line did not the fact of a full or distended bladder compressed against the sacro-lumbar prominence play so important a part in bringing about this injury, for in a large majority of the cases of rupture the patients have been under alcoholic influence or their bladders were in the vesical wound was delayed much longer than eight or ten hours the chances of success were correspondingly imperilled. In the few cases where failure of vesical union occurred, the urine escaped through the abdominal wound, the omentum enveloping the bladder and conducting the extravasation forward. The latter point I assume is more due to the dependent position of the belly in animals.

In the successful case of Walters, where, in man, laparotomy was performed, the operation was done ten hours after the accident. The wound was in the fundus, two inches in length, the urine sponged out from the peritoneal cavity and the abdominal wound closed. A catheter was left in the bladder to act as a drain for a number of days and then used intermittently for three weeks. In the two cases where laparotomy was resorted to without success, in one, Willett's case, the operation was performed twenty-eight hours after the injury, but the patient died twenty-two hours thereafter; in the second, Heath's, the operation took place forty hours after the accident, the same procedures were employed and in both a drainage-tube was inserted through the abdominal wound. Death occurred in Heath's case seventy-six hours after the operation.

It must be evident from the preceding data that surgical interference to accomplish anything must be especially prompt in the intra-peritoneal ruptures, hence every aid to an early diagnosis must be resorted to in a suspected case of this injury. Failing the above symptoms, there is a measure of comparative safety to be used and which is applicable to each form of rupture for diagnosis and for treatment. I refer to the digital exploration of the bladder by the perineal incision, such as is made for median lithotomy. In a case of doubt in 1871, I employed this method to decide whether in a fracture of the pubis with severe symptoms I had not with a lacerated urethra or ruptured bladder, and was enabled to recognize, though not to successfully treat, a rupture on each side of the bladder from penetration of bony fragments. Latterly this means of exploration has been popularized by Sir Henry Thompson, and I can speak from experience to the case with which the bladder may be explored. It is true that my own and others' experience is chiefly made up of such cases as would permit the bimanual method to be made use of. Whether in a rigid or tumefied abdomen the upper part of the bladder could always be reached, I am not certain, but the finger plunged to its full depth would either recognize or exclude the extra-peritoneal ruptures, and the short time of urethral wound would not be likely to affect the results of the thorough exploration by a catheter introduced through the perineal wound of the parts of the bladder beyond the finger's reach.

The efficacy of this plan of action was seen in the following case that has recently been under my charge in the New York Hospital:

CASE.—An Italian laborer, aged twenty-eight years, was admitted to the New York Hospital, November 20, 1883, having been injured a short time previously by a bank of earth falling on him while engaged in making an excavation for a gas-pipe in the street near by. The accident occurred about ten o'clock in the morning, and on inquiry it was ascertained that he had had no alcoholic drink that day, and had urinated not long before the receipt of his injury. The mass of earth that fell upon him struck most heavily on his pelvis and left hip. When he was admitted no shock existed and his general condition was excellent. There was noticed a slight ecchymosis of the scrotum and a spot of blood at the meatus urinarius. This fact led the house surgeon to pass a rubber catheter, which gave exit to a moderate amount of bloody urine which became clearer as it flowed. Palpation over the supra-pubic region gave rise to a little pain; considerable tenderness was felt over the left hip, but no evidences of pelvic fracture were obtained.

2 St. Bartholomew's Hospital Reports, 1879.
3 Medico-Chirurgical Transactions, 1879.
THE MEDICAL RECORD.

The patient passing urine with some difficulty and at times bloody, the catheter was passed during the next twenty-four hours three times. General condition good, though increased tenderness was then experienced in the hypogastrum.

November 22d.—The injury had been considered until to-day as a slight urethral laceration, but the marked increase in the supra-pubic dulness, which now extended four inches above the pubis and across into each groin, with tenderness, led to a closer examination of the patient. The catheter passed readily into the bladder and only occasionally gave exit to blood-stained urine. The urine itself was passed at times voluntarily, and was not apparently diminished in amount. The temperature was but 99°. Abdomen not distended, though its walls above the dulness somewhat rigid. Condition still good. No signs of fracture elicited, but the finger in the rectum detected a softer spot on the left side of the prostate, which was decidedly painful. The ecchymosis of the scrotum and perineum was now very pronounced.

November 24th.—The temperature had risen to above 100°, pulse 104, and patient began to be restless and disposed to vomit. Tympanites increasing, with abdominal tenderness out of all kind of dulness but above it. A last hypodermic needle was given; the hypogastrum drew out some bloody fluid with an acid reaction and urinous odor. Nothing distinctive could be felt in the rectum. The patient was etherized and an incision, under sublimated irrigation, 1 to 1,000, was made three and one-half inches long in median line, midway between symphysis and umbilicus, until the suprapelvic cellular plane was reached, where a large cavity, containing at least a pint of bloody, undecomposed urine, was found. The finger could be carried its full length behind the symphysis, but nothing was detected. To effect a more complete diagnosis, as well as to allow of the carrying, if possible, of a drainage-tube from the hypogastric opening downward, the perineum was paralysed, the patient was put into the lithotomy position and on a staff introduced into the bladder a median incision was made, opening the urethra just anterior to the prostate. The finger passed in here toward the bladder revealed a rent running along the left side of the roof of the prostate which was lost in the wall of the bladder itself. Its upper limit was not defined, possibly to avoid extraneous damage to the parts so favorable as they already were. Through the supra-pubic incision a large silver catheter was carried, and, aided by the finger in the perineal wound, was caused to pass through the laceration of the bladder and emerge from the lower wound. To the eye of this catheter a thread was attached and a large rubber drainage-tube pulled through as the sheet was withdrawn, the rent being closed by sutures to the skin, and a second drainage-tube was then passed into the bladder and its external end also fastened in the perineum. The cavity of the extravasating bladder were carefully washed out with a warm sublimated solution of 1 to 2,000, and iodoform gauze placed over each wound, though so lightly that urine could readily flow through the dressing.

The progress of the case was in every way most satisfactory, as is shown in the following notes from the case-book of the hospital. Dressing reapplied at 7 p.m.; temperature, 100°; all urine escapes through tube.

November 25th.—Condition improved, little pain; temperature, 101° all day; dressings changed and tubes irrigated.

November 28th.—Patient doing well; temperature still elevated (100°). Tube in bladder removed on 27th, urine passed over the other tube, which has been shortened daily from the perineal end.

December 2d.—Temperature normal. Urine is still forced through tube into abdominal incision; tube removed from this opening and placed in perineum.

December 5th.—Patient himself removed tube from perineum last night and much pain followed; replaced this morning, it drains thoroughly. Cavity washed out daily with sublimated solution.

December 9th.—Patient removed tube last night and it could not be replaced; urine voided by the penis with little pain.

December 24th.—Wound in perineum closed, wound in abdomen only a linear ulcer. Allowed to go out of the hospital to-day.

Theoretically the incision for lateral lithotomy would more perfectly attain the end of draining the bladder, but it is certainly of greater risk than the median cut, too much so to be used for diagnostic purposes. Should a rupture of the bladder be recognized, the drainage of the bladder can be accomplished by leading in a rubber tube or catheter, which is generally well borne for several days, as Thompson's cases show; or the neck of the bladder may be stretched by a glover-stretcher, which was done by Howe; or the neck of the bladder may be sufficiently nicked to impair its tightness of action; or, again, in these cases like Mason's, where the extravasation was posterolateral, the incision may be boldly converted into the ordinary lateral cut.

It will be seen on analyzing 18 successful cases given in portraits and cross-sections (for unfortunately I am not able to verify all of Rivington's successful cases), that the extravasated urine was either cut into or opened itself in three instances. In one case aspiration was performed, in 5 cases the catheter was tied in, in 2 cases lateral cystotomy was done, in 1 perineal section, in 4 others an encrusted piece of bone was removed by a subsequent lithotomy (these are, however, no use to us in the present consideration), in 1 laparotomy and vesical suture was performed, and in 1 case the treatment is not stated. In other words, in the 12 cases of extra-peritoneal ruptures to be used for deductions, drainage of the bladder by a catheter and by incision was employed 8 times and evacuation of the extravasated urine 4 times. These are so evidently the aim and end of surgical treatment, the results are to my mind only additional arguments to the procedure set forth in the case presented with these remarks.

In a case of intra-peritoneal rupture, where other lesions do not contra-indicate interference, the examples of Walters, Willetts, and Heath are to be followed. The knowledge obtained in cases of this sort are, however, no use to us in the present consideration, to the knowledge of Zong, and Czerny, but also to test the accuracy of the approximation by injecting milk into the bladder before closing the abdominal wound. Stein 1 has recommended that the lips of the rent in the bladder should be sewn in the abdominal wound. This is only applicable, however, to wounds of the top and front of the bladder. The peritoneal cavity should be carefully cleansed after the vesical wound is sutured, not only by the "toilet" of sponges but preferably by douching or pouring in two or three times among the intestines water that has been recently boiled, but sufficiently cool to be safe. This will supply a very fair aseptic fluid and avoid the necessity of using the solutions of sublimate, thymol, or carbolic acid that have been suggested, but which apparently at times exert a deleterious influence in the abdominal cavity.

THE HOSPITALS AND MEDICAL ASYLUMS IN FRANCE.

THE MEDICAL RECORD.

PRACTICAL HINTS REGARDING THE METHODS OF EXAMINATION EMPLOYED AS AIDS IN THE DIAGNOSIS OF NERVOUS DISEASES.

By A. L. Ranney, M.D.,
Professor of Applied Anatomy in the New York Post-Graduate Medical School and Hospital.

(Continued from page 325.)

The eyelids. These may afford valuable aid in diagnosis. The upper lid sometimes drops over the eyeball and cannot be raised, constituting the condition termed "ptosis." This indicates a paralysis of the third cranial nerve. Again, when the facial nerve is paralyzed, the eyelids of the affected side cannot be closed. Puffiness of the lower eyelid, especially in the morning after rising, suggests the possibility of kidney disease. Alcoholic patients often exhibit a quiver of the muscular fibres of the eyelids. Spasm of the lids produces the peculiar wrinking so often seen in St. Vitus' dance and other nervous affections. In imbeciles and cretins the lids are often obliquely placed.

The expression of the eye may often be characteristic of certain nervous diseases. Melancholics exhibit the downcast eye. Maniacs may look excited, suspicious, or distrustful. A vacant stare is often present in dementia. Some forms of brain disease exhibit in the eye an air of exaltation. Masturbators seldom direct their gaze at the questioner, but look furtively about as if to avoid scrutiny.

The mouth. The lips are sometimes paralyzed. The pronunciation of the labials is then rendered indistinct or impossible, and a facial deformity is also created. The various diseases in which the mouth is chiefly affected will be considered separately.

A. In Bell's paralysis the lips are rendered incapable of movement on one side only, and the mouth is drawn toward the opposite side by muscles which are no longer antagonized, on account of the facial paralysis. The act of whistling is rendered impossible, because "puckering" of the lips requires a contraction of symmetrical muscles of the face. The saliva is no longer retained, and the patient "drools." All expressions, except that of repose, are those of a face alive on one side and dead and motionless on the other; hence, they would be particularly grotesque and striking (were it not so frightful and distressing) even to a casual observer.

In those rare cases where the facial nerve of both sides is impaired, symptoms similar to those mentioned above exist, except that the tongue has its normal capabilities of movement, save in the perfect articulation of the labial consonants only, and that a complete absence of facial expression is present.

The following rules will prove of value in making a diagnosis of the seat of the exciting cause of the condition. They are based entirely upon anatomical facts, and are therefore very important, because they admit of no exceptions:

1. If the paralysis be limited to distinct parts of one lateral half of the face, the lesion affects only individual branches of the nerve, and is outside of the cranium. An apparent exception to this rule is sometimes met with in connection with lesions of the crus cerebri—paralysis of the lower half of one side of the face being clinically observed to occasionally accompany a paralysis of the motor olivary nerve on the same side as the lesion.

2. If the fauces and palate exhibit paralytic changes, the lesion is within the cranium or in the temporal bone.

3. If the sense of taste be lost in the anterior two-thirds of the lateral half of the tongue on the same side as the facial paralysis, the lesion is either within the cranium, or in the temporal bone, above the origin of the chorda tympani branch.

4. If the sense of hearing is rendered very acute upon the same side as the facial paralysis, the lesion is probably within the temporal bone and involves the ganglionic enlargement found upon the nerve in the aqueduct of Fallopian.

5. Facial paralysis dependent upon cerebral lesions is commonly associated with hemiplegia, which may be upon the same side as the lesion, or on the opposite side.

6. Crossed paralysis of the "facial nerve and body type" indicates a lesion of thepons Varolii posterior to the line which connects the trigeminus nerve with its fellow at their escape from the pons (Gubler).

7. If the lesion be situated in front of Gubler's line the facial paralysis and the hemiplegia will be on the same side.

B. The lips and tongue are particularly affected also in that disease of the medulla called Duchenne's disease, or glosso-labio-laryngeal paralysis. So marked is this loss of power, in severe cases, that a most characteristic facial deformity is induced. As the disease is commonly bilateral, the lips usually hang apart from each other and cannot be approximated. The tongue lies trembling and immovable in the floor of the mouth, if the paralysis be complete; but if paresis only exists, it can be imperfectly protruded with difficulty, and is tremulously and slowly retracted. If the paralysis be unilateral, the healthy side of the tongue becomes full and prominent, in comparison with the affected side, when called into action. Speech and mastication are seriously embarrassed. The saliva is constantly expectorated, because swallowing is performed with extreme difficulty.

C. The facial muscles as well as the tongue exhibit a peculiar tremor in paralytic dementia. Small bundles of fibres composing parts of the tongue, or the delicate muscles of the face, are thrown into non-rhythmic contractions by emotion, or the performance of any voluntary movement, as when showing the tongue or teeth. These fibrillary tremors may sometimes exist even in the quiescent state of the muscles. The tongue occasionally exhibits coarser movements of a convulsive character. Late in the disease it may become atrophied or shrivelled.

The effects of this form of tremor upon speech are aggravated by an imperfect co-ordination of the muscles.

This article comprises, in substance, the subject-matter of a course of lectures delivered by the author before a private class of post-graduate students.
cles of the tongue and lips, which is simultaneously de-
veloped. Long or difficult words are omitted in conver-
sation by these patients in a half-unconscious way, and
the terminal syllable of other words is commonly left off.
The speech becomes thick, and of a tremulous character.
The shortest words possible are employed by the patient
to convey his ideas. A distinct pronunciation of con-
sonants and polysyllabic words, such as "constitution," "infallibility," "prognostication," etc., is impossible;
hence, a test is thus afforded between carelessness of
utterance and a physical inability to articulate.

An unnatural quietude of the muscles of the face and a
slight disparity of the pupils are prominent features of its
stage of development.

It is well to note, in this connection, a test which is
of some value in deciding as to the existence of this
special form of disease. Extend the patient's fingers
and place them between your own, and a delicate,
"parchment-like" tremor will be felt, which is due to
an otherwise imperceptible tremor of the hand-muscles.

D. The lips participate to a marked degree in severe
types of facial spasm. In the clonic form the muscles
on one side of the face are violently contracted and as
suddenly relaxed. This is commonly affected simul-
taneously with the angle of the mouth. The spasms are
marked by distinct paroxysms, whose duration varies
from a few seconds to an hour or so. If the spasm is of
a tonic variety, mastication and articulation are inter-
fered with, and the paroxysms are of longer duration.

It is always well to search carefully for curious teeth
in these cases; but the spasms may be due to cold,
wounds, injuries to the trigeminal nerve, or chokes.
E. The lips may indicate some form of defect in the
heart's action, if blue or purple in color. Scars at the
corners of the mouth are strongly suggestive of previous
syphilitic ulceration, a point of importance in the treat-
ment of some forms of nervous disease.

F. The gums should be inspected. If pale,
anemia exists. If blue along the line of junction with
the teeth, lead-poisoning is present. If the teeth are
loosened and the gums are soft and bleed easily, mer-
curial poisoning may be suspected; this is rendered
positive if the breath has the "mercurial odor" and the
saliva is excreted in very large quantities. Various ca-
chesias, phosphorus-poisoning, purpura, and scurvy pro-
duce marked and often characteristic changes in the
gums.

G. The teeth may afford much valuable information
respecting the possibility of hereditary syphilis. Hutch-
inson has described the characteristics of such teeth
with accuracy and detail. It is impossible to quote his
deductions here, but the peculiarities of syphilitic teeth
are now generally well recognized, and are often a
valuable aid to the neurologist, both in diagnosis and
treatment.

H. The tongue. Some diagnostic points regarding
the tongue have been touched upon already. When
the face exhibits any form of paralysis, it should be al-
cways carefully noted if the tongue exhibits fibrillar tre-
mors; also whether it can be protruded in a straight line
and moved freely in all possible directions. In testing
speech, those words should be employed that require the
normal power of movement of the lips (the labials) and
of the tongue (chiefly the consonants). It should be
also noted whether the words are clearly, rapidly, and
distinctly articulated, or if the utterance of words is
slow, thick, or slurred. Ragged edges in the tongue in-
dicate epilepsy, because it is frequently bitten during
the paroxysms. Imperfect mastication of food and diffi-
culty in swallowing may be due to loss of power in the
tongue. A "furred condition" of one lateral half of the
tongue indicates some irritation of the branches of the
fifth cranial nerve; hence, the presence of decayed
teeth, diseases of the gums or the maxillary bones, etc.,
should be carefully searched for. The tongue may be
paralyzed on one side or on both. This condition is not
infrequently due to hemorrhage, softening, or tumors of
the brain, and it occurs in connection with embolism or
the general paralysis of the insane.

Spasm of the tongue may be perceived in connection
with chorea, epilepsy, hysteria, facial spasm, and as a re-
result of slight compression or irritation of the hypoglossal
nerve. Fibrillar tremors of the tongue are often en-
countered in patients afflicted with paralytic dementia.

![Image 8: Syphilitic Teeth (Hutchinson)]

![Image 9: Syphilitic Teeth]
ing about in the orbit, and again turned up beneath the eyelid, so that the cornea is covered and only the white sclerotic is to be seen; the mouth is twisted to one side and distorted; the tongue is thrust between the teeth, and, caught by the violent closure of the jaws, is bitten, often severely; and the foam which issues from the mouth is reddened with blood. The turgescence of the face indicates obstruction of the venous circulation; the cheeks become purplish and livid, and the veins of the neck are visibly distended.

During the fit of exacerbation, in an attack of tetanus, or lockjaw, the aspect of the sufferer is sometimes frightful. The forehead is corrugated and the brow knits, thus expressing the most severe type of bodily suffering; the orbicularis muscle of the eye is rigid, and the eye itself staring and motionless; the nostril is widely dilated, indicating the extreme distress of breathing; the corners of the mouth are drawn back, exposing the teeth, which are firmly clinched together; and the features, as a whole, have a fixed and ghastly grin—the so-called “risus sardonicus.” During such paroxysms, as in those of epilepsy, the tongue is liable to become protruded between the teeth and to be severely bitten.

In chorea, the facial muscles participate in the general eccentricity of movement. Watson thus describes the peculiarities of this strange affection: “The voluntary muscles are moved in that capricious and fantastic way in which we might fancy they would be moved if some invisible mischievous being, some Puck or Robin Goodfellow, were behind the patient and prompted the discordant gestures. With all this, the articulation is impeded; there is the same perverse interference with the muscles concerned in the utterance of the voice. By a strong figure of speech, the disorder might be called ‘insanity of the muscles.’”

In catalepsy the patient lies often with eyes open and staring, yet without expression indicative of life; more body are often frightful. In rare cases consciousness may be retained throughout the attack.

The deformities of face and intellect which seem to be the result of long residence in abnormal atmospheric conditions, or of certain well-defined localities, are illustrated in that race of people found in Valais and the adjoining cantons of Switzerland, called “cretins.” Many of these wretches are incapable of articulate speech; some are blind, some are deaf, and some suffer from alien of these privations. They are mostly dwarfish in stature, with large, head; wide, vacant features; goggle eyes; short, crooked limbs, and swollen bellies. The worst of them are insensible to the decrees of nature, and in no class of mortals is the impress of humanity so pitifully defaced. They are usually the descendants of parents afflicted with goitre.

The hand.—Among certain forms of nervous disease characteristic deformities of the hand are sometimes encountered. These will be considered separately. Tremor and spasm of the fingers are also developed, in some cases, and require a hasty description.

The deformities of the hand that are commonly observed include (1) that of so-called “progressive muscular atrophy;” (2) that of a spinal disease known as “amyotrophic lateral spinal sclerosis;” (3) that of injury of the ulnar nerve; (4) that of injury of the muscular-spinal nerve; (5) that of injury of the median nerve; (6) that of paralysis agitans; and (7) that of gout and rheumatism.

The tremors of the hand include (1) those of a condition called “athetosis;” (2) those of chorea or St. Vitus’ dance; (3) those of paralysis agitans; (4) those of the general paralysis of the insane; and (5) those produced by circumscribed lesions of the nerve-centres.

In progressive muscular atrophy the ball of the thumb is often the starting-point of the disease. This eminence gradually shrinks and disappears. It should be remembered that the disease affects symmetrical and homologous parts; hence both hands are liable to present the same deformity. Gradually the muscles between the bones of the hand shrink, so that the bones stand out unnaturally. Fibribillary twitchings over the affected muscles should always be looked for, as they are seldom absent. The temperature is lowered over the atrophied muscles.

In amyotrophic lateral spinal sclerosis the hand, when affected, is strongly flexed upon the forearm, the fingers are shut tightly upon the palm, and the thumb is drawn inward toward the fingers. Attempts to straighten the fingers, thumb, or hand will be strongly resisted, and cause pain. In course of time the affected muscles become markedly shrunken, thus adding to the deformity described. Fibribillary twitchings may be easily excited in the affected muscles, provided they do not spontaneously exist.

When paralysis of the ulnar nerve exists, adduction of the hand is no longer performed in a perfect manner, since the flexor carpi ulnaris can no longer act in unison with the extensor carpi ulnaris. Flexion of the hand is performed imperfectly and by means of the flexor of the radial side of the forearm only, since that muscle is supplied by the median nerve. The ability to move the little finger is almost entirely abolished. Complete flexion
of the inner three fingers is rendered difficult and sometimes impossible. The fingers cannot be separated from each other, or compressed into a close lateral juxtaposition, owing to paralysis of the interossei muscles; and flexion of the first phalanx and extension of the terminal phalanges of all the fingers are rendered impossible for the same reason.

When the ulnar nerve is paralyzed above the wrist, so that the interossei and lumbricales are alone paralyzed, the hand assumes a diagnostic attitude, the so-called "claw-hand," in which the extensor communis digitorum muscle extends the first phalanges of all of the fingers, while the other two rows of phalanges are flexed by the flexor superficialis, the lumbricales being no longer able to flex the first row of phalanges or to extend the two other rows). This same condition of the hand may, however, be produced by a condition of progressive muscular atrophy of these muscles.

It must be remembered that this condition, if dependent upon ulnar paralysis alone, is more marked in the two inner fingers than in the three outer, since the lumbricales are supplied in part by the median nerve. This clinical fact seems to stamp the action of the lumbricales as similar to that of the interossei. Finally, the effects of ulnar paralysis may be manifested in the movements of the thumb, since it supplies two muscles which control it. On the other hand, flexion of the first phalanx, with extension of the other two, can be performed in all the fingers by the aid of the interossei which are supplied by the ulnar nerve. The position of the thumb is peculiar; it is extended and adducted and thus closely applied to the index finger, as in the hand of the ape. The hand, when flexion at the wrist is attempted, is strongly adducted by the action of the flexor carpi ulnaris, because the antagonistic muscle of the radial side is paralyzed. The act of pronation of the hand is seriously impaired. The inner three fingers can be brought into a partially flexed condition, since the flexor profundus digitorum muscle is partly supplied by the ulnar nerve. These combined effects give to the hand a peculiar appearance, and it is one which is so peculiar that paralysis of the median could hardly be mistaken by an anatomist for any other deformity. When the paralyzed muscles begin to show the results of atrophy, the deformity in the forearm and in the ball of the thumb will further assist in the diagnosis of this affection.

The musculo-spiral nerve is more frequently affected with paralysis than any of the nerves of the upper extremity. It is particularly liable to both peripheral and central causes of paralysis; thus, in cerebral hemiplegia the muscles supplied by this nerve are, perhaps, more commonly affected than those supplied by any other nerve, while paralysis of these muscles is common as the result of chilling of the upper extremity, traumatism, and lead-poisoning.

The anatomical situation of the musculo-spiral nerve and the peculiarity of its course around the humerus probably explain the frequent occurrence of paralysis, since it may be easily compressed by sleeping upon the arm. It is common to meet with this type of paralysis in patients who have used their arms as a pillow, or in drunkards who have slept in some constrained position upon benches, steps, etc. Persons who have fallen exhausted and have rested upon the arm, and soldiers who have slept upon the damp ground, often arise with this form of paralysis. It is stated by Brenner that the coachmen of Russia, who are in the habit of sleeping upon the box with the reins wound around the upper arm, are victims to this condition; and Bachon reports the same result as common among the water-carriers of Rennes, since they pass their arm through the handle of the heavy water-pails to more securely compress them against the chest. The habit of the Russians of tightly bandaging the arms of infants to the body, and allowing them to sleep with one side of the arm in a prone position, seems to promote the frequent occurrence of this trouble.

Among the other forms of traumatism which conduce toward this form of paralysis may be mentioned the use of poorly padded crutches, the kicks of animals, cuts, stab wounds, fractures of the humerus, dislocation of the humerus at the shoulder-joint, and the development of an excessive amount of callus at fracture sites.

Rheumatic affections and a neuritis of the musculo-spiral nerve are reported as causes by Bernhardt and others; and cases of hysterical origin have been rarely but positively authenticated.

Finally, lead-poisoning must be mentioned as one of the most common causes of paralysis of the muscles supplied by the musculo-spiral nerve. The existence of this form of poisoning will have generally been indicated, previous to the appearance of paralysis, by colic, jaundice, and arthralgia, as the muscles are seldom affected until the latter stages. The extensor communis digitorum muscle is usually affected first, and the paralysis gradually extends to the other muscles of the upper arm and musculo-spiral nerve. The muscles of the arm are much less frequently affected than those of the hand and forearm; but in severe cases the muscles of the upper arm are involved, and the thumb and the index-finger cannot be extended or abducted; the patient cannot supinate the hand when the forearm is extended (this position being assumed in order to include the action of the biceps muscle), nor can the forearm be half bent and the hand half supinated by the supinator longus muscle; and finally, when the patient is instructed to flex the forearm, when placed in a position of half flexion and semi-pronation, the supinator longus muscle lies flaccid, and does not become tense and hard as in health. The loss of power in the triceps muscle renders it impossible for the patient to extend the forearm upon the arm when the arm is first raised above the head; nor can the forearm be extended with the same degree of force as the healthy side in any position of the arm. When the hand is laid upon the table, the patient is unable to raise the hand from contact with it, but the lateral movements of the fingers are retained.

In gout the joints become enlarged and seriously crippled by deposits of urate of soda, that cause prominent nodules upon the fingers. These often ulcerate.

The index and middle fingers are the ones most frequently deformed. Occasionally one finger will be drawn toward the palm by gouty inflammation in the sheath of its flexor tendon. If this deformity be found, always examine the other hand to see if a similar deformity is not more or less developed on both sides. If so, it is almost a positive sign of gout.

The diseased condition, called "athetosis," because the fingers do not maintain a fixed position, is characterized by a continual motion of the fingers and toes, and an inability on the part of the patient to retain them in any fixed attitude. These patients cannot keep the hand closed or open, even for a short period, although the fingers are to some extent under the control of the will. The toes are not commonly affected to the same degree as the fingers. The movements of the fingers and toes are perpetual, not being entirely arrested during the intervals of being asleep. The tremor of paralysis agitans, or "shaking palsy," is markedly aggravated by voluntary muscular effort or mental excitement. Except in very aggravated cases, it ceases during sleep. During the daytime it is more or less persistent and uncontrollable.

In imbeciles rhythmic movements of the hands are
commonly met with. They are in marked contrast to the irregular and spastic movements observed in St. Vitus' dance. During an attack of acute hydrocephalus, or "water on the brain," the thumbs are usually flexed upon the palm. Langdon Down has described the so-called "woolly hand" of the idiot; the skin being too abundant for its size, and forming wrinkles upon it.

In all diseases which cut off the nerve-fibres from their centres of nutrition, or " trophic centres " as they are called, or after injuries to the nerves, the skin of the hand, as well as of other parts, may become smooth, shining, and affected with eruptions or ulceration. The nails and hair may also give evidences of imperfect nutrition.

The Gait and Attitude of the Patient as a Factor in Diagnosis.—Among the symptoms which are brought to the notice of the neurologist by his perceptive faculties, none are more positively diagnostic than the abnormalities of gait and attitude which are frequently encountered. It will simplify description to consider first the more common abnormalities of gait, and subsequently the characteristic attitudes produced by nervous affections.

Gait of hemiplegia.—This condition (in which one lateral half of the body is paralyzed) is evidenced by a characteristic gait, if the paralysis is not so profound as to prevent all attempts at walking. The arm hangs limp or more or less rigid on the affected side. At each step the paralyzed half of the body is lifted, in order, as it were, to swing the weak leg forward. This movement causes the shoulder to tilt toward the healthy side, and the pelvis to be raised, while, at the same time, the leg is not bent at the knee as in health. The shoe of the paralyzed leg trails along the ground as it is swung forward, and the toe becomes worn off rapidly, a clinical point not to be overlooked. The back is not arched, as in the spastic form of paralysis, and the feet do not tend to cross the median line.

Gait of paraplegia.—Both legs (or, to be more accurate, the lower half of the body) may be more or less paralyzed, and yet the patient can walk. How different is the gait, however, from that of health! These patients shuffle along without raising either foot from the ground to any appreciable extent, so that they cannot be said to step. The progression is extremely slow, because the length of the step (if it may be so called) is very short. The heel of one foot rarely passes the limit of the toe of its fellow, if the paraplegia is well developed. This gait differs from that of spastic paraplegia chiefly in the absence of the stiffness of the legs and the interlocking of the knees, which are both present in the other. The so-called "hopping gait" is not developed as in the other form.

Gait of spastic or tetanoid paraplegia.—In the early stages of this disease a combination of paresis, muscular rigidity, and occasional tremor exists. The feet appear to be firmly glued to the ground during attempts at walking, and are scraped along with a characteristic noise. The feet often cross each other in walking, and the knees are liable to become locked together. These subjects are particularly prone to fall in spite of the use of canes or crutches, because the slightest irregularity in the pavement may catch their shoe as it is slid along the ground. These patients sometimes exhibit a "hopping gait" when the muscles of the calf become affected with spasm. The back is strongly arched and the chest is thrown forward. The patient throws his weight first on one cane and then on the other, in order to lift his body so as to move his feet.

Gait of paralysis agitans.—The tottering and trembling gait of these subjects, with a tendency to trot rather than walk when under full headway, is characteristic. The shaking hands are usually held out in front of the body, which is bent forward as they run. These subjects are generally well advanced in age. The head is projected forward and held stiffly when walking, and the "vertebra prominens" stands out in bold relief. Fig. 13 illustrates this point very well.

Gait of pseudo-hypertrophic paralysis.—These subjects are always children. The immense calf muscles are strangely in contrast with their paralytic symptoms. When they attempt to walk the gait has been aptly compared to the "waddling of a duck." The back is excessively curved in the erect posture, so that a line dropped from the shoulders falls behind the hips. The peculiarities of attitude of these patients will be considered later.

Gait of locomotor ataxia or tabes dorsalis.—These subjects stride as they walk. The legs are flung about in an uncertain and apparently aimless manner, although the steps are taken with marked deliberation. The feet are brought down with the heel projecting, thus creating
A "stamping" and "hopping" gait. These patients keep their eyes steadily upon the ground when walking. They have no motor paralysis, as is shown by testing the various muscles separately; the abnormal gait being due purely to an inability to properly co-ordinate the various groups of muscles, which are frequently subjected to severe and unexpected falls, and generally resort to the use of two strong canes.

Gait of hysterical palsy.—The feet are dragged or shuffled along in the paraplegia of hysteria, but one foot is usually more affected than its fellow. These subjects use a crutch, or cling to articles of furniture as they sluggishlv move about a room. It is liable to pass away suddenly and is usually developed as suddenly.

Gait of progressive muscular atrophy.—When the thigh and calf muscles are affected, or those of the back or abdomen, the gait is seriously altered. As a rule, these subjects walk as a sailor does upon land; only the "roll" is exaggerated, and the trunk is peculiarly poised upon the legs. The gait is, however, modified by the seat and extent of the muscular degeneration; as it is produced in each case by the inability of a certain set of muscles to perform their normal functions.

Gait of cerebellar disease.—Like all ataxic subjects, these patients stand with their feet wide apart, to increase the balance or external stability; they walk along apparently imperfect co-ordination of the muscles of the legs. Sometimes they stagger and reel like an intoxicated person. If the feet are exposed the toes will be seen to be in constant motion when an effort to stand in one spot is made.

Gait of reflex paralysis.—This is generally of the "hemiplegic" variety. One leg is dragged along behind the body, the majorlity of cases.

Gait of cerebro-spinal sclerosis.—In this disease we meet a very characteristic gait. Slight jerking movements of the head and neck can be perceived in the early stages. Later in the disease the symptoms of marked inco-ordination of the muscles are apparent. The gait is then extremely unsteady and irregular, but totally unlike that of long motor ataxia, in which the muscles of the trunk as well as those of the legs are affected. These patients do not walk deliberately and in a straight line, but shoot suddenly forward or to one side, and are very apt to knock against articles of furniture in moving about a room and to fall violently.

The attitudes assumed in the more severe forms of nervous disease which tend to produce abnormalities of attitude. The limits of this article will preclude more than a cursory view of this subject. A volume would be required to properly exhaust the headings already touched upon.

Among the more common causes of abnormalities of attitude due to nervous lesions may be mentioned epilepsy, tetanus, hydrophobia, spinal meningitis, hysteria, catalepsy, hydrocephalus, chorea, ataxia, arthropathy, the many forms of cerebral and spinal paralyses, the different types of tremor and muscular atrophy, contracture, or reflex spasm.

Of the characteristic attitudes some are observed only in the erect posture of the patient, and others when the patient is sitting. Some of them are noted when the patient is sitting; while again others are present in patients confined to bed. Attempts at movement of any kind sometimes increase the deformity; while again walking may gradually limber up other patients and render the defects of movement less apparent.

In connection with the description of facial evidences of nervous sensory and motor conditions of Bell's palsy, Duchenne's disease, paresis of the muscles of the eye, paralysis of the third nerve, the convulsions of epilepsy and tetanus, the condition of catalepsy, and the facial spasm of St. Vitus' dance have been alluded to and in part described.

When the hand was considered the attitudes of progressive muscular atrophy, paralysis agitans, and the results of paralysis of the median, ulnar, and muscular-spiral nerves were described separately. The deformities of the hand in gout, and the attitude of the thumb and fingers in hydrocephalus, ataxiosis, and imbecility were also mentioned. It is not necessary, therefore, to again describe them.

It remains for me to touch upon some of the more important attitudes which have as yet been omitted.

In acute hydrocephalus the tuberculous deposit at the base of the brain creates a characteristic attitude when the condition is well developed. These children bore their head into the pillow and roll it from side to side. The thumbs are flexed upon the palms during sleep, even before the severity of the attack is reached. The pupils are at first contracted; but they become dilated when coma develops from the pressure of the deposit of tubercle upon the brain. The abdomen is markedly retracted.

Linked with cerebro-spinal meningitis we notice the rigid contraction of the muscles of the trunk, resulting in a curvature of the back. The head is also thrown backward and the muscles of the neck are more or less rigid. Fever and an eruption are also present.

After a "stroke" of paralysis, a state of rigidity and contracture of the paralyzed muscles often develops. It causes, as a rule, a state of permanent flexion in the upper limbs and extension of the lower. This post-paralytic contracture, if developed late, indicates a descending degeneration of those motor fibres of the spinal cord that have been cut off from their so-called "trophic centre" by the exciting lesion. It is always associated with a marked increase of the spinal reflexes; a point of great clinical importance. This condition is known as "tetanoid" or "spastic" paralysis. The peculiar gait of these subjects has been previously discussed.

In pseudo-hypertrophic paralysis the child first gives evidence of the commencement of the disease by a weakness of the legs and a clumsiness in walking which is exhibited by frequent stumbling and falls. Gradually the patient assumes a characteristic attitude and gait.

The attitude is very peculiar. In the standing posture the back is thrown beyond the proper position, so that a vertical line dropped from the shoulders frequently falls behind the sacrum; this antero-posterior curvature entirely disappears, however, when the patient is in the sitting posture. The feet are widely spread, and rest on a base of support. The heels are usually drawn upward by a contraction of the tendo Achilles. In the effort to preserve the balance the arms are held at the side with the hands extended, and the slightest touch may cause the patient to fall. Another remarkable feature of the disease is the difficulty which is experienced in rising from the recumbent, or even the sitting posture. The sufferer uses surrounding objects as a means of rising, drawing the body upward by the hands. When unable to reach such support he rests with his legs, which are taken to rise are thus described by Gowers: "If laid, for example, on his back upon the floor and told to rise, he would first with great difficulty turn on his face; he would next get on his knees, his head being almost between his thighs; free with position of his body he would gradually extend himself, so that he stands upon his feet and hands with all his limbs extended; finally he would extend the hip-joint by grasping the thigh with the hand and pushing up the body, as it were, by the arm." This movement of "climbing up the thighs," as it has been termed, is an indication of weakness in the muscles which straighten the knee and also those.
which extend the trunk upon the thigh—the extensors of the hip-joint.

The chief of these patients is associated with an oscillation of the body from side to side, or a waddling movement. The advance made at each step is very small, and a difficulty seems to be experienced in flexing the thigh upon the abdomen.

The muscles of the calf exhibit early a firmness and increase in size which is not proportionate to their motor force—as that is far below normal. Soon they become excessively developed, as do also those of the buttck; while the other muscles of the leg commonly grow smaller from atrophic changes.

The latisimus dorsi and the lower part of the pectorals major muscles exhibit marked wasting in a very large percentage of cases. In some instances all the striated muscular fibres of the body, including even the heart, may become affected.

In spinal meningitis of the acute form the patient lies with the legs and thighs flexed, and shows evidences of great suffering in the countenance. The muscles of the neck are attacked by spasms which draw the head backward. The patient dreads all movements, because they increase both the pain and the spasms of the muscles.

Children affected with acute myelitis are often delirious and have febrile symptoms. The paralyzed limbs lie motionless and the muscles are fascicled. Tremors and twitchings in the facial muscles and the tendons of the wrist are often observed, but they are the result of a rapid elevation of the temperature rather than a symptom of this special disease.

(Tob continued.)

A FRONTIER STUDY OF DIPHTHERIA.

BY T. J. HUTTON, M.D.,
PERUGO FALLA, MINN.
FORMERLY RESIDENT PHYSICIAN LONG ISLAND COLLEGE HOSPITAL, BRIGHAM HALL ASYLUM, AND BORN-BEAR ASYLUM.

Few boast when diphtheria is discussed. Both lay and professional refer to it with qualms of the solar plexus. Some of our best men have again been consulted on this subject, but have nothing new to offer; they are silent as to the cause; they give no statistics of results; they differ as to the indications; and they distinctly enumerate forty-three different remedies that might be of use in an ordinary case of diphtheria. Then, if these do not suffice, "symptomatics, roborants, stimulants, febrifuges, externally, internally, or hypodermically," may be drawn on. If there be irony in these facts it is not mine; and as to these men, we hold them in the highest esteem; they are among the ornaments of our profession. Then, too, a glance at the mortality lists tells how much we do not know about diphtheria—" the sepulchres make all the ground uneven.

Can nothing more be done? Yes, something can be done. While some must weep, others must watch, and give the result of their watching; and from such views and opinions, ever so conflicting, truth and progress must result. It may be slow—better slow than not at all. Considering how complex are the human organism and disease processes, it may not be wise or profitable to seek specifics for every malady; but it must be reasonable to hope to trace causes and test methods of treatment so far that this or that malady shall not prove an holocaust in every house, or hamlet, or community it visits; else of what use is the healing art? why should it not fitly fall into ridicule, since, when assistance is most needed, as in this malady, it can render little or none? There are communities in our States to-day in which diphtheria rages; but where, whether due to our real or supposed helplessness, medical aid is not invoked. It behoves us to gain this battle. . . . How long to me it seems till some one come!"

My experience with diphtheria has been limited, but very peculiar. It has given me a fixed opinion as to its cause, and a successful plan of treatment. To this theory and practice I shall therefore adhere until better advised. A brief statement of my views (including results) by provoking friendly discussion, may help on the good work. During my first ten years in practice I had not treated a single case, but within the past three years I have treated sixty-four patients afflicted with diphtheria. The singular, simple, easily analyzed conditions under which all these cases occurred, give to this report whatever it contains of value.

1. The sixty-four cases were included in seventeen rural outbreaks, confined to seventeen houses. Three of these outbreaks occurred in summer; fourteen in winter.

2. The county-seat (population 7,000, founded 1873) has never had an endemic, nor an epidemic of diphtheria.

3. All these outbreaks occurred in houses that were comparatively new.

4. None of these houses had ever been occupied by any other family.

5. They are in a belt of country—the new Northwest—where white men never lived before; hence, the soil was not saturated with sewage, and there was no accumulation of filth on the surface. One of these houses had been built and occupied but sixty days.

6. Diphtheria had never before occurred in this region; hence.

7. It was not an heirloom, and had it come by visitors or emigrants, it would in all probability have attacked the county-seat, the centre of travel and trade.

8. Each outbreak was far removed in time and place from all the others; one did not follow the other.

9. Every house attacked was small and greatly crowded.

11. It was of the malignant type; many families lost five and six members each.

Derived from this singular experience with it, and also from the plan of treatment early adopted, my creed concerning diphtheria is as follows:

1. Diphtheria is caused by ochescia or crowd-poison.

2. It is an emergency—an event or combination of circumstances which calls for immediate action or remedy.

3. It is at first a local disease, resembling the animal poisons—snake-bite, mad-dog bite. Properly treated in this stage it is one of the most curable of diseases.

5. This poison is not identical with that of measles, croup, or scarlet fever, nor is it intimately related to them.

6. Diphtheria may occur sporadically; any small, overcrowded, ill-ventilated house may prove a diphtheria factory.

7. Its period of incubation is from twelve hours to several days.

8. Soil and strata have no causative effect.

Crowding can occur in any temperature; practically it occurs most in cold weather.

10. In the local stage there is but one indication—to destroy the false membrane already formed; prevent further formation and spread. For this only two remedies are required as a rule.

11. In the stage of systemic infection there are two indications—the foregoing, and to support the system. A remedy or combination, internally, with food and stimulants, permits this indication.

12. An abundance of pure air is the first requisite in treatment.

13. Being an asthetic disorder, and prone to heart-
failure, rest in the recumbent position and warmth to the extremities assist in the cure.

14. The physician must not only prescribe, he must administer the local treatment, when present, and see to it that food and medicine are administered punctually in his absence.

15. The physician should visit severe cases three times a day; all cases at least once a day for the first nine days.

16. The physician should not despair, though called late. I have seen patients, apparently moribund, restored by fresh air and food alone. So have other observers.

Two desperate cases, in which, as a last resource, he had the children carried about in the open air all night and day, with their mouths open, and as much as possible facing the wind. Both patients recovered. The two remedies used in the local stage are lunar caustic and chlorate of potassa. Twenty grains of the former in one dram of water is applied thoroughly ever hour or two to the affected parts, and continued so long as there is formation of membrane, whether two days or seven. A saturated solution of the chlorate is used as a gargle every ten to fifteen minutes. One ounce and a half of potassa is ordered to eight ounces of water. The nasal passages are administered internally, if the patient be too young to gargle. I use none but Squibb’s. Common liquid food. This has been the sole treatment when called early.

With the second stage, or to forestall it, comes the second indication, to support the system, “the disease being of perhaps more lowering character than any other with which we are acquainted.” As a rule, three remedies meet this indication: Chlorate of potash, tincture of iron, and quinine. For adults these formulae are used:

**B.**
Tincture ferri chloride.................. 3 v.
Quin. sulph.......................... gr. xvj.

**S.**
A teaspoonful every two hours.

**B.**
Potass. chloral.......................... 3 iv.
Aq. dest.................................. 2 iv.

**S.**
A teaspoonful every two hours.

These are administered alternate hours, night and day, if patient be awake.

Five remedies—lunar caustic, chlorate of potassa, tincture of iron, quinine, and carbolic acid—meet both indications fully as a rule. In all cases carbolic acid is used as a disinfectant, and in nasal cases it is used in the form of nebuliser or in glycerine, or in one per cent. aqueous solution.

In the septic stage the diphtheria patient can hardly be overfed or over-stimulated. Many die for want of food and stimulants to tide them over, the popular notion being that sick people do not require food, especially those who manifest febrile action. Two quarts of milk, each pint holding a fresh egg in solution, one cupful of home-made beef-essence, properly seasoned, a pint of pure port wine, or half that quantity of pure brandy, form a fair skeleton of one day’s rations for an adult. Food and stimulants are administered every hour.

**Results.**—Of forty-one patients thus treated from the early stage throughout, ranging in age from ten months to twenty-four years, not one death occurred. There was but one patient of the nursing age. Of twenty-three first seen after septic infection had taken place with various degrees of intensity, four died, three within twenty-four hours after my first visit, the fourth within thirty hours. I have already cited evidence that these outbreaks were malignant, and have already stated that a form of disease seemed moribund when I first saw them.

The only original point in the treatment is the continuous local use of lunar caustic until membrane ceases to form. It is original so far as my knowledge extends. The great benefit resulted from a single application had been recorded by many observers, Sir William Jenner among the number.

Besides the point in treatment just mentioned, there are other articles of my creed that will appear new. It is not my desire to bolster them up with strained arguments, but it is no less than a duty to state why I adopted them. If they will not stand in their own strength, down they go. I am in search of facts; not to pervert truth. The first article shall be considered last, as it is the chief, and requires lengthier statement; to it nearly all others converge.

9. Diphtheria may occur at any temperature, but occurs mostly in cold weather. Three outbreaks in warm months; fourteen in cold months. Of the three summer outbreaks these are the facts: The three houses are eight and sixteen miles apart, and the attacks occurred in different seasons. The people of each are unknown to each other. Two of the three were sixteen miles apart, and in different seasons were suddenly changed into boarding-houses, the one of twenty men, the other of thirty men and women. In the third family, in less than two weeks after the great crowding (for the houses were small log-houses in the country, which could not comfortably accommodate more than three souls) diphtheria broke out violently, removing five members of one family and three of the other. In the third instance a family of ten persons, consisting of parents and eight children, one of seven years and others of fifteen and younger, having a frame out-house attached, just large enough to hold the cook-stove. In less than two weeks five of these children had died of diphtheria, and my first conquest over this malady was achieved in saving the other three, who were very low when I was called. The county commissioners rewarded me very liberally for this work, for this house was situated on the poor-house farm. For the purposes of this report I asked Mr. Sheldon, the keeper of the poor-house farm, to take the measurement of this house for me only last week. He reported that a prairie fire had consumed the log-hut, but that the exact outside measurement of the foundation was thirteen by sixteen feet. Subtracting fifteen inches for the unhewn logs, and the foundations are so placed and three feet wide by fourteen and three-fourths feet in length; ceiling in proportion, about six and a half feet in height, the sole eating-room, sleeping-room, sitting-room, home of ten souls!

I simply state facts which can be proved by one hundred credible witnesses. There was no diphtheria in this county when the first, second, and third of these outbreaks occurred. Does it not seem that the poison which caused the disease must have been generated in each of these homes? And do not the facts in these three instances point—call it ever so slightly—to ochleisism, or crowd-poison, as the cause of diphtheria?

Then, again, from many outbreaks that occurred in cold weather other facts are gleaned. It can be proved by the Signal Office reports from this district that many of these outbreaks occurred when the temperature had averaged thirty and forty degrees below zero (Far.) for many days previous to the outbreaks. This would have been death to all ordinary surface germs; but it has already been shown that in those cases (one house only sixty days erected) there could have been no saturation of soil with sewage or accumulation of surface filth—pretty city theories. More than this, I attended an outbreak on the night of January 17, 1883, at a temperature of sixty degrees below zero (Fahr.), when the surface of the earth and all of bodies of water were frozen solid as a rock; at least three feet in depth. This was at the house of Peter R—, Dane Prairie, Ottertail County, Minn. The cold ride was rewarded, the young woman recovered; but this man lost three children from this disease soon.
after, treated by another, because he considered fifteen dollars too much for his twenty-mile midnight ride, at sixty below zero. What sewage vapors, supposing them there, would emanate from a soil thus frozen at this temperature, and covered with snow too? I have asked this question of many of our best engineers, apropos of this report, and they replied, "Don't ask a mule that question—it is absurd—no foul gases could escape from the soil at that temperature." The same must be said of surface filth, if it were there.

So, then, soil and strata, as causative agents, are ruled out at least in this case. "Why had it not occurred in this house before? The house had been erected some years ago. I cannot say, but will state some facts. To my own knowledge this was the coldest night in five winters, causing the inmates to huddle closely together in the one living room. The family proper had been increased by one every year, and then there was the district schoolmaster and a young lady visitor—nine at home—in the one small living room.

7. If two cases can prove anything, here are two which prove that the period of incubation need not be more than twelve hours. Both are exactly alike. (1.) A very intelligent young man drove into the country from the county-seat (which had had no diptheria), on Sunday afternoon, and remained in the family of an old friend of his father, unknown to him, had another visitor—diptheria. He remained all night, however, and early next morning he returned to town stricken with it. (2.) The other young man, a duff-headed new-comer, likewise on Sunday afternoon, visited a friend's house, three miles from town.

Two years before, the only child there, a daughter, aged ten, had diptheria. Next morning this visitor was down with diptheria so that he could not return to town. He had lived some months prior in town. During this time there had been no diptheria in town.

6. Needs no discussion; each of seventeen outbreaks seemed to prove it.

5. Of sixty-four cases here reported no single instance was noted as having been diseased with croup, measles, or scarlet fever. If this virus were identical with theirs, they must have appeared; if intimately related, they would have been likely to have appeared. Conversely, five years ago an epidemic of scarlet fever visited this place, but no diptheria with it, and four years ago an epidemic of measles, but no diptheria with it. In five years' practice here I have seen none of these cases, and it bears down the old croup. Their occasional co-existence proves nothing. The malarial and typhoid miasms often commingle, and the diptheritic symptoms are usually observed in the later stages of these diseases (measles and scarlet fever) when the popular dread of the disease striking in has caused all fresh air to be shut out, and throats are tender.

4. (1.) The case just cited of a young man (7. No. 2.) who left town Sunday afternoon for a visit to a house in the country which had had diptheria two years before, and was taken down with it there early next morning, seems to prove that the virus may live two years. He had lived in the town some months. The town records show there had been no diptheria then. (2.) A family living in the country was visited by diptheria, causing the death of three children. Meantime one child, a boy of seven, was absent on a visit. The house was disinfected and three months had elapsed; then the family physician gave permission to the absent child to return. Within two weeks after his return he was buried—with diptheria. (For this record I am indebted to a very intelligent physician from the southern part of the State. It did not occur in my own practice.)

3. Many careful observers regard it local at first. Watson called it "a severe inflammatory disorder of the throat." Ellis says, "the primary seat of the disease may be the mucous membrane of the tonsils, palate, uvula, or nares." West: "Although the soft palate and tonsils are the parts on which the deposit is first observable, it often does not remain limited to those situations." Sir William Jenner, regarding it primarily local, advised one application of lemon caustic. Many others, whose names I cannot now recall, regard it local at first, and the closely, candidly observed facts prove it. In my sixty-four cases even the untaught parents so regarded it. If there are cases in which the membrane is first deposited in the stomach, bowels, or anus, as some assert, it must be very exceptional and does not annul the law that the "tonsils, palate, uvula or nares" are the primary seat. For one patient was restored by local treatment alone. How could this be if the cause, the virus, the disease, were not then local?

That it is an animal poison is rendered probable by the fact that in the early stage the types of these are subdued by the same identical remedy, nitrate of silver. I have treated dissection wounds and mad-dog bite successfully with this sole remedy, and snake-bite is so treated. It is standard treatment, "but it is imperative that it should be adopted at the moment of receiving the bite." 7

2. All the facts—the ease with which it yields to early treatment, the great difficulty experienced in subduing it later on—prove it an emergency "which calls for immediate action or remedy." I find that the people apprehend the more readily the profession that the disease is of local origin, that it is at first a local disease, and that it must be treated "right off."

1. That it is caused by crowd-poison, and by this I do not mean "a morbid condition induced by the crowding together of sick persons under one roof," as Gunston defines it, but by the crowding of too many well persons under the same roof and in the same room.

The following are the special facts which lead me to think that overcrowding was the great pathogenic agent:

1. Excessive overcrowding was manifest in every house attacked.

2. Excessive overcrowding was the only unsanitary condition present. Promises new. No filth, no sewage.

3. None of those attacked had been exposed—the disease did not previously exist in the locality.

4. There were no paludal causes. If there were, the extreme cold (forty to sixty degrees below zero) would have rendered them inoperative.

5. Three outbreaks in summer, fourteen in winter (practically 100 per cent. another case but nothing was here). They occurred mostly in winter, because there is more crowding in winter. All hands are in-doors.

6. Was the virus borne in the air from Orion or the Pleiades, or even from the moon or the Alphey mountains, and dropped quietly into one house out of a pretty well settled county, forty-two by fifty-four square miles in dimensions? This, though the generally received theory—a mysterious something coming somehow, from somewhere afar off—is absurd; and both this and the fact that, strain my mind as I may, I can conjure up no other reasonable cause to which to attribute it under the simple conditions described, counts another argum... in favor of ochleus.

But why go to Calcutta to find Black Holes that kill, when they exist all around us? Why invoke nebular and antipodean causes, when the real cause may lie at our feet? Peter Parley tells us of an ancient philosopher who was much given to star-gazing. Once, while indulging in his favorite pastime, he fell into a mud-puddle, and then swore off. I fear that, like this sage, we have been going away too high to find the essential facts of diptheria. We do not apply the knowledge we have. We forget that while the exceptional man, the rara avis, deserves the pretty climax of compliments paid him by William of Avon, the average man ranks not so high, and the lower man approximates more closely to the brute.

1 West, p. 335.  
3 Edition of 1806.
and serpent—he swallows in his own filth, or fans himself to death with his own venom. Said Mr. Beecher—who is a good physiologist—in passing through this region a few months ago: "In this pure air I should think few physicians would be needed." I replied, "The air here is as pure as any on this continent, but don't you know that a man is a veritable hawk—that living as well as dead, he breeds putrescence." "Yes," he replied, "I know that man is the most poisonous animal in the world."

Since the above was written I have treated five more cases. All recovered. A child, four years of age, and his mother, aged twenty-four, had it in one house. In the same instance the family consisted of seven children, aged from eighteen months to fourteen years, the parents, and a hired man. On my arrival three of these children were dead, and the fourth—the youngest—lay dying. I reached the house toward midnight, and this child died soon after daylight. The remaining three lay prostrated with the same genuine, malignant diphtheria. I sprinkled the room thoroughly every hour during the night with a solution of carbolic acid, and ordered the walls and ceiling to be whitewashed next day, and the floors scrubbed with a solution of carbolic acid, and that it must also be added to the whitewash. This, with my usual treatment, resulted in the rapid recovery of these three. I almost forgot to state that first of all I made provision for entrance of air.

SCARLATINAL ANGINA FOLLOWING EXPOSURE TO A CASE OF EQUINE SCARLATINA.

By J. W. STICKLER, M.D.,

Thomson & Co.

In the early part of February 1884, I was informed by Dr. Fenner (D. V.S.) that he had a case of equine scarlatina. I immediately went to see it. The horse was twelve years old; there was considerable swelling of the nose, sheath, and extremities; the latter showed a uniform oedematous enlargement; sheath somewhat sensitive to pressure; submaxillary glands enlarged and sensitive; throat inflamed and painful; thin watery discharge from nostrils; eyes suffused; mucous membrane of nostrils showed a bright red eruption; the spots were about as large as a pin's head; pressure caused them to partly disappear; I collected some of the nasal discharge and examined it microscopically. It contained, besides flat nucleated epithelial cells and extraneous matter, numerous small spherical bodies which were very active. When Dr. Fenner was called to see the horse he gave him a bolus; but in his effort to push his hand far back into the throat, he abraded the skin of his forearm on one of the animal's teeth. In a few hours a slight inflammation began, followed by the formation of a pustule with a red areola. About the seventh day after receiving the abrasion and exposure to the breath of the horse, the doctor experienced chilliness, loss of appetite, headache, and nausea. In a few hours his temperature began to rise, and his throat became sore and painful. Pulse 120 (February 20th). His tongue was somewhat furred at first; later, glazed, red, and its papillae very prominent, so as to give it a typical strawberry appearance. There was sufficient exhaustion to make it necessary for him to remain in his bed several days, the time of confinement in his room being about fourteen days. His urine was examined, but no albumen found in it. There was no desquamation of the cuticle. There developed upon the right side of his thorax "herpes zoster" about one week prior to his visit to the horse, other than this there was no eruption developed. The disease was, and still is, of the opinion that he was dealing with a case of scarlatinal angina, due to exposure to the breath of the horse, or to inoculation with the virus from its mouth. The diagnosis "scarlatinal angina" was made because of the characteristic appearance of the tongue and throat, in connection with the constitutional disturbance, which was more severe than generally obtained in simple sore-throat. Dr. Fenner had not been exposed to any case of human scarlet fever, so far as he knows, so that it is only fair to assume that he contracted his sickness from the horse. This case is interesting because it is one of the many noted in the literature that has been recorded in recent medical literature. It is, moreover, in perfect agreement with Dr. Copland's statement, made in his "Medical Dictionary," to the effect that scarlatina has been communicated from horses to man.

That horses have scarlet fever I think there is no reasonable doubt. If the literature upon the subject (as condensed by Dr. J. C. Peters) be consulted, there will be found much to support a belief in its existence, and but little that is unfavorable to such belief. I have succeeded in reproducing it in a mild form in two colts, and if it is communicable from man to the horse, why should it not be again transferred from the horse to human beings?

Whatever may be said for or against this theory, one above is a true record of what actually resulted from exposure to a horse having the symptoms regarded by many veterinarians as characteristic of scarlet fever.

Progress of Medical Science.

THE HEART IN PNEUMONIA.—Dr. De Giovanni finds that, as a general rule (Annali Univ. di Mod.) the heart in pneumonia is increased in volume. But this increase varies in different cases in extent, time, and mode of origin. The nervous system is an important factor, although not the only one, in the variations of the cardiac area. By hastening or retarding the movements of the heart, it influences the general circulation; and by action in direct opposition or contraction of the general it affects the local circulation, and also influences the temperature of the body by now checking and now encouraging the radiation of heat. The author combats the opinion that the fever follows faithfully in its oscillations the morbid process. Elevation of temperature does not invariably correspond to a new extension of the inflammation. The variations of the cardiac area often coincide with modifications of the nervous system and with fall of temperature; nervous depression, often with general prostration and profuse sweating, favors dilatation of the heart. In the thirty cases of pneumonia examined by the author, increase of the cardiac area was found in all. The heart may be dilated, and in some, particularly in those suffering oscillation in temperature, the dilatation is the cause of the attack. In the majority of cases the cardiac area is increased by dilatation of the right heart, but there is sometimes a general dilatation. Although the embarrassment to the circulation in the lung may be very great, the right heart does not always dilate in proportion to the obstruction to the pulmonary circulation, but may remain almost in the normal state; and from this it is seen that it is not the increase of the intracardiac pressure only which causes the dilatation. In each case the share which the embarrassment of the circulation, the general and the local nervous function, and the original cardiac organization, take in its production, must be determined by exact study of the dilatation. The liver is also generally enlarged, and its increase may precede or follow that of the heart. The author insists on the great practical utility of these researches. If the cardiac dulness increase, there being no great embarrassment to the circulation in the lung, the resistance of the heart is not of the best, either from original want of activity in the left ventricle, or from affection of the wall, or from gastro-hepatic complication. From the knowledge of the cardiac dilatation, one can foretell that the patient is not going to do well, even if the other symptoms do not show it, and can draw valuable conclusions as to treatment according to the factors producing the dilatation.
THE MEDICAL RECORD.

New York, March 29, 1884.

ANTISEPTIC FIELD-SURGERY.

In how far the principles of Listerianism may be available on the battlefield, has been shown by the results obtained by Reyher and Bergmann in the Russo-Turkish war, and by the English surgeons in Egypt. Reyher gave instructions that no wounds were to be examined at the front, either with fingers or instruments, except in cases of injury to blood-vessels and when the walls of a cavity were wounded. His instructions may be summed up thus: "Oclude the wound provisionally, lay the wounded part in a suitable position on the litter, and render it provisionally immovable."

The dictum of Nussbaum—"The fate of the wounded man lies in the hands of the surgeon who first attends him"—has been repeatedly proven to be true, and the statistics of Reyher and Bergmann show what antisepsis can do, even amid the difficulties attending the surgeon on the battlefield. Reyher had 81 cases of gunshot wounds of the knee; of these 18 were treated antiseptically throughout, 15 recovering. Forty cases had been treated non-antiseptically before he saw them; 34 died, and of the 6 who recovered 5 lost their limbs. The remaining 23 cases were treated altogether without antiseptic precautions, and 22 died. Bergmann had 15 cases of compound fracture of the knee-joint. They were treated antiseptically, 14 recovering, and 2 losing their limbs.

At a late meeting of the Woolwich Military Medical Society, an account of which may be found in the British Medical Journal of February 23d, Surgeon-Major Godwin read a paper on this subject, which was ably discussed by several prominent surgeons. Sir James Arthur Hanbury, in the course of his remarks, stated the problem in this manner: What is the best line of action toward the wounded, between the fighting line and the field-hospital, in order to secure satisfactory results from the very outset? This is undoubtedly the question which must be correctly answered in order to arrive at the best results; and he well says that "the most important duty will be the selection of sitting places for immediate treatment (dressing-places), and in a future war surgeons must be selected for this task, as upon their judgment will depend the lives of many men." But there are other requirements which must be complied with before this. That the surgeon at the dressing-place should carry all the materials for antiseptic dressings is almost impossible. That each soldier should carry with him the necessary materials for dressing his wounds is both possible and feasible. As to the materials which the soldier should carry, many valuable suggestions have been made. Surgeon-Major Godwin states a broad truth when he says that it does not matter very much what preparation is used, so long as it is light, dry, antiseptic, and therefore absorbent, as salicylated lint or cotton, boric lint or cotton, or absorbent cotton, or, better still, cotton-wool. In place of Esmachine's tampons (in his field-dressing) he suggests a fold of cotton-wool, because, in case of a lance or sabre wound, the tampon cannot be used. Dr. W. F. Stevenson's suggestion of salicylated spongio-pilina or salicylic wool is exceedingly valuable, and easily prepared. This dressing is divisible into pieces of about four inches square, each piece containing ten grains of salicylic acid, antiseptic wax (containing eucalyptus, or carbolic or boracic acid) being plastered over the surface. This wax cleanses the surroundings of the wound, and renders it perfectly aseptic. This packet also contains antiseptic bandages, light and easily adjusted, for binding on the dressing.

Sir Joseph Lister advocates the use of iodoform for the first dressing. In the form of iodoform-wool it is most excellent antiseptic dressing, and possesses the advantages of being very little soluble in water, or in wound-discharges, so that a small quantity lasts a long time; besides, it is almost entirely free from irritating properties. With this combination of advantages there can scarcely be a better first dressing than dusting the wound over with iodoform powder, and then covering it with some absorbent substance. Iodoform forms one of the ingredients of the portable dressing recommended by Lesser, of Leipsic, which was highly praised by Sir Joseph. This consists of two parts of boracic acid and one of iodoform powder. It would be better, however, to use the iodoform powder pure, because the antiseptic should be carried in small bulk, and boracic acid is far less effective than iodoform. Lesser recommends that the soldier should have a cartridge filled with this powder; around this is a bandage four yards long, similar to those proposed by Dr. Stevenson, somewhat like antiseptic gaze, or made of open cotton texture impregnated with spermaceti; around this again is a piece of absorbent cotton, the whole enveloped in a three-cornered handkerchief, which can serve so many purposes.

Whatever the packet carried by the soldier may consist of, it should be sewed on to his coat. The haversack is a bad place for it, because it is often lost; and his pockets, should he have more than one, are too much taken up by tobacco and other articles for his immediate personal comfort. Surgeon Longmore states that the soldiers in Egypt were instructed to carry the field-dressing in the left-hand trousers' pocket; but on examination many of them were found to have no left-hand pocket in the trousers, there was only one pocket, and that on the right side.

After the first dressing on the field, and when carried to the field hospitals, the soldier is in a position to have more careful attention paid to him. Surgeon Marston thus describes the field-hospital dressing on the day of the battle of Tel-el-Kebir: 'The wounded part was first washed with a 1 in 20 solution of carbolic acid, and then dusted lightly with iodoform. A piece of protective was
then dipped in the carbolic solution, and placed upon the
wound, then two or three layers of boracic lint, and
above that the gauze bandage. This dressing answered
perfectly well. As regards the spray, we need only say
that even Professor Lister stated that he thought it en-
tirely unessential and out of place in the field-hospital,
as indeed it is in almost every other place. Corrosive
sublimate he regards as the most valuable antiseptic for
the hospital, and states that while not soluble in less than
sixteen parts of cold water, it is soluble in one and a half
times its weight of cold glycerine, a very important point,
for by first making a solution of it in glycerine, a little of
this may be poured into water, and the solution is ready.
For a ready dressing, old sheathing or other rags may be
torn up and soaked in a solution of equal parts of glyce-
rine and sublimate, and two hundred parts of water. They
are then hung up to dry, after which they are ready for
use.

On only one point do we take issue with Professor
Lister. He states that if a sponge be purified with a 2
to 1,000 solution of sublimate, it will remain pure, whether
kept for a week or a year. The experience of many
surgeons has already shown that this is not always true.

THE MEDICAL SERVICE ON TRANSATLANTIC
STEAMERS.

We are pleased to notice that our leading editorial of Janu-
ary 26th, calling attention to the present defective medical
service on transatlantic steamers and the grave public dan-
ger resulting therefrom, is arousing attention in outside
circles, and may soon lead to satisfactory results. The
New York Tribune, ever foremost in the good work of
reform, has taken the matter in hand, and seems deter-
mined to test the accuracy of our statements.

The Tribune of Tuesday, the 18th inst., reports a long
and searching interview with Dr. J. A. Irwin, who has been
the leader of the recent agitation on this subject in
England; the issue of the following Thursday contains a
series of sweeping contradictions by the principal steam-
ship agents in this city, and that of Tuesday last Dr. Ir-
win's reply.

If, as is unquestionable, the efficiency of this service is
a matter of first importance not only to those who travel
by sea, but also to the American people at large, since it
should constitute our strongest barrier against the
importation of infectious disease, no pains should be spared
to ascertain the truth of these conflicting statements, and
if even one-half of the charges advanced can be substi-
tuated, a thorough and radical reform should be enforced
by Act of Congress.

When confronted by a Tribune reporter with the state-
ment of Dr. Irwin that, "of one hundred and forty-one
surgeons who, during the first six months of 1882, had
medical charge of English steamers, carrying passengers
to America, sixty would have been ineligible through
lack of professional qualification for any medical appoint-
ment in the English army, navy, prison, asylum, or poor-
law services," the agent of the White Star Line is re-
ported to have said: "That is absolutely false, and if
you want to use my name you can do so." The doctor
replies that his statement, published in all the leading
English papers and never before contradicted, is founded
upon an official Parliamentary return, issued by the
English Board of Trade in compliance with an order of
the House of Commons, and giving the name, age, and
qualifications of every surgeon employed on these steam-
ers during the period named. He adds, that his state-
ment was reiterated by Sir Lyon Playfair, M.P. (Chair-
man of Committees in the House of Commons) on the
occasion of a deputation to the President of the Board of
Trade inaugurated by the British Medical Association.

The significance of this return, taken in conjunction
with a common neglect of sanitary precautions and the
insufficient means of combating disease on board these
steamers, lies in the fact that there exists a high mortality
among passengers to this country—a mortality which is
declared by those well qualified to judge to be far in
excess of the necessities of transit. The steamship
agents deny this. They say, "There is very little need
of medical attention on shipboard;" "There is very
little sickness on the sea;" and in one instance, "It is
all humbug;" but the facts are unmistakably against them,
and by the facts the case must be judged. Official sta-
tistics, collected at Washington and published by Dr. T.
J. Turner, prove that the mortality upon European
steamers carrying passengers to this port during the ten
years ending December, 1880, was at the rate of 44.6 per
1,000 per annum, while on fifteen particular steamers
during 1880 it was as high as 70.6 per 1,000 per annum.

And, as Dr. Irwin somewhat pertinently points out, an-
other Parliamentary return, issued last year, shows, that
upon the two lines (the Anchor and Guion) whose represen-
tatives are loudest in their denial of sickness occurring
on board there was, during the period dealt with, a larger
proportion of deaths to those carried across than on any
of the other regular English lines.

The steamship agents are in this quandary: they must
either disprove official returns, both American and Eng-
lish, defend a service whose inefficiency results in serious
loss of life, or honestly admit the necessity of reform.
But the controversy cannot end here. The interest of
the public forbids it, and we cordially encourage our
public-spirited contemporary to continue his investigation,
promising him the sympathy and support of the medical
profession.

TEACHING THE PHYSIOLOGY OF NARCOTICS AND
STIMULANTS IN THE PUBLIC SCHOOLS.

Under the stimulus of temperance agitation there have
been introduced into the Legislatures of several States
bills making it obligatory to teach in the schools the
physiology and hygiene, with especial reference to the
effects, of alcohol and tobacco.

There can certainly be no objection to such a measure
if it is carried out sensibly, and not along the lines laid
down by fanatics. It will do no good to teach children that
tobacco is a deadly poison to the human system when
they all the time see their paternal parents thronging upon
and enjoying it. Nor would it be right to instruct chil-
dren to the effect that alcohol is uncompromisingly and
uniformly harmful, for they may grow up and find they
have been deceived. Let children be taught the hygiene
which medical science indorses, not that of the apostles
of teetotalism and of anti-tobacco societies.
MEDICINE IN TEXAS.

Under the stimulating influences of medical journalism, as represented by the enterprising Courier-Record, medical affairs in Texas are beginning to have a more promising outlook. The profession has heretofore been in a somewhat disorganized condition. The State Society has existed de jure for fifteen years, but it has never yet accomplished very much, either in uniting the profession or promoting medical science. At the next meeting, however, which occurs on April 22d, at Belton, as we are informed, a change will be initiated. Extra efforts are making to secure a large representation and to make the Society take some step in organizing a State Board of Health and in securing a law to regulate the practice of medicine. The question of starting a medical college is also being actively discussed, and the meeting of the State Society will furnish an opportunity for initiating some definite action thereupon.

That Texas needs the purifying influence of a State Board of Health and active medical organizations there is no doubt. The Courier-Record furnishes an interesting illustration of the fact in a letter written by a Texas "doctor," living in one of the new counties, to a "chum" in another State. This remarkable document reads as follows:

"I found to my relief, when I arrived here, that there is nobody to interfere with my business, and that it is all a mistake about you being examined. They ain't no board of health in this State, and nobody asks no questions. The only thing, office rent is high, and has to be paid up in advance, as everything else. I got into practice without difficulty; sent for right off to a respectable lady with womb complaint, and got a good paying case; also some other cases the first week I was settled. The doctors are inclined to be oafish and unsociable, but the people is friendly enough; it is because they don't want anybody to come in competition. You can come along without being afraid of any examining board or license."

The letter shows, in an amusing and striking way, not only the state of medicine in Texas, but the feeling that is gradually being developed among quacks and irregulars by the creation of Health Boards and licensing bodies. We trust that Texas will soon cease to be a place from which a "medical man" can write that "there ain't no board of health."

MEDICINE IN VIENNA.

"Medicine in Vienna during the Last Hundred Years," is the title of a work by Dr. Theodor Puschmann, Professor of Medical History at the University of Vienna. As its name implies, this is principally an account of medical progress at the Austrian capital during the last century. But before introducing us to those personages who have rendered themselves illustrious of late years at the University of Vienna, our author gives a graphic sketch of the early struggles incident to the permanent establishment of that medical faculty which to-day sheds its light abroad to even the remotest haunts of the disciples of Asklepius. How uncertain, how infirm, how grotesquely unpromising were these first beginnings!

In 1744 Maria Theresa requiring a physician, sent to Leyden for the gifted Van Swieten, who, after much preliminary persuasion, was induced to come to Vienna. Van Swieten, who was not only a scholar, but a man of action as well, succeeded in inaugurating a series of preliminary reforms in medical and surgical matters. That such reformation was necessary is abundantly evident when we read that some time previous to Van Swieten's advent (1718), the regular professors of medicine and surgery received but from one hundred and ten to one hundred and seventy florins yearly! These are certainly statistics well calculated to make even the most enthusiastic disciple of the healing art tremble.

The activity of Van Swieten in the cause of medical reform seems incredible; and although he was unable to execute all the projects which he contemplated, enough was accomplished to entitle him to the position not only of a reorganizer but of a rector of the Vienna Medical School.

The impulse which Van Swieten had given to medical study expressed itself almost immediately in increased literary activity—a movement, by the way, which not only made itself felt among the faculty of the university, but was manifest also among the large body of practising physicians.

It was reserved for the physician Anton Stoeck to profit by the fruits borne by the reforms inaugurated by Van Swieten.

Stoeck inaugurated a series of investigations on animals as to the specific effects of certain drugs. Among others he sought to elucidate the pharmaco-dynamic importance of Hyoscyamus niger L., of Datura Stramonium and Pulsetilla nigricans L.

The great fault of Stoeck's investigations is, however, his inability to separate collateral phenomena from those obtained through the agency of the specific principle resident in the drug itself. It is, however, in that portion of the work which deals with the recent history of the medical faculty that the most interesting matter will be found.

Rokitansky, Meynert, and Billroth constitute a potent spell in themselves. Of the latter it may truly be said that he has long occupied the position of dictator in matters of general surgery. Nor is this fame of the great surgeon founded alone upon his own individual achievements; but, on the contrary, a brilliant constellation of disciples will serve to bear witness to the genius of the teacher, when the master is no more. Czerny, of Heidelberg, Menzel, Steiner, and Von Winifred, of Lüttich, are among those whose fame is more or less the outgrowth of their professional connection with Billroth. In our own land, where science may truly be said to bear a cosmopolitan stamp, the name of Billroth has long been famous. Many of us have had the opportunity of witnessing his wonderful address in the amphitheatre; and his courtesy and respect toward Americans will not soon be forgotten.

Dr. Puschmann has certainly given us the best history of medicine in Vienna which has ever appeared, and his book will be found most interesting, particularly to that large class of American physicians who are well acquainted with the medical institutions of Central Europe.
THE MEDICAL RECORD.

THE LAYITY AND FREE DISPENSARIES.

We are always glad to publish such a letter as may be found in our last issue, on the "Advice Gratefully," etc., and especially when, as in that instance, it comes from a layman, for it has not been until lately that the laity have duly appreciated the nature and extent of the injury they do in countenancing or aiding the army of free dispensaries that are saddled upon this and other cities.

Fortunately they have been waking up slowly to the fact that indiscriminate charity is one of the most serious obstacles in the way of those who have the welfare of the poor at heart. Indeed, such pseudo-charity in the end entails much mischief, not only encouraging improper persons to seek for aid, but discouraging the really deserving, who see the ease with which frauds may be successfully practised, and therefore lose the incentive to make an honest effort toward self-support. "Help the poor to help themselves" is a principle that should underlie all others in the administration of public and private charities.

For such seasons as these we are sorry not to have a good word to say in behalf of a public appeal for the University Medical College Dispensary, in which, by the way, laymen appear to hold the most prominent positions, though well-known medical men are also associated with them. We read in the circular that "the managers beg leave to state, in thus appealing to the charitably disposed, that no pains will be spared in providing suitable medical and surgical aid to the deserving poor of our great city." This is doubtless true, and well stated; but it may strike the reader as somewhat odd, at this particular epoch in the crusade against indiscriminate charity, that not a word is said as to whether the dispensary authorities refuse advice and medicine to improper persons. Possibly there was an unintentional oversight or omission in the case, and we therefore call attention to it, since it is but just to several of our worthy institutions that the public should know such a surveillance is exercised, and improper persons are rejected, while small charges are made for medicine, sufficient to defray its actual cost. But it is also difficult to realize that such an institution has any claims upon the profession or the public in its particular situation, where there are a number of excellent dispensaries, capable of caring for all who may attend them; while one in particular, only across the street—the Out-door Department of Bellevue Hospital—is not only well equipped, but, unfortunately for the public good, dispenses its good offices without any adequate discrimination and gratis. Bad there as this abuse is, will it not be still further increased by this new institution, struggling to get upon its feet? Can it be possible that the dispensary is only charitable to the extent that it helps to sustain a college that must be supplied with patients at any cost for its clinics? Let such institutions, if this be the case, not expect too much of the profession or the public until they can establish their claims to be custodians of charitable gifts by offering certain guarantees that the worthy only shall be admitted to the benefits of their trust.

There is no difficulty in such a plan. All cases that apply can be investigated without great difficulty, and this is especially easy if the society in question co-operates with the Charity Organization Society. This plan has been inaugurated by one of the leading dispensaries in this city, and has been found to work satisfactorily to the patients, while outside physicians can have no just ground of complaint, as each dispensary physician is directed not to secure as a patient any one who can pay an ordinary fee.

News of the Week.

REPORT ON CHOLERA EPIDEMIC IN EGYPT.—The report of Surgeon-General Hunter to Earl Granville, on the cholera epidemic in Egypt, has been received. It is observed that he takes strong ground against the idea of its importation from India, opposes the contagiousness of the disease and the germ theory, and ridicules the sanitary cordons against cholera as practised in that country, declaring their utter inefficiency as fully demonstrated. He thinks the disease originated in Damietta, and is the result of the unsanitary condition of the Delta of the Nile.

YELLOW FEVER AT RIO is on the increase, eight-three cases having occurred during the three weeks ending February 16, 1884, and the consul states that "the weather is extremely hot and showery, with signs of the yellow fever becoming epidemic."

DEATHS FROM CHOLERA IN CALCUTTA.—Ten deaths from cholera are reported to have occurred at Calcutta during the week ending January 26, 1884.

TOO LARGE A DOSE.—In the article by Dr. J. H. Arton, of Winnipeg, Manitoba, page 280, the dose of morphine should have been 1/2 of a grain instead of 4 as published. Although obviously a typographical error, it is proper to prevent any chances of misunderstanding by thus calling attention to the fact.

MEDICAL VIENNA.—At the meeting of the Royal Society of Physicians, February 29th, Dr. Kowalski exhibited a patient suffering from ulcerative laryngitis, incipient phthisis, and suppurative otitis media. Tubercle bacilli were found in the discharge from the ear. Professor Albert exhibited a healthy man who in the upper cervical region had a hoary excrescence which extended down the inner border of the sterno-mastoid. Professor Albert had recently seen a similar growth in a child. Professor Weinleichner had seen several such cases in children. Dr. Mayall reported three cases of colotomy. Two were cases of cancer of the rectum, one was a case of entero-stenosis from the pressure of a non-malignant tumor. The operations were successful. Dr. Weichselbaum read a very important communication, in which he stated that he had discovered tubercle bacilli in the blood of acute military tuberculosis. They were not numerous, and care had to be exercised in order to find them, yet they undoubtedly existed. The discovery furnishes a new criterion for diagnostiating the disease.

Dr. Zemann called attention to the fact that Dr. Paltanap had previously found the bacilli in the blood of cases of basilar meningitis. Baumgarten had also found bacilli in the blood of animals.

Dr. Kowalski reported some experiments in which he had caused tuberculosus in hens by feeding them with tuberculous matter.
THE MEDICAL RECORD. [March 29, 1884.

MEDICAL PARIS.—At the meeting of the Académie de Médecine, March 4th, M. Charpentier read a paper upon the value of sulphate of copper in obstetrical practice. This substance was, he said, an efficient antiseptic, and it had hemostatic and astringent properties. It was cheap, and not offensive in odor or dangerous. M. Charpentier used the one per cent. solution.

THE CENTRAL COLLEGE OF PHYSICIANS AND SURGEONS held its annual commencement on February 29th, graduating a class of twelve.

FIFTEEN HUNDRED NEW DOCTORS have so far been created this spring, with some fifty colleges yet to hear from.

THE DRUGGISTS' PROTECTIVE UNION.—We have received a letter from Mr. Justin Wohlfarth, of this city, in which he states that we have misconceived the object of the Druggists' Protective Union. This is, he says, simply to have patent medicines sold by druggists only and sold at full price. We gladly make this correction, but must confess that the objects of the Union have been greatly misconceived both by the public and by some of the druggists themselves. We have been told by prominent druggists that the Union intends to keep up the prices of proprietary mixtures as well as patent medicines. We feel no lack of sympathy for the druggists in their efforts at reform, but experience has demonstrated the futility of attempting by artificial methods to keep up prices or limit competition.

RECEPTION AT THE NEW YORK POST-GRADUATE SCHOOL.—The New York Post-Graduate School tendered a reception to the more prominent members of the medical profession of the city, on Friday evening, March 21st. There were about one hundred and fifty gentlemen present. The whole building was thrown open and the guests were shown the various facilities offered for special instruction, and for dispensary and hospital treatment. The dead-house, the histological and pathological laboratory, the orthopedic and photographing room, the anatomical, neurological, and laryngological rooms attracted especial attention. There were also a number of rooms handsomely fitted up for private patients. A supper was served in the amphitheatre. No formal speeches were made, but the College received many expressions of congratulation at its prosperity.

NITRIC ACID IN BOUGUS BUTTER.—The Committee on Public Health of the New York Assembly have made their report on the bogus-butter industry. They say: "The secret of rendering and preparing the lards and fats is beyond all question the use of nitric acid or other chemicals, which destroy the natural smell, render the article more insoluble and indigestible, and serve as an agent to prevent decomposition or putrefaction. But nitric acid is a poison. While not averring that oleomargarine is necessarily always unwholesome, the Committee believe that it is likely to be so, and to a large extent would necessarily be injurious if used by children or persons in delicate health, and is not in any sense, or can be, a wholesome substitute for pure and natural butter." They recommend the total prohibition of its manufacture as the only adequate remedy, and as the laws requiring its sale only under its real name have confessedly failed to have any effect, this seems to be the only way to put a stop to the evil.

"THE NEW CODE SENTIMENT is fast gaining ground in Georgia," so writes a correspondent from Macon.

NOT FOOT-AND-MOUTH DISEASE.—The veterinary surgeons who have made an investigation in and near Neosho Falls, Kan., now say that the foot-and-mouth disease does not exist there. They agree in the statement that the disease which prevails is not contagious, and one of them has come to the conclusion that it was caused by wild yre full of ergot, which the cattle had eaten. The Kansas Legislature has passed a bill accepting the provisions of any national law concerning such diseases which Congress may enact.

THE MARYLAND BOARD OF HEALTH.—The Governor of Maryland has expressed the opinion to the Legislature that the State Board of Health has not produced results worth the money expended on it, suggesting that it might as well be done away with.

WORKING OF THE MEDICAL REGISTRATION LAW IN PENNSYLVANIA.—In 1881 the medical profession of Pennsylvania secured the passage of a law compelling the registration of all medical practitioners. Last summer the Clearfield County Medical Society brought suit against a quack who had recently been discharged from the Western Penitentiary, and who had registered as having been in practice fourteen years. He was indicted on three counts: first, practising without a diploma; second, practising medicine and surgery without registration; third, making affidavit to a false statement. He was acquitted on the first two, but convicted on the last.

THE MEDICAL JURISPRUDENCE SOCIETY, of Philadelphia, is the name of a new organization here. Dr. S. D. Gross has been elected President, George W. Biddle, Esq., and Dr. John J. Reese, Vice-Presidents, Dr. Henry Leffmann, Secretary, and Hampton L. Carson, Esq., Treasurer. The Society now numbers about sixty members. It will hold stated meetings on the second Tuesday of each month.

A CAT AND A DOLL SPREADING DIPHTHERIA.—A good deal of prominence was given last fall, says the Sanitary Engineer, in the papers to the occurrence of diphteria in a family in Amsterdam, N. Y. Two children died at intervals of several months, and a third was taken sick. The Board of Health appointed a committee to investigate, which examined the house and its surroundings, and obtained a statement from the attending physician. They have recently made their report, finding that there were no bad conditions existing in or about the house sufficient to explain the appearance of the disease, and they conclude that it came from a cat which was fondled by the child which first fell ill. This cat was found at the time to have a swollen throat and to be suffering from a discharge from the mouth and nostrils. It died a few days afterward. Three days after the death of the cat the child fell sick with malignant diphtheria and died in about a week. During its illness it played with a doll which was afterward given to a younger child, as it was supposed to have been properly fumigated with sulphur-fumes. This child, shortly after being allowed to play
with the doll, also fell ill of diphtheria and died. The third child also played with the doll and fell ill, but recovered. The Board of Health, therefore, traces the reappearance of the disease in the family after the death of the first child to the doll.

THE DECLINE OF ANATOMICAL STUDY IN CALIFORNIA.

—A cheerful practice, says Life, is undermining the cemeteries of San Francisco. The price of cadavers having advanced steadily for four years, the medical colleges found a scarcity of good reliable subjects. The Professors therefore clubbed together and hired a venal sexton to make a midnight raid upon the graveyards lining San Francisco's favorite drive, and anticipate the day of reckoning for a small consideration. Things ran smoothly until last month, when an able-bodied savant was buried. A burst of thunder sound startled the citizens the following night; there was a patter of buttons and coffin-nails upon roofs far and wide, and the sexton's wife awoke next morning to find herself a widow. It seems that the savant, a doctor himself, had directed a quantity of dynamite and fulminating silver to be interred with him, and the unsuspecting caterer to the college was thus trapped. The simple ingenuity and effectiveness of the invention seems to have tickled the San Franciscans, and the cemeteries are now being 'honey, combed with torpedoes and blasting-powder, fuses and percussion-caps to such an extent that the science of anatomy is practically brought to an end.

THE MOVEMENT TO ASSIST DR. FORBES.—The friends of Dr. William S. Forbes, who was recently acquitted of a charge of complicity in grave-robbing, have already raised a considerable sum of money to reimburse him for the large amount spent in legal and other necessary expenses. The committee appeals to the profession to support, in a general manner, a movement so laudable as that of sustaining a professional brother against adverse circumstances. In its address to the profession the committee states that, independently of the personal annoyance and the professional damage sustained, Dr. Forbes was compelled to incur, in defending his character, expenses amounting to nearly four thousand dollars. As the suit was instituted while he was acting in the interest and service of a public institution, and of the profession in general, it seems unfair that he should be compelled to bear this burden alone. It is to be hoped that a very general subscription, of even small amounts, will testify to the feelings of the profession in this matter, as the wish is to show the empathic sympathy of Dr. Forbes' professional friends. Contributions may be sent to either Dr. D. Hayes Agnew, Dr. Richard J. Levis, or Dr. J. William White.

A NEW NATIONAL BOARD OF HEALTH.—Mr. Pettibone, M.C., has introduced into the House a bill entitled “A Bill to Protect the Public Health” (H. R. 5,603), of which the first section reads as follows: “That the Surgeon-General of the Army of the United States, the Surgeon-General of the United States Navy, and the Supervising Surgeon-General of the Marine Hospital Service shall hereafter constitute the United States Board of Health. Such Board shall have full power to make such regulations as may be necessary for the government of the quarantine service of the United States and the protection of the public health; and all the power and authority now provided by law for the control, management, and regulation of the public health of the United States shall be, and the same are hereby, vested in said United States Board of Health.” The bill further provides that the consular officers shall send in reports of matters affecting public health, that the Navy Medical Department shall institute needed sanitary investigations, and that the Marine Hospital Service shall have charge of the quarantine service.

A TRIBUTE TO TEMPERANCE AND PEDESTRIANISM.—Dr. Richardson and Dr. Norman Kerr, of London, are forming a committee with a view of raising one thousand pounds as a testimonial to Weston, the pedestrian, as a substantial recognition of the extraordinary pluck and endurance exhibited by him in his recent five thousand mile walk.

A CURIOUS CORRECTION.—Dr. Squibb, in his last Ephemeris, corrects in a straightforward and commendable manner his misstatement as to the attendance at the New York County Society. He publishes also a letter from the late President, Dr. Webster, in which the misstatement referred to is criticized in somewhat strong language. Having done his duty so far, Dr. Squibb turns about and preaches a curious homily upon the unutility of using “harsh and affronting language,” and upon the utility of politeness. What the Ephemeris says is true, but the occasion for saying it is a remarkable one. Dr. Squibb published an item, which he should not have published, not only because it was false (which he did not know), but because it was malicious. Dr. Squibb knew perfectly well that his item would be eagerly copied and quoted; he knew it would injure an old and honorable Society. When the President rebukes him with natural, though perhaps unnecessary vehemence, he turns and reads him a lecture upon good conduct. Dr. Squibb seems to think that when a man is struck he should continue to be suave and polite.

MEDICAL BERLIN.—At the meeting of the Berlin Medical Society, February 13th, Dr. G. Siegmund read the history of a case of chyluria in a man of forty-five. The filaria was not present in this case, and Siegmund did not believe in it as a cause of chyluria. The Society devoted its whole session to a discussion of the disease. Berlin medical circles are much pleased over the fact that Professor Frerichs has been raised to the order of nobility. This is the fourth physician who has received lately the honor, the others being von Langenbeck, Ranke, and Lauer.

At a meeting of the Therapeutical Society, March 4th, Dr. Miller read a paper on the “Fermentations in the Human Mouth and their Relation to Dental Caries.” He said that fermentations develop acids, acids attack the teeth, then micro-organisms finish the process. He gave the following table:

<table>
<thead>
<tr>
<th>Ferment</th>
<th>Quantity</th>
<th>Amount</th>
</tr>
</thead>
<tbody>
<tr>
<td>Corrosive sublimate</td>
<td>1 to 500,000</td>
<td>1 to 100,000</td>
</tr>
<tr>
<td>Permanganate of potas.</td>
<td>1 to 2,000</td>
<td>1 to 400</td>
</tr>
<tr>
<td>Carabolic acid</td>
<td>1 to 1,000</td>
<td>1 to 500</td>
</tr>
<tr>
<td>Salicylic acid</td>
<td>1 to 125</td>
<td>1 to 75</td>
</tr>
</tbody>
</table>
THE MEDICAL RECORD.

[March 29, 1884.]

THE SIMS MEMORIAL FUND.

To the Medical Profession and Others throughout the World:

The great achievements of Dr. J. Marion Sims call for some lasting testimonial than obituaries and eulogies. To him medical science is indebted for much brilliant and original work, especially in gynecological surgery. Those who have been benefited by his teachings and new operations, and such as have had the direct advantage of his personal skill are among the first to recognize and acknowledge this debt.

It is a mark of honor that the first strong impulse to the study of gynecological surgery in America. It is believed that the medical profession everywhere, the vast number of women who owe their relief from suffering directly to him, and those who realize the benefits he first made possible, will gladly unite thus to honor the man through whose original and inventive genius such work has been accomplished.

At the suggestion of many friends, therefore, the subjoined committee has been organized, and it is proposed that a suitable monument be erected to his memory in the city of New York.

Reports of Societies.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, February 1, 1884.

ROBERT F. WEIR, M.D., PRESIDENT, IN THE CHAIR.

DR. ROBERT F. WEIR read a paper (see p. 337) entitled

THE TREATMENT OF RUPTURE OF THE BLADDER BY PELVIC DRAINAGE.

The paper being open for discussion, DR. WM. T. BULL said that he felt sure that all surgeons who had had experience in these cases would feel obliged to Dr. Weir for calling attention to the points which he did.

The speaker thought that one might dwell more upon the

DIFFICULTY OF MAKING A DIAGNOSIS,

especially in hospital cases. He was reminded of a case which he met several years ago, of a man brought to the hospital with a history simply that he could not pass his water. A catheter was introduced without meeting with any obstruction, and a very small amount of bloody urine was withdrawn. The patient at the time was in a kind of collapse. After a time a catheter was again introduced, and another small amount of bloody urine obtained. An aspirator needle was then introduced, and quite a quantity of bloody urine was withdrawn, apparently from the bladder. The aspirator needle was thought to enter the bladder, although the catheter and needle could not be made to meet. In fine, it was very difficult to make any diagnosis. The patient died the next day, in the interval. The fundus of the bladder was ruptured, and that a great quantity of blood and urine was external to the peritoneal membrane.

Another point in reference to diagnosis, which Dr. Weir mentioned, he did not think was always a positive one, viz., passing a catheter into the bladder and finding that very little urine escaped; then passing it a little farther, and finding a great flow of fluid, this latter coming from the peritoneum. The speaker recollected a case that occurred in Bellevue Hospital, where the man was admitted without any history, and was supposed to have peritonitis. Urine was drawn, it was supposed from the bladder, but it really came from the peritoneum. The only thing that excited remark, was the very great quantity of nutrient urine.

He believed that if one felt confidence in the safety of EXPLORATORY INCISIONS,

they would be resorted to. He himself would certainly employ them if indicated.

DR. GEORGE P. SHRADY remarked that Dr. Weir's case furnished a valuable point in diagnosis. He thought, however, that the palpation and percussion over the abdomen furnished more important diagnostic signs. In fact, it was hard to understand how dulness on percussion could exist after the bladder had been emptied of its urine by catheter or aspirator without its indicating some extra-peritoneal extravasation.

DR. WEIR said that in one reported case of rupture, dulness existed, and there was a tumor; but these disappeared under the use of the catheter.

DR. BULL asked what would be the effect of SEWING THE BLADDER WOUND into the peritoneal wound in case of intra-peritoneal rupture.

DR. WEIR said that in intra-peritoneal rupture of the bladder he would do laparotomy, and close up the bladder wound with sutures. In extra-peritoneal rupture he would not attempt to close the wound.

DR. A. A. SMITH read the histories of two cases illustrating

POINTS IN THE DIAGNOSIS OF THORACIC ANEURISM.

The history of the first case was as follows: M. F., aged thirty-four, United States, seaman, was admitted to Bellevue Hospital January 15, 1884. The family history was negative, as was his labor.

The patient herself had been well until over two months ago, when she began to suffer from dyspnoea, hoarse cough, and pain in the left chest.

On admission the patient was intensely cyanosed, was in cold perspiration; pulse rapid and feeble; respirations were diminished in frequency, were very labored, and were noisy or stridulous in character. The voice was wholly unaffected, but her cough was hoarse and husky. The face was swollen and congested, and the countenance presented a startled and anxious expression. Her suffering was intense, and she was unable to lie in the horizontal position. As the accents of the symptoms began to pass off, she became drowsy, but tried in vain to obtain refreshing sleep. The paroxysm lasted about fifteen minutes after her admission to the ward. During the paroxysm she was given Magendie's sol. morph., 1/8, hypodermically. This relieved her greatly.

Physical examination: Consolidation of left apex, and a slight pleuritic effusion on the left side. There was a very probable occurrence of the heart sounds above the umbilicus. They were more distant in the region of the liver. The patient probably occurred about two weeks ago, as per previous history. There is slight pulsation on the left side, at about the junction of the second rib with the sternum; and abnormal transmission of heart sounds along the trachea just below the larynx.

Diagnosis: An aneurism of the aorta (probably involving the termination of the transverse, and the beginning of the descending portions of the arch), making a pressure upon the trachea and left primary bronchi. There is not sufficient evidence of pressure on the recurrent laryngeal nerve. A double murmur was found over upper sternal region. The respiratory murmur was considerably weaker over the left side than on the right.

January 16th.—The patient passed a quiet night. This morning, on being moved, she had another paroxysm, similar in every way to that of yesterday, but rather more severe, and lasting about three-quarters of an hour. She was given Magendie's sol. morph., 1/8, hypodermically. Also cupric sulphate, gr. x., and zinc sulphate, gr. xx., per os. These latter were followed by a free expectoration, which seemed considerably relieved. The patient says that the paroxysm of yesterday was the first one of the kind she had had. During these paroxysms, the obstruction seems to be in the larynx, and from their nature and the absence of any affection of the voice they are unquestionably due to spasm of the glottis. In the intervals between the paroxysms the patient has the same hoarse cough, and her respiration is the same in character as during these, the difference being only in degree.

January 19th.—Patient has had four paroxysms since the last entry. All of these have occurred in the evening, or during the night, and have been similar to the first, excepting that they seem to be growing more severe and last a longer time. The expiration and inspiration seemed considerably relieved. The patient says that the paroxysms of yesterday were almost equally labored and difficult. During one of the most severe paroxysms, which occurred last night, she became for the time being delirious, and threw herself about the bed in the most frantic manner. The paroxysms come on very suddenly, and are preceded, as a rule, by dry retching. During the paroxysms her pulse is feeble, and at times almost imperceptible, and hence Hoffman's anodyne, 1/2, hypodermically, was given her, and she seemed much relieved by this. If the stethoscope is applied to the larynx during a paroxysm, the difficulty in breathing, the stridor, seems to be located there. Oxygen by inhalation has also been used, and seemingly with good effects.

Treatment: Potass. iodidi, gr. x. t.i.d.; whiskey,
THE MEDICAL RECORD. [March 29, 1884.

3 ss. q. 4 h.; mist. hydrocyan., 3 Jill. q. 4 h. During the
paroxysms: Mag. sol. morph., m. xj.—xv.; Hoffman's ano-
dyne, m. xx., hypodermically; oxygen by inhalation;
sponges wrung out in hot H₂O.

During the most flatus, paroxysms for the last four days
have occurred daily, lasting ten to twenty minutes. The
intervals between the paroxysms are growing shorter,
and the duration of the paroxysms is also less than upon
her admission, although this may be due to the treatment
that she receives.

January 24th. The paroxysms have been gradually
freshening more frequent during the last two days.
Throughout the day yesterday it occurred at intervals
of about two hours, and the average duration of each was
somewhat longer.

The patient has been taking but little nourishment,
and has been falling rapidly. During the paroxysms,
oxogen has been administered, and has relieved the
cyanosis very much. This morning the paroxysms be-
came still more frequent, and began to follow each other
with great rapidity, scarcely an appreciable interval
elapsing between them. Her expiration seemed to be
more difficult, while inspiration was much less labor.
The slightest movement, or even word, would seem suf-
ficient to inaugurate a new attack. The attacks of dysp-
noea have greatly increased by the presence of the exu-
culation, at times the pulse being almost inapprciable.
At about 1 P.M. to-day she became very pale; she re-
sisted to take oxygen, became restless and partly uncon-
scious, her pulse being very feeble and rapid. She re-
mained in this condition for some time, then suddenly
commenced vomiting blood (dark-colored) in large quan-
ties, and soon died.

Autopsy.—Right lung normal. Left lung partially col-
lapsed, and containing very little air. Left primary bron-
chus flattened by the pressure of the aneurism, and the
lumen considerably occluded. The heart slightly en-
larged by simple hypertrophy with no valvular lesions.
At the point of union of the transverse with the descend-
ing portions of the arch of the aorta was found a secu-
lar dilatation of the artery, partially surrounding the
cosophagus, which had ruptured into the cœsophagus
and into the left primary bronchus. It was the size of a
small fist, and had caused pressure upon the left primary bron-
chus, producing flattening of it, and upon the left pneu-
monia. This was thought also that there was
pressure upon the left recurrent nerve. There
was slight erosion of two or three vertebræ. The stom-
ach was found to be greatly distended by large clots
of blood, which were of an exceedingly dark color. The
other organs were normal.

Dr. SMITH remarked, in commenting upon the case,
that the point of interest during lifetime was whether the
disease was an aneurism or a mediastinal tumor.
A visiting physician had pronounced in favor of the latter.
Dr. Smith related the history of a

SECOND CASE,
in which solidification of the lung accompanied the neu-

August H.—, a German, by occupation a bookbinder,
was admitted to Bellevue Hospital December 7th. Family
history good. Is not intertemperate, but drinks beer
occasionally. Two years previous to admission he had
a sore on his penis, followed by a bubo, but has never
had secondary or tertiary manifestations, so far as could be
ascertained. He has had a cough for three months, and
for the same length of time has had occasionally attacks
of diarrhea with sanguineous stools. About ten days
before admission he was seized, after exposure to cold
and wet in a cellar, with a chill, pain in left side, a se-
vere cough, some fever, shortness of breath, and great
debility. He was confined to bed. Five days later the
spasms commenced with blood.

On admission he was still suffering from cough, dysp-
noea, no pain, however, debility, and profuse perspira-
tions. Physical examination revealed a diminished ex-
pansive movement on the left side. Vocal fremitus was
absent on the left side, except near the sternum and spine
and in the infra-spinal fossa.

Dullness over the left side in front as low as the fifth interspace; behind as low as the inferior
angle of the scapula; below this there is dulness, but
not so marked. There is bronchial breathing and bron-
chophony in left side as low as the fifth interspace,
minimizing from above downward. Behind there is bron-
chial breathing as low as the inferior angle of scapula;
below this the respiratory murmur is almost lost. Since
coming into the hospital the patient has had attacks of
cyanosis quite marked, and assumes the half-lying postu-
re almost constantly.

The heart is normal in size, but there is a milial sys-
tolic murmur heard.

On the second day after admission the sputa was
decidedly pneumonic; the temperature was 103°. On the
third day the temperature became normal, the rusty sputa
ceased, and the patient seemed much better, although the
physical signs did not change. On the fourth day, for
the first time, he complained of some pain in the left side when
he attempted to lie on that side. The pain was located
in the region of the nipple.

His condition was so much better on the 18th (eleven
days after admission) that he was asked to be discharged.
His discharge card came so late in the day he was permitted to
remain until the next day. At midnight of the 18th he
sat up in bed suddenly, coughed violently, and the blood
gushed in torrents from his mouth. He died in a few
minutes.

Autopsy.—Just on the anterior surface of the de-
sceding arch of the aorta is an aneurism pressing
forward on the posterior wall of the left bronchus, and
opening into it by a semilunar valve-like opening.
The aneurism was as large as an English walnut. Lungs:
Left lung showed red and gray hepatization over the
whole of it. Pleuritic adhesions quite marked. The up-
ner lobe was more markedly consolidated than the lower.

The histories of these two cases were somewhat simi-
lar. Some interesting questions suggest themselves.
Had the pressure on the left primary bronchus anything
to do with the development of pneumonic consolidation
in the upper lobes? Might the pressure on the pneu-
moaerie have had anything to do with the development
of consolidation in the lobe? If pneumonia is always a constitutional disease, the only
explanation in these cases would seem to be coincidence.

In the discussion of these cases

Dr. BEVERLEY ROBINSON thought that the lung solidi-
fication was probably a coincidence. He had gener-
ally seen collapse of the lung tissue, but not solidification.
He referred to the fact that spasm of the glottis is some-
times produced by pressure on the trunk of the vagus.

TYNDALL ON EVOLUTION.—Professor Tyndall says on
this subject: "If asked whether science has solved, or
is in our day likely to solve, the problem of the universe,
I must shake my head in doubt. Behind, above, and
around us, the real mystery of the universe lies unsolved,
and, as far as we are concerned, is incapable of solution.
The problem of the connection of the body and the soul
is as insoluble in its modern form as it was in the pre-
scientific ages. There ought to be a clear distinction
made between science in the state of hypothesis and
science in the state of fact, and inasmuch as it is still in
its hypothetical stage, the ban of exclusion ought to fall
upon the theory of evolution."
MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, March 24, 1884.

ANDREW H. SMITH, M.D., VICE-PRESIDENT, IN THE CHAIR.

BLINDNESS FROM THROMBOSIS OF THE RETINAL BLOOD-VESSELS IN Facial Erysipelas.

Dr. H. Knapp read a paper on the above subject in which he first referred to the literature of the subject, and said that blindness from erysipelas was an infrequent occurrence, yet more frequent than textbooks would lead us to conclude.

Schultze, in "Ziemssen's Cyclopedia," describes the condition in a few lines, and says there is swelling of the lids with redness, protrusion, and immobility of the eyeball, haziness of the cornea, ulceration of the cornea from exposure, then more or less sudden blindness, not rare incomplete amnesia, and in the majority of cases permanent blindness; in only rare cases restitution. Stille's reference, in the "International Encyclopedia," is still more meagre.

The most complete article on the subject was published by Schwendt in 1883, who had collected thirteen cases, and Dr. Knapp was able to add twelve. The condition of immobility of the eyeball probably does not occur without orbital cellulitis. The blindness occurred in the inflammatory stage in some cases, in the stage of convalescence in others.

Dr. Knapp then gave a résumé of the description of the disease as it had been given by different writers, and as because of the paucity of cases; also gave the histories of three recorded cases.

The second class of cases were those in which ophthalmoscopic observations were made in the early stages of the disease, as noted by Williams, of Boston, and other observers. In general there has been lack of ophthalmoscopic examinations during the first stage of the affection.

Dr. Knapp then gave the history of his case, which was under the care of Drs. Gulecke and Schottke, and which he had opportunity to observe with the ophthalmoscope almost from the beginning to the end. A married man, forty-one years of age, had lived in the tropics, had had syphilis with secondary and tertiary symptoms, which were aggravated when his business called him North. Now he came with the unexplained history of an attack of erysipelas, which began upon the nose, and spread to the pharynx, cheeks, and orbits. The erysipelas progressed, and eight days from the beginning of the attack the patient was totally blind in both eyes.

The media were perfectly clear, there was not even any opacity of the vitreous. The fundus at first was opaque, could be distinguished only by the convergence of the blood-vessels, which were tortuous, and there were also numerous dark hemorrhages. On the fourth day of the blindness the veins had not changed. The arteries were then bright red lines, and there was no doubt that blood had been carried into the anterior of the eye, because there was evidence of new hemorrhages, shown by red extravasations around the optic disk, motility of the eyeballs was restored, the optic disk gradually became visible, was pale and atrophic, and the veins looked like beads. Gradually some of the blood-vessels were interrupted by white portions as thick as the calibre of the vessels themselves. These white portions in the course of weeks extended, and finally coalesced, and nearly all the veins were converted into white lines; only a very few contained blood.

Dr. Knapp then made some general remarks concerning erysipelas, which he regarded as an infectious disease, of traumatic origin always. He then turned to the ophthalmoscopic pictures of the cases under consideration and gave his views concerning the successive steps in the morbid process, which were illustrated by large colored plates. They may be summarized as follows:

**First.** The blindness was produced by compression of the central retinal arteries, and subsequently thrombosis of the retinal veins, both having been directly observed with the ophthalmoscope one day after the occurrence of the rapid, almost sudden loss of sight.

**Second.** The ophthalmoscopic appearances observed from the beginning to the end showed no neuro-retinitis, but the successive stages of a thrombosis.

**Third.** The degrees of the swelling of the orbital tissue, or the establishment of collateral circulation from the choroid, permitted the return of a limited flow of blood into the retinal arteries, which, however, was impeded by the blooded veins, leading to renewed extravasations, to the thrombosis, and shrinkage of the arteries, and finally to atrophy of the optic nerve.

**Fourth.** Perivasculitis played no, or only an unimportant part in the pathology of the case.

**Fifth.** The white segments in the veins and arteries were white thrombi, and not hypertrophy of the walls of the blood-vessels.

**Sixth.** The thrombus was present, in all probability, also, in the orbital veins, but did not, as in other cases, extend to the central sinuses.

Dr. E. G. Loring had been very much interested while listening to Dr. Knapp's paper. While he had severe atrophy of the optic nerve, he did not remember to have examined a case during the progress of the disease. In the cases which he had examined there had been simply an exhibition of white atrophy of the optic nerve, without any of the changes in the blood-vessels illustrated by Dr. Knapp, and there were no hemorrhages, and evidently an entirely different condition from that commonly accepted as the result of lesions occurring with and after erysipelas.

There was one case on record to which Dr. Knapp had not referred, and in which the appearance was precisely as described by him, namely, a case reported by Dr. Calkin.

With regard to the manner in which the inflammation extended, Dr. Loring thought it was by direct propagation along the walls of the vessels themselves; that it was a pure phlebitis, and he referred to two cases which favored this view—one a case of phlebitis of the neck, the other phlebitis of the leg—in which the propagation was directly related to the inflammatory process in the veins.

With reference to compression of the blood-vessels Dr. Loring thought that the vessels in the choroid might be choked, and that thrombosis might occur, and yet produce no effect whatever upon the circulation.

With regard to the condition of the vessels—that they remained of the same size in different parts—he thought was evidence of inflammation of their walls, and that the process was inflammation and hypertrophy of the walls of the vessel. That thrombi were within them he had no doubt, but the essential feature of the process he believed to be phlebitis, which arrested the current and ultimately gave the picture presented.

Dr. T. R. Poole thought it not so easy to explain the phenomena by such complete compression of the central retinal vessels with thrombi, for if so, we should suspect to have the disappearance of both sets of vessels, arteries and veins.

In cases of blindness with atrophy of the optic nerve, due to other causes, and with the same size of the blood-vessels, it was difficult to accept this explanation, which, however, without doubt, must remain true for many other cases.

Dr. Poole also preferred to assume that the veins ruptured, and so gave rise to the hemorrhages, rather than that the extravasations were due to diapedesis, for in diapedesis there is escape of white blood-corpuscles mostly, with only a few red ones.

Dr. W. F. Holcombe queried whether the essential nature of the orbital difficulty might not be a phlebitis, and not due to pressure alone. He also queried whether some of the cases might not be essentially orbital periost
titis described many years ago by Denmar as of specific origin.

Dr. Knapp, in closing the discussion, said that a certain number of the patients had syphilis, but whether it had anything to do with the condition described he was unable to say positively. The case referred to by Dr. Loring had escaped his search. He had one hesitation in accepting the view that the change affecting the vessels was due to phlebitis, and that was there was absolutely no opacity about the veins. That it was a phlebitis was decidedly apparent from the possibility of the organization of the thrombus, according to modern views. It was certainly an inflammation of the inner coat of the blood-vessels, and so far he agreed with Dr. Loring. But as to its being an inflammatory process which crept along the blood-vessels, he thought that view could not be established in this case. That it was so in other cases, for example, where it has been found to have followed the vessels into the dura mater, etc., there was no doubt.

With regard to the hemorrhages being due to dia-pedesis, Dr. Knapp said he thought that such extravasations were due to rupture of the vessels, until a few years ago Dr. L. E. G. von Berlin, of Berlin, described retinal hemorrhages occurring in puerperal anemia, and explained them by transudation through the coats of unhealthy vessels, and Betman, of this country, also had demonstrated the escape of blood in quantity sufficient to constitute a hemorrhage without rupture of the coats of the vessel.

The Vice-President referred to the case of a man who had diabetes mellitus, erysipelas of the face, albumen in the urine, movable eyeballs, no exophthalmos, but sudden and total blindness a short time before his death.

REPORT OF THE COMMITTEE ON COLLECTIVE INVESTIGATION OF DISEASE.

Dr. David Webster, Chairman of the Committee, reported that the histories of about fifty cases of intussusception had been sent in, many of which were very interesting, and required more time for consideration than could be devoted to them this evening. He therefore moved that when the Society adjourns, it adjourns to meet April 7, 1884, and that the subject of Intestinal Obstruction, to be reported by the Committee, be made the special order for the evening. Carried.

REPORTS OF THE SPECIAL COMMITTEE ON "AN ACT TO INCORPORATE A COLLEGE OF MIDWIFERY," AND "AN ACT TO REGULATE THE PRACTICE OF MIDWIFERY."

Dr. W. M. Chamberlain, Chairman of the Committee, submitted the following majority report:

To the Medical Society of the County of New York: Your Committee, having carefully considered a draft of "An Act to Incorporate a College of Midwifery," also a draft of "An Act to Regulate the Practice of Midwifery," and having heard the arguments of the promoters of these acts, are of the opinion that it is not expedient for this Society to endorse or support the said acts.

The question of the conditions under which others than registered physicians shall practise midwifery seems to be an important and difficult one, and in our opinion might properly be referred to a special committee, or to the Comitia Minoris for examination and report.

Signed: W. M. Chamberlain, M.D., Chairman. Edward L. Partridge, M.D. Arthur M. Jacobus, M.D. Chas. Carroll Lee, M.D.

Dr. A. W. Warden submitted the following minority report:

To the Medical Society of the County of New York: The undersigned, a part of your committee appointed to investigate and report to the Medical Society of the County of New York concerning two acts proposed for State legislation, presented to the Medical Society of the County of New York for approval by the promoters of the proposed "New York Maternity and School of Midwifery," reports as follows:

First. In regard to the proposed "New York Maternity and School of Midwifery," your committee recommends that the Medical Society of the County of New York do not endorse or commend the incorporation of such an institution, because it is not conducive to the elevation of the medical profession and the good of the community.

Second. In regard to the proposed act in relation to the practice of midwifery in the State of New York, your committee find such proposed law to be not advisable, and counsel that the Medical Society of the County of New York, in the interest of maintaining a high standard of qualification for the practice of midwifery and all branches of the profession of medicine, and in the interests of the people of the State of New York, do not approve any State legislation giving the right to practice midwifery, or any branch of the profession of medicine, to persons other than qualified and registered (male or female) physicians.

Signed: A. W. Warden, M.D.

On motion the reports were accepted.

Dr. Harwood moved that the minority report be adopted.

Dr. Manley moved, as an amendment, that the majority report be adopted.

After some discussion Dr. Jacobs moved that the further consideration of both reports be postponed indefinitely.

The motion was put and declared lost.

Discussion ensued and was participated in by Drs. Polk, Jacobi, Johnson, Warden, and others, and then the vote on the amendment to adopt the majority report was taken and lost by a large majority.

Discussion again ensued, and was participated in by Drs. Jacob, Polk, Jacobs, Mundé, Cole, and others.

Dr. Spitzen moved the previous question. Carried.

The vote was then taken on the minority report and it was adopted.

Pending the consideration of the bill now before the Legislature, with reference to incorporating a college of midwifery, the Society adjourned.

TETANUS TREATED WITH QUININE AND CHLORAL—RECOVERY.—Dr. James H. T. Webb, of Chicago, III., relates the history of a child, two months old, who had pushed a carpet tack, with a leather head, up its nose. Several days later Dr. Tebbetts was called in, and found the child in a convulsions so convulsions had terminated in two days already. The tack was found wedged against the inferior turbinate bone and was extracted, when about a drachm of sanious pus and broken-down tissue was discharged. The convulsions continued, the temperature was 106° F. and pulse 170. Eight grains of chloral hydrate and five grains of quinine were given per rectum, when the general convulsions ceased, but not the cramps. Next morning the temperature was 104°. Ordered three grains of chloral hydrate every three hours for twenty-four hours, and five grains of quinine every six hours per rectum. This last medicine was continued for three days; at the end of that time the temperature was normal and there was only a slight cramps. Dr. Tebbetts adds: "It would seem that in quinine we are to look for great assistance in these cases, and that, when given in full doses, even in children, the convulsions lessen in severity and may cease altogether. Toy-pistol tetanus, in the practice of Dr. Hosmer Johnson, has been cured by large doses of quinine; and Dr. Jones, of New Orleans, also reports recoveries of cases of tetanus after large doses of quinine. In convulsions with chloral hydrate during and after the severer paroxysms, quinine seemed to hold the disease in check until the system had recovered its tone. Cinchonism did not appear."
New Instruments.

A NEW INSTRUMENT FOR EXSECTIONS.

By JOHN A. WYETH, M.D.,
NEW YORK.

I wish to call the attention of surgeons in this country to a most excellent and useful instrument recently brought to me from London by my friend, Dr. J. N. Oakes, of Ohio. The Inventor is a Mr. Gowan, of Guy's Hospital, and the original instrument was manufactured by Moyer & Meltzer, of London. I have had it reproduced, with certain modifications, by Tiemann & Co., of New York City. For the rapid, safe, and easy division of bone it is, in my experience, unequalled by any other form of saw. I have tried it in exsections of the humerus and shoulder-joint, the elbow-joint, the hip-joint, cutting through both trochanters with perfect facility, the radius, the metatarsus, and the acromion process and spine of the scapula.

![Fig. 1.](image)

Fig. 1. represents the instrument made by Tiemann & Co., after Mr. Gowan's model. It consists of a handle about a foot long, made of metal and covered partly by vulcanized rubber. This handle is hollowed out for the passage of the steel bar b, which runs the entire length of the apparatus to act on the jaw of the forceps. On a portion of its inferior edge, at about its middle, cogs are cut in which the teeth of the lever a catch, and the degree of pressure of the jaws c on the bone to be held is regulated by the pressure of the fingers of the operator upon the lever a. The saw e is in shape like a chisel, and works into a shield at d. Method of using: The bone to be excised having been exposed, with its periosteum peeled off in common with all the contiguous tissues, the operator, holding the handle of the instrument in his left hand (the saw being entirely removed), depresses the lever a, draws back the bar b, and opens the jaws c wide enough to insinuate them about the bone. As soon as this is accomplished the bar b is pushed forward against the heel of the jaw and the lever a is pressed toward the handle. With the right hand slide the saw into the shield d down until the teeth engage against the bone. A slight oscillation of the handle of the saw with requisite pressure carries it through the bone with remarkable rapidity, and without wounding or bruising the contiguous soft tissues. The shield d not only rotates, but is reversible, and can be changed from one side to the other. In the modified instrument I have had constructed a narrower saw and shield, so that it may be used in exsections of small bones closely related to each other, as the metacarpal bones.

The modified exsector is seen in Fig. 2, and is cheaper as to cost and simpler as to mechanism than the preceding. The handles work with a double-jointed motion, and have a fixation-clamp, f, like the Russian needle-holder. By opening or closing the handles, the jaws, g, are separated or closed. The action of the rotating shield, h, and the saw, i, are the same. I am sure that this instrument will be of great use to the profession, and while the idea is not novel, Mr. Gowan deserves great credit for his perfection of it.

AN IMPROVED MODIFICATION OF DR. ROBERTS' TROCAR AND CANULA FOR ASPIRATING PERICARDIAL EFFUSIONS.

By BEVERLEY ROBINSON, M.D.,
NEW YORK.

The instrument, of which a wood-cut and detailed description follows, is not new. It is merely, as I believe, an improvement upon the one referred to above. The additions to, or modifications of, Dr. Roberts' instrument consist: 1. In the larger side-tube e, added to the penetrating needle. This of itself is not new, since we find it now attached to many improved forms of aspirators. It was first used by Pottain. 2. The stopcock d. 3. The stuffing-boxes o and f. These are also found in some improved aspirators. 4. The small spring h, which catches in the notches i, k, etc., while the inner tube b is being slowly withdrawn, and the holes l and l', which are placed at distances exactly to correspond with the outer tube e when the spring is stopped by one or other of the notches first found as the handle is drawn back. These are additions which make the instrument a more accurate one than the original one by Dr. Roberts. 5. The conical opening o, and the thicker end of the steel blunt needle n, as well as the hermetically fitting anterior portion of the stuffing-box f, are all intended to prevent the possible entrance of air into the pericardiac sac, and are, so far as I know, new and useful additions to the instrument.
With Dr. Roberts' instrument, "if the canula becomes plugged with flakes of lymph, the handle can be unscrewed, the inner portion withdrawn, and the hose attached to the end of the penetrating needle, which then acts as a large ordinary aspirating needle."

With my modification no such risk of the entrance of air into the pericardial sac is incurred, and, besides, to clean out the penetrating needle, by means of the steel bar, if it should have become obstructed by fibrin, or lymph, is more practicable than to suck back this material into the aspirating pump.

The instrument consists of three principal parts, $A$, $B$, and $C$. $A$ is a canula, or aspirating needle, the front part of which is an ordinary aspirating needle provided with a stopcock at $d$ and a short tube, $e$, projecting from the canula at an angle of forty-five degrees and situated one-half inch in front of the stopcock. This short tube serves to connect the canula with the aspirating pump or the vacuum by means of air-tight mounts and rubber tubing.

The lower extremity of the canula $A$ has an opening, $o$, with a conical bore into which the stuffing-boxes $f$, $f$ of the parts $B$ and $C$ fit closely and form an air-tight joint.

The Fig. $B$ is a tube which fits closely into the canula $A$, and shuts off the vacuum hermetically by virtue of the stuffing-box $f$. It ends in the spiral tube $g$, one inch long, made of a flat piece of steel, and is curved, forming the quarter of a circle having a radius of one-half inch. "The outer extremity of the spiral is pierced with a hole, and there are also two fenestrae just above to give exit to the fluid."

The stuffing-box of this tube is provided with a small steel spring, $h$, with a pin. $i$ and $k$ are small notches in the tube, into which the pin of the spring fits accurately; the two points marked $l$ and $l'$ are openings in the tube which correspond with the small tube $e$ (of the canula $A$), in order to establish connection between the vacuum and the aspirating needle for aspiration. $m$ is a metal handle checked on one side.

Fig. $C$ consists of the same metal handle $m$ and the same hermetically fitting stuffing-box $f$, but is not provided with a steel spring. $n$ is a steel bar or blunt needle fastened into the handle $m$. The end of this steel blunt needle is one-half millimetre thicker within three-fourths of an inch of the point.

The stuffing-boxes $f$ consist of two parts screwed together, and contain in the inside a leather washer which prevents the passage of air, making the stuffing-boxes absolutely air-tight. When being used, it is essential that the checked side of the handle $m$ must be horizontal with $d$ and $e$, to prevent the point $f$ of the canula from piercing the spiral part, $g$, of the tube $B$.

When tube $B$ is introduced into the canula $A$, the handle $m$ is drawn out gently until the small spring, $h$, snaps into the notch $i$ with a perceptible jerk. Then connection between the tube $e$ and the canula is made by means of the opening $l$ and, as the spiral part of the tube $B$ is concealed in the canula below the point of the canula, and the instrument is ready for use.

It is then introduced, and in order to protect the point from doing any harm in the cavity, the tube is introduced up to the handle (its full length) and the spiral part of the tube protrudes from the canula, as shown in Fig. $A$, thus covering the point; and connection with the tube $e$ is made by means of the hole $l'$ (see Fig. $B$).

If the canula becomes plugged up with flakes of lymph, etc., etc., in the course of the operation, the tube $b$ is withdrawn.

In order to prevent the admission of air into the canula, the tube $b$ is withdrawn slowly until the small steel spring snaps into the notch $k$. The stopcock is then closed, thus shutting off the air. Now the tube $b$ can be withdrawn and the blunt needle $e$ introduced, the stuffing-box $f$ is fastened into the conical opening $o$, the stopcock opened, and the blunt needle introduced to its full length, by which operation the canula is cleared without admitting the least air. The instrument is marked on the surface in inches, like the one of Dr. Roberts, "so that it can be seen at what depth the point is situated."

---

**DOUBLE-BLADED SAW FOR REMOVING PLASTER CASTS.**

By A. H. MEISENBACK, M.D.,

ST. LOUIS, MO.

In removing plaster of Paris casts, oftentimes a great deal of time is unnecessarily consumed, on account of the imperfection of the instruments employed.

There are various forms of shears devised for the purpose, but any one having used them well knows that there are many objections to them, such as clogging, not leverage enough to force the jaws through the plaster, or not space enough between the limb and the cast to insert the jaws advantageously. A saw has some advantages over other means, principally on account of the rapidity of its penetration; yet a single-bladed saw of ordinary construction has the disadvantages of making only one cut at a time, and not being able to be used in situations oftentimes desirable, such as the bend of the elbow, over the ankle, etc.

The saw illustrated obviates most of the above-named objections. It is constructed with double blades, parallel to each other. The blades are of the form of a Hey's saw, only larger, one cutting surface being rounded and the other square. The blades $A$, $B$ are attached to the shaft $D$, $E$ by screws, as shown. The shaft consists of a square part, $D$, and a tapering part, $E$. The square part is made in two halves, with a hinge, as shown at $D$. The blade $A$ is attached to the stationary part of the shaft, and the blade $B$ to the movable part of the shaft. At the end of the blades is a spring, $C$, which is notched so as to firmly hold the blade $B$ in position, By having one blade movable it can be easily cleaned. The distance between the blades is $\frac{1}{8}$ of an inch. This is the best width, for it allows the strip cut out to be easily removed with a chisel or knife, which would not be

---

1. Also Herstein & Co., instrument makers of St. Louis, have manufactured a very good instrument for me.
the case if the strip cut out were wider. The whole length of the shaft is 6¼ inches. The blades are 1¼ inch wide and 2½ inches long. The teeth of the saw blades should be very fine, so as to insure rapidity in cutting. The mode of using it is as follows:

Cut the entire length of the cast to a depth of one-fourth or one-third of an inch, chip out the strip thus cut with a chisel or knife, and continue the operation until the entire thickness of the cast is cut through, or a portion of the cast is reached which is not thoroughly saturated with plaster, and which can easily be cut through with scissors or a knife. The cast can be removed, or if it is desired simply to make it fit more snugly, a bandage can be put around it, drawing the cut surfaces together, and thus making it fit closely again until the time for removing it entirely. All casts loosen on account of reduction of the swelling, and also on account of atrophy of the soft parts from pressure and non-use, and the cast must almost always be tightened before the time has expired for its removal. This operation is much simplified, and there is much time saved by the employment of the instrument illustrated.

Army and Navy News.

**Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from March 16, 1884, to March 22, 1884.**

BACH, DALLAS, Major and Surgeon. Leave of absence still further extended seven days. S. O. 50, par. 1, Headquarters Department of the East, March 14, 1884.

MATTHEWS, WASHINGTON, Captain and Assistant Surgeon. To be relieved from duty in the Department of Missouri, and to report to the Surgeon General of the Army for duty in his office. S. O. 62, par. 12, A. G. O., March 15, 1884.

BLACK, CHARLES S., First Lieutenant and Assistant Surgeon. Assigned to duty at Fort Concho, Texas. S. O. 30, par. 6, Headquarters Department of Texas, March 10, 1884.

GIBSON, R. J., First Lieutenant and Assistant Surgeon. Relieved from duty at Fort Hays, Kans., and ordered to Fort Wingate, N. M., for duty. S. O. 58, par. 3, Headquarters Department of Missouri, March 18, 1884.

CROSBY, WM. D., First Lieutenant and Assistant Surgeon. Relieved from duty at Fort Huachucha, A. T., and ordered to Fort McDowell, A. T., for duty. S. O. 20, par. 1, Headquarters Department of Arizona, March 15, 1884.

EDIE, GUY L., First Lieutenant and Assistant Surgeon. Assigned to duty at Fort McIntosh, Texas.

ROBERTSON, REUBEN L., First Lieutenant and Assistant Surgeon. Assigned to duty at Fort Ringgold, Tex. S. O. 33, par. 3 and 4, Headquarters Department of Texas, March 17, 1884.

**Official List of Changes in the Medical Corps of the Navy, during the week ending March 22, 1884.**

STREETS, T. H., Passed Assistant Surgeon. From Museum of Hygiene, Washington, for duty in the Coast Survey service.

HALL, W. H., Passed Assistant Surgeon. From the Naval Academy to the Museum of Hygiene.

STEWART, HENRY, Surgeon. Ordered before the Retiring Board.

**Another Case of Supernumerary Testicle.—Dr. H. S. Hutchinson, of Lewisburg, Pa., writes: "Being in Kingston last fall, one night I happened into the bar-room of the hotel where I was staying, just as those present were making a wager that a certain man, Wm. F. — also present, could not show three testicles. The wager being made he exposed his scrotum, when I was requested to examine it. I did so and found to my surprise three distinct testicles, the third being in the left side of the scrotum, behind and a little above the other, and about the size of an English walnut. The same sensations he said were produced by pressure as in the other testicles. The spermatic cord seemed to join with that of the other before entering the inguinal canal. The man had more than ordinary sexual power.**

**A New Antagonist to Alcohol.—The kola nut of Guinea, or garu nut of Soudan, the fruit of the sterculia acuminata, cola acuminata of Daniell, has recently assumed a new importance by its remarkable property of antagonizing the effects of alcohol. It has long been known that the kola nut contains caffeine, to which may be attributed the lessened desire for sleep and sense of physical well-being caused by the consumption of it; for which reasons it has long been extensively and highly valued throughout a large portion of Africa. Unlike the coffee bean, however, it contains no tannin. It has recently been discovered that when chewed, it antagonizes the effects of alcohol, and constant use of it is said to dissipate the desire, even in old drinkers. Whether it is superior to the aromatic spirits of ammonia for the treatment of an "acute drunk" is not yet definitely known. The nuts are much more available for constant use, however, than any liquid, and if the claims put forward be true, the "dinner-out," by taking a few of them along with him, need not be disturbed by thoughts of the next morning's headache.**

**The Regulation of Prostitution.—M. E. De Laveleye, in a letter to the Pull Mall Gazette, gives the following account of what has been done of late with regard to the regulation of prostitution. He says: 'The Municipal Council of Paris and the General Council of the Seine have both alike passed a resolution absolutely in condemnation of the official recognition of debauchery. The Governments of Italy and Belgium have appointed Commissions of Inquiry upon the question. At Colmar, in Alsace, the odious legislation has been abolished, and the military and medical authorities, at first opposed to the abolition, have now congratulated the mayor, M. Schlumberger, on the amelioration which has taken place in the health of the troops. The maladies in question have been doubled in twelve years at Copenhagen since the introduction of the regulation system. This was proved by the statistics communicated to the Hague Congress by Dr.
Giersing. The same maladies had, he proved, diminished in the towns not subjected to the regulations. In Finland the local boards, with a vindictive severity, visited the entire population, men, women, and children, being periodically subjected to the odious examination; yet in Finland the physical scourge is extending its ravages right and left. In Italy, Belgium, and Holland specialist doctors of the most distinguished character proclaim loudly the inefficiency of the system, while in Spain a group of the most eminent practitioners, including most of the Castilians, have rebuked their adhesion to our principles. There is a proposal in Holland to consider the possibility of some international law to suppress the white slave trade. Your House of Lords, I believe, has in hand something of the same kind.

**Mercury in Diphtheria.**—Dr. E. Snyder, of St. Paul, Minn., writes us urging the claims of mercury in diphtheria. The practitioner who knows how to use intelligently mercury, tincture of iron, and inhalations of slacking lime, need not, he thinks, be afraid of diphtheria. Dr. Snyder gives an initial dose of calomel and soda. He then applies the olate of mercury to the throat externally.

**Antiseptic Measures in Obstetric Practice Carried Too Far.**—Dr. D. W. Phillips, of Vallejo, Cal., writes us that he has become a convert to the Listerian system, has recently been extending his practice so as not to be charged with laxity of caution closely bordering upon criminality. Owning a large ranch, he supplements his private practice with veterinary duties. He injects a four per cent. solution of carbolic acid into the vagina of his cows before labor is expected, for several days, and also for several days after labor. Trying the same process on a favorite mare with foal, he and his syringe were kicked into an adjoining field, happily without serious injury.

**A Difference in Opinion.**—**The Lancet.**: "It may be said with safety and literal truth that medicines never played a more important part than they do now, that they never did so much good and so little harm as in the present practice of medicine. Let one month be imagined in London without chloroform, opium, atropine, quinine, iron, salicylic and its compounds, carbolic acid, iodide of potassium, ammonia, without common laxatives or cod-liver oil, and suffering and death would be immensely increased." Says Dr. Oliver Wendell Holmes: "I firmly believe that if all the drugs in the pharmacopoeia were thrown into the sea, it would be better for mankind, and worse for the fishes."

**Local Protective Union for Pharmacists.**—A call has been issued for a meeting of pharmacists in order to discuss the practicability of organizing a local pharmaceutical society. The object of the proposed society will be to protect the druggist and the public against the encroachment of irresponsible traders. Many representative men are engaged in the movement.

**Metrorrhagia From the Use of Salicylate of Soda.**—Dr. John D. Mulhane, of Steubenville, O., writes: "Referring to your article on 'The Action of Salicylate of Soda on the Uterus' (Medical Record, January 19th, page 69), I had a colored lady, four months pregnant, to whom I gave large and frequent doses of the above drug for arthritic rheumatism. After four days she complained of a mucous and bloody discharge, to account for which I was at a loss, till I saw above article. The drug was at once stopped. The discharge ceased, which at the time appeared to be a total cessation of menstrual flow. I have every reason to think it was due to the soda."

**A New School of Pharmacy.**—At the annual meeting of the King's County Pharmaceutical Society, held in Brooklyn, February 13th, a committee was appointed to confer with the authorities of the Long Island College Hospital in reference to the establishment of a school of pharmacy at that institution.

**A Case of Dislocation of the Stapes.**—Dr. Geo. O. Williams, of Greene, N. Y., sends us the history of a young man, who was severely wounded in the nose by a shot, and who, when seen, had.u been struck on the right ear after the discharge of cannon. Examination disclosed the following: Right ear, hearing 78. No discharge. Tymanum rather more translucent than normal, and appeared flabby. A complete outline of the stapes was clearly distinguishable, lying flat against the membrane which covered it loosely, exactly as if a smooth silk handkerchief was laid over an ordinary rup. The articulation between the head of the stapes and processus longus was interrupted as if from dislocation, the head being thrown outward.

**A Fasting Ataxic.**—It appears from a statement, which we owe to the courtesy of Mr. Charles Carey, of Bromsgrove, says the British Medical Journal, that there is, in the workhouse of that union, a man whose power of sustaining life for a considerable period without food is very remarkable. The man is named Hunt, and he is suffering from locomotor ataxia, with marked brain symptoms, and complete loss of vision. He said that he was "ordered not to eat anything by his Heavenly Father," and for thirty-five days he had no food, with the exception of a small piece of toast on the sixth day of his fast, and drank no liquid except water. During this period he did not show any signs of unusual weakness; he was able to sit up in bed, his movements were quick and prompt, his voice loud, and his manner abrupt; he had been invalided for about three years, and is unable to stand. Lately he has modified the rigor of his fast, and has consented to take milk and eggs.

**Persistent Cough Due to a Needle in the Chest-Wall.**—Dr. James H. Tabettes, of Chicago, sends us the history of a young man, who had suffered for two weeks from a persistent cough. On examining the chest, he found on the right side at the posterior portion of the axillary space between the sixth and seventh ribs a black thread, and by pulling upon it he extracted a bent and rusty needle. The cough ceased. Dr. T. does not say whether it penetrated the pleural cavity.

**A Case of Transposition of Viscera.**—Dr. H. Illoway, of Cincinnati, O., sends us an interesting and very complete description of a case of transposition of viscera in an otherwise healthy Austrian, aged forty-five. Dr. Illoway asks whether the case would be of sufficient interest to be shown at the college clinics in this city.

**Salt Pork in the External Auditory Meatus.**—Dr. Geo. O. Williams, of Greene, N. Y., writes: "A young lady was suffering from earache. On using the head-mirror, a greasy reflex was obtained from the deep portion of the auditory canal. With a small dental crochet a piece of salt pork as large as, and of similar shape to, a good-sized bean was removed. It had been introduced ten days previously as a domestic prescription for earache."

**Something New in Blood-Letting.**—A writer in the British Medical Journal had a patient over fifty years of age, who fell into a stupor, and from which he did not recover, and distended venous blood-vessels. He proposed bleeding, but the attendants were horrified. He then took an aspirator and quietly introduced it into the left jugular vein which was much distended, and four ounces of blood was taken. In half an hour the result was so satisfactory, that the operation was repeated, and six ounces more were taken. She soon recovered, and in the course of a few days her nervous friends had any idea that she had been bled, until the process was subsequently explained to them.

**An Old Woman.**—The Allgemeine Medicinische Central- Zeitung states that there lives in the village of Zwanowka, Russia, a woman who is one hundred and thirty-one years old. She is still in "blooming health." She has had twenty children, of whom two only, aged seventy and eighty, are living.
Original Lectures.

ON THE

METHODS OF STUDYING THE BRAIN.

ABSTRACT OF THE CARTWRIGHT LECTURES, DELIVERED BEFORE THE ALUMNI ASSOCIATION OF THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK, FEBRUARY 2, 4, AND 6, 1854.

BY BURT G. WILDER, M.D.,
PROFESSOR OF PHYSIOLOGY, COMPARATIVE ANATOMY, AND ZOOLOGY IN CORNELL UNIVERSITY, AND OF PHYSIOLOGY IN THE MEDICAL SCHOOL OF MAINE.

(Continued from page 32.)

LECTURE III.

SOME POINTS IN ENCEPHALIC ANATOMY WHICH ARE NOT INFREQUENTLY OVERLOOKED OR MISUNDERSTOOD.

As announced in the first lecture, the third comprises two parts, dealing respectively, with (a) certain facts in encephalic anatomy, and (b) methods of illustration and description.

In the choice of anatomical matters, three objects have been kept in view: 1, in general, the illustration of the methods described in the earlier lectures; in particular, 2, the elucidation of euclian circumscriptio; and, 3, the correction or qualification of statements or figures in two English manuals of descriptive anatomy, Quain and Gray.

If any are startled at the intimation of possible imperfection in works to which students refer with confidence, and upon which, it is to be feared, some teachers too implicitly rely, they have only to compare the accounts of the brain in any two similar anatomical treatises, or in different editions of the same. In Quain, for example, so great are the textual and pictorial improvements of the edition of 1882 over that of 1877, that our admiration for the excellence of the one is qualified both by surprise at the defects of the other and by fear lest still further change may be required.

In respect to the macroscopic anatomy of the brain, the shortcomings of the two admirable works above named may be treated as: a, omissions; b, inaccuracies; c, statements or figures liable to cause misconception.

a. Omissions. — Balbus postcornu. — As previously stated, the mesial wall of the postcornu presents not only the calcar, but also, just dorsal of it, an elevation which Henle calls Balbus cornu posterioris. It is not mentioned in the last edition of Gray, and in the last of Quain it is for the first time described, but not figured.

Cauda striati. — That the human striatum is prolonged as a slender "tail" following the remarkable curvature of the medinicum and terminating at or near the tip of the latter, is indicated in Cuvier's "Leçons d'anatomie comparée," in the editions of 1800–1805 and 1836–1846. This feature of the striatum is also described in the paper by Reichert, Meynert, also, as stated by Dalton, by Gratiolet, Dodd, and Hirschfeld, and more recently Dalton himself in the paper just mentioned.

In Quain the cauda is described as "passing nearly to the extremity" of the medinicum, but it is not distinctly shown in the figures. In Gray its existence is not recognized at all.

Cimba (Tractus transversus pedunculi, Gudden). — According to Gudden and Forel, in many mammals, and sometimes in man, there crosses the crus cerebri, between the pons and the tractus opticus, a fibrous fasciculus which is said by Meynert to have been observed first by Inzani and Lemoigne.

Even if Henle is correct in stating that this fasciculus is only exceptionally present in man, some reference to it should be made in textbooks like Gray and Quain.

Striae longitudinales callosi. — Here may be noted the lack of recognition, not only in the works above named, but in all others that have come under my notice, of the easily determined relation between the furrows and ridges along the meson of the dorsal surface of the callosum and the anterior cerebral arteries. Whether or not the pressure of the arteries is the sole cause of the two parallel furrows and the three corresponding ridges (Striae longitudinales, Nerivi Lancisi, etc.), the arteries lie in the furrows in all the brains examined by me in which the latter are distinguishable.

b. Inaccuracies. — Under this head may be embraced errors which are comparatively trivial, which have no direct bearing upon larger questions of morphology or physiology, but which deserve attention, both because they go to make up descriptive anatomy, and because so long as they remain on the principle falsus in uno, falsus in omnibus — distrust of other matters may be entertained.

"Centrum ovale magius." — The name is placed in quotation-marks in order to indicate at the outset the fact that what is commonly understood thereby has no real existence. Not only in Quain and Gray, but in nearly every anatomical treatise published during the last hundred years, where the following statements, expressed or implied, either in words or in figures, or in both:

"When the dorsal portions of the cerebral hemispheres are removed by a section coinciding with the dorsal surface of the callosum, the latter forms, with the cut surface of the hemispheres, a continuous and unbroken area of alba (white or mediullary substance), bordered on one side by the convoluted cinerea (gray substance, cortex) of the gyr. This area is the centrum ovale magius, to distinguish it from the centrum ovale minus — the area of alba bordered by cinerea which is seen when either hemisphere is sliced at some distance dorsal of the callosum."

The facts are, however: 1. The dorsoesial line of the callosum is not straight, but curved throughout its whole length; so as to necessitate a choice of the parts with which the plane of section is to coincide. 2. A horizontal straight line drawn lateral from most points in the dorsoesial line of the callosum will intersect the prosccia, so that the latter is exposed by the section described.

So far as I know, this error was first corrected by Dalton. In the course of description of some macroscopic sections of the brain before the New York Academy of Medicine, March 6, 1879, Dr. Dalton stated that "the centrum ovale (magus) as represented in the books did not exist, and was a picture of the imagination. The reason was that the corpus callosum, instead of being a plane, was an arched commissure, and it was

1 As reported in THE MEDICAL RECORD, April 9, 1880.
impossible to make sections which would show what the book illustrated."

The callosum is not only arched, but arched both ways. The general and splenial ends are lower than the intermediate portion, and the lateral portions are higher than the mesial. It may be compared to an inverted saddle. The relative levels and thicknesses of the mesial and lateral portions are such that the lower surface of the latter is higher than the upper surface of the former, and the two prococcal cells are opened by a section such as is usually described.

Commissura fornicis.—In 1861, Reichert represented the fornix, as transected at or near the plane of the medicoamina], as consisting of thick lateral masses conjoined across the meson by a thin lamina, to which he gave the name Commissura corporis fornicis, or Commisson des Géneis.

Notwithstanding the classical nature of the work just referred to, I have yet to see a recognition of the name or of the anatomical feature indicated thereby.

In reality, in an adult human brain well hardened by alcohol, the thickness of the fornix along the mesial dorsad of the dieace is not more than 1 mm., one-fourth or one-fifth that of the thicker part of the lateral masses.

The complete circumcision of the tip of the medicoamina by nervous matter.—Without discussing here a point which was referred to in Lecture I, and which will be considered more fully farther on, it may be admitted that, along a line extending for most of the length of the medicoamina ("cornu descendens"), the proper nervous wall is abrogated so as to constitute the rima (part of the so-called "great transverse fissure"), and that along this line the body of the thalami terminating the pro-plexus finds its way into the cornu. These parts are commonly described so as to imply that the rima and the plexus extend to the extremity of the cornu, and that the latter therefore is in no part of its length completely surrounded by a continuous wall of nervous tissue.

In Gray the rima is said to extend "to the end of the descending cornu." In Quain the statements are even more explicit: The rima is said to extend "from the extremity of the descending cornu;" the choroid plexus "to the point;" and the choroid artery to enter "at the lower end." The same are expressed or implied in most works upon Descriptive Anatomy, and in Leu- ret and Gratiolet, notwithstanding the very clear represen- tations given of the thick, muscular wall by Rémy and vious or urgent physiological argument applies to the brain, but, from the purely morphological side, the as- cect which should be considered in advance of both de- scriptive anatomy and the study of function, there is equal need to determine the extent and manner in which the encephalic cavities are circumcised.

Judging from personal experience, from common re- port, and from standard and current anatomical litera- ture, as a basis for the comprehension of the structure of the brain, nothing is more essential than a clear and correct idea of ecalian circumcision, and, at the same time, nothing is more difficult to obtain.

The neurological expert may not need to be informed, and there are doubtless graduates in medicine who merely "follow a trade," and, like the poorer class of mechanics, hold thinking to be a waste of the time that might be spent in learning practical rules of thumb. But among the more earnest and intelligent members of the profession there are surely many who, at some period of their course, have been haunted and almost tor- mented by the fact that they have no clear idea of the figures in the descriptive portions of their anatomical manuals with the ideas which seem to be inculcated in the embryological divisions of the same works or in treatises upon comparative anatomy. These morpho- logical notions constitute, as it were, principles of anat- omy which are at variance with what are commonly sup- posed to be facts. This result is a state of intellectual unrest quite comparable with the moral disquiet which is caused by an endeavor to harmonize the golden rule with the habit of self-indulgence.

It would seem that some of our anatomical prede- cessors were less burdened with morphological scruples. Two centuries ago Helkiah Crooke wrote as follows:

"Archangelus makes mention of a passage which is in the middle and hath a double issue, one directly into the ventricles we speak of, the other into the palate and so into the lungs. This passage is known to but few. [The italics are mine.] Neither can it be found but in a sound brain when the man cometh to a sudden and unlooked-for end and is presently dissected; for the passage of the brain is so narrow that a knife of a short time so fall and close together that the passage is clean obliterated."

Nur need we go so far back for misconception as to the relations of the encephalic cavities. Tiedemann and

---

1 This sounds almost like a prophecy of the comparatively recent determination of the manner of formation of the hypophysis as a diverticulum from the mouth. See Quain, ii, 834, and the papers there mentioned.
Solly described the lateral ventricles as resulting from the folding over of the hemispheres; the existence and position of a communication between the third and the fifth ventricles was distinctly denied by Heidemann, Leuret, Gratialet, and others; in the eighth edition of Quain such a communication is admitted to exist in human embryos and some animals, and it would be hard to place in a single column a greater number of perplexing misstatements than occur in Todd’s account of the ventricles in the “Cyclopedia of Anatomy and Physiology.”

In the text of the latest editions of Quain and Gray occur very few positive errors with regard to occipital circumcision.

The figures, however, are less satisfactory. Admitting that each figure fairly and correctly illustrates one or more experiments in encephalic anatomy, nevertheless, in the works above named, and even in the more elaborate treatise of Henle, besides errors and omissions in regard to other matters, every figure where the immediate occipital parietes are represented either fails to convey any information at all, or indicates the reverse of the truth with regard to occipital circumcision. This feature of the illustrations would be less puzzling if the extent and manner of occipital circumcision were fully illustrated in special figures or treated in the text otherwise than indirectly, or even if it were stated that the encephalic cavities are or are not completely inclosed, but that the figures are not designed to illustrate the matter in detail.

Original Articles.

THE TREATMENT OF CROUP BY TRACHEOTOMY.1

BY JOHN H. RIPLEY, M.D.,
PROFESSOR OF DISEASES OF CHILDREN, NEW YORK POLYCLINIC.

If anything more than clinical observation were needed to impress upon the profession the importance of the subject of membranous croup, it could be obtained from the mortuary returns of the Boards of Health of New York City and Brooklyn. During the last five years there have been reported to the Brooklyn Board of Health seventeen hundred and sixty deaths from croup. Dr. Lewis S. Plichar,2 in 1877, reported that it had risen in the scale of deaths in Brooklyn, from eleventh place in 1870, to fifth place in 1876. In New York City, during the last five years, there have been registered thirty-eight hundred and forty-three deaths from the same disease. So that we may say a yearly average of seven hundred families have been compelled to watch a low death of a child by suffocation, while we still leave a margin for a number of families that must witness the same struggle repeated with a second or even a third child. Now this woful mortality results not from the fact that croup is so remarkably prevalent in these two cities; but because it is in large majority of cases fatal. It was with the view of combating clinical theories, and adding something to our general stock of therapeutical knowledge of the subject, as I suppose, that Dr. Smith presented his paper for discussion.

In 1865 I ascertained, from a medical journal of good standing, that a solution of lactic acid, fifteen to twenty drops of an ounce of water, thrown into the fauces and larynx every half-hour, or even every hour, by means of an atomizer, together with the internal administration of fifteen grains of the bicarbonate of soda every hour, would cure every case of true croup in from seven to ten hours. This was vouched for by a physician of excellent standing, who had been seventeen years crystallizing his views. I made a note of it at once. This cure, like many which physician uses since it received it, has become a lost art. Up to the present time, it would seem that the only solvent for croup membranes which has acquired any enduring fame is lime-water. This remedy has the advantages that it is an efficient solvent of these membranes under favorable circumstances, and that it is, if not powerful for good, at least harmless for evil. As rules every physician uses it in some form for croup, it has from time to time received a good deal of unmerited praise. A small proportion of children attacked with true croup will recover under any plan of treatment. During the last three years I have known of six recoveries without surgical interference. In two of them purest mintry if was given credit for in result; in two the continued application of ice to the larynx; in another a single thirty-grain dose of calomel caused the membrane to exfoliate; in the fifth a solution of bichloride of mercury exhibited locally and constitutionally effected a cure; finally, in the last case, the parents believe that the discharging of the three doctors in attendance and the subsequent adoption of the measures used by themselves saved the child’s life. Cumulative illustrations could be furnished, and are from time to time published in the medical journals, showing, not that cures for croup have been discovered, but how very strong theories can be reared on very weak bases. In the use of Dr. Smith’s new combination I have had no experience, but I will say it has commended itself to me.

My faith in lime-water, like Jacobii’s, has diminished since I have seen so little result in cases where I could freely apply it to the parts invaded, namely, to the trachea and bronchi after tracheotomy.

Dr. Jos. O’Dwyer, of this city, not knowing that some what similar attempts had been made before by others, began a series of experiments on croup children by tubbing the larynx. He has kindly written to me the result of his experience:

DEAR DOCTOR: In compliance with your request I send you the following epitome of my experience in the treatment of croup by tubbing the larynx. During the past three years I have used various modifications of a bivalve tube introduced into the larynx through the mouth, in thirteen cases of croup.

Relief to the dyspnea, more or less complete, was obtained in all except one, and lasted from a few hours up to the third day. The ages varied from five months to five years.

The onset of irritation produced in the larynx was in some cases very considerable, in others slight; a quiet sleep following the introduction of the tube being the rule. Difficulty of taking nourishment by the mouth existed in all except one, which was a septic case. One case, a little girl aged three and a half years, lived ten days after the tube was removed, dying of double pneumonia.

On three of the most favorable cases tracheotomy was subsequently performed, one of which recovered.

Ten of these cases were examined after death. In seven membrane was found in larynx, trachea, and bronchi. Two of these seven had also well-marked pneumonia; in one it was doubtful whether there was some infiltration or not; in four there was none that could be detected. One case was only partially examined, trachea and larynx, and membrane found in both. One case had double pneumonia, which was known to exist before the development of croup. Very little membrane was found in this case, the stenosis of larynx being principally due to swelling of the mucous membrane; and lastly the case of pneumonia above noted. I enclose the last modification of the bivalve tube that I used; the object of leaving it in this form being simply to make it self-retaining. A fatal objection to it is the open space left below, through which the swollen mucous membrane protrudes. I have abandoned its use and recently had

2 Croup and Tracheotomy in the City of Brooklyn, May, 1879.
made a plain elliptical tube, which I also enclose, but which I have not yet tried. Should it not prove self-preserving in its present form, I believe it can be so modified as to make it so.

Yours sincerely,

J. O'Dwyer.

It would seem, from this report, that one child was rescued from croup by the tube, although it subsequently died of pneumonia. Although this procedure, said to have originated with Dessault and subsequently condemned by Trousseau, has been repeatedly practised without much success, it certainly could succeed in a limited number of cases if it were possible by any means to differentiate the suitable ones. Thus far in the history of the treatment of croup, tracheotomy has done more harm than all croup operations combined. The further remarks in this paper will for the most part relate to this operation, and I propose first to consider the indications.

Indications for tracheotomy.—It would seem that there could be no indication where there is no croup, and yet I have known of operations being proposed where certainly there was no croup, as in the larynx or tubes beyond, but only nasal obstruction with mild catarrh of the larynx. Once I saw a case of double pneumonia with laryngeal catarrh, supposed to be croup, which had been subjected to a most exhausting course of emesis by turpeth-mineral. These mistakes could not occur where the physical signs are relied on. On the contrary, the experience of the author of the paper which is before us, in losing a child from suffocation during the night, that he thought would not need tracheotomy before morning, is not exceptional. Miscalculations of this kind will occur, and the only way to avoid so painful a result is to have a competent person on duty who has been sent out last half a dozen times to operate for croup and found the children dead when I arrived. In one of these cases the attending physician had not seen the child for twelve hours before calling me. The night-time is the most dangerous part of the twenty-four hours during which to leave a croup patient without a watcher.

Now, while I am in favor of closely watching cases of croup, and of being prepared to operate promptly, I am not, as a rule, in favor of very early operations. I agree with Dr. Smith that the operation should be done sufficiently early to give the operator time to do it carefully, and when once it has been decided that there is no probable chance without it, it is cruelty to the child to delay. There are cases which justify, perhaps demand, early surgical interference. Infants under two years of age, and especially those less than a year old, succumb very rapidly, often rather suddenly, to the disease, and we may not wait too long. Profound blood-poisoning or other complication may exist, which makes it dangerous and even prejudicial to recovery to delay. The operator may live a distance from the patient and be so situated that it is impracticable to postpone operating. But, ordinarily, I should say we ought to wait until the respiration becomes continuously laboured, with marked symptoms of cyanosis and beginning failure of the vital powers.

A teacher of medicine, justly distinguished in other diseases of the respiratory organs, was accustomed to advise his students that whenever croup had advanced so far that inspiration was accompanied with epigastic and supra-ternal recessions, an operation would be useless. Of course, these symptoms are pathognomonic of prevesicular obstruction, especially laryngeal stenosis, and until they appear an operation is not indicated. A croupy cough, stridulous breathing, and aphonia may be present, and yet no sufficient stenosis of the larynx exist to demand tracheotomy. Early operations are not infrequently unnecessary operations—a harmless catarrhal laryngitis being mistaken for a pseudo-membranous croup, or a mild case of croup being operated on which would have recovered without surgical interference. Unnecessary operations are to be avoided for the following reasons: 1. Because they are of immediate danger to the child's life. 2. They endanger it secondarily by erysipelas, abscess, and other consequences. 3. They may permanently injure the trachea and larynx.

If I agreed with those who believe that tracheotomy predisposes to pneumonia, I should still more strongly urge against early operations.

Contra-indications.—In regard to contra-indications, I am confirmed by additional experience in the opinion that I expressed four years ago, viz.: "That tracheotomy for croup is always a justifiable operation if the paramount factor in causing death be apnoea." I would tracheotomise a child dying of croup even although I knew it to be suffering at the same time from extensive bronchitis, pneumonia, or uremia, or all three of these complicating diseases. There is a prevalent opinion that it is possible to distinguish favorable from unfavorable cases before the operation, and thus the operator is enabled to "select his cases. If this were so it seems to me that it would be very inhuman in a surgeon to practise it. Surely he should not abandon a number of children to certain death by suffocation on account of endangering his reputation as a successful operator. But, as a matter of fact, a prognosis based on the condition of the child before the operation is unreliable. Especially is this true when such prognosis rests on the result of a physical examination of the child, which may be accepted only as true in one of the cases which he reported at the last meeting. The physical sign which is of most value before operation in respect to the lungs is percussion. Generally this sign will give increased resonance over both lungs, and that, of course, excludes pneumonia. The auscultatory signs are so obscured and perverted by the laryngeal and bronchial sounds, that they have also been of little service. The pulsation of the bronchial membrane which have fallen into the larger bronchi, that little reliable information can be obtained by auscultation. I have known many a case of supposed bronchial croup clear up as soon as the tube was in the trachea. Severe nephritis and profound toxemia of course lessen the chances of recovery. Uremia especially seems to increase the tendency to the formation and extension of membrane.

Although infants under one year old are not very promising for tracheotomy, still such cases are not entirely hopeless, as is shown by statistics. One of the most remarkable instances of recovery at this early age was a child eleven months old, under the care of Dr. C. F. S. I cannot speak of the extent of the cellular infiltration about the neck, the nose and pharynx were the seat of membrane, and the constitutional symptoms were marked (MEDICAL RECORD, vol. xxii., p. 512). If diphteritic deposit on the faucets or in the nasal passages has preceded the onset of the croup for a number of days, I consider it a favorable circumstance. For, in my opinion, the disease is self-limited, and the nearer we get to the termination of it before the larynx is invaded, the less the danger of extension of membrane into the bronchi. Malaria, erysipelas, and other complicating diseases prolong its course and increase its severity. In certain published reports of discussions on the subject of tracheotomy for croup I see that a number of surgeons argue against the operation in diphteritic croup, because, as they say, all such cases terminate fatally; whereas, in "genuine membranous croup," as they call it, the operation sometimes saves life, and hence they advocate it. Even the author of the paper under discussion, who is the standard-bearer in this city of those who believe in maintenance of conditions as contagious, thinks that the croup which has prevailed in New York City during the last few years is diphteritic; so that to question recovery from diphteritic croup is to ignore a considerable part of Dr. Smith's statistics. If contagious, systemic poli-
soning, albuminuria, and secondary paralyses are sufficient proofs that cases were diphtheritic, then we can show recoveries from diphtheritic croup after tracheotomy. In seventy of my own operations in which I have carefully noted whether the croup were primary, or occurred secondarily after several days' illness from nasal or pharyngeal sources, or one of the eruptive diseases, the proportion of recoveries in twenty-five cases of late croup was forty per cent.; in primary, twenty-four per cent.

**Prognosis.—**The prognosis after the operation will depend in a majority of cases on whether membrane forms to such an extent below the tube as to involve external pharyngeal poles, and so produce secondary or bronchial croup. Pneumonia, whether catarhal or croupous, has been, in my experience, an exceedingly rare cause of death after tracheotomy, and I do not see why it should be otherwise. Diphtheria itself has very little tendency to localize in the deeper air-passages, except by extension of the membrane downward from the larynx. Ascending groups are mentioned as occurring, but they do not often come under observation. Only those children die of lung complications, as a rule, that first have croup. The inflammation of the mucous membrane of the bronchi only keeps pace with the exudation of membrane upon its surface, so that, long before either the exudation or the inflammation can reach the airways, they have finally closed, and death takes place. This has even proved true in two cases of adults that I have seen, although, for obvious reasons, they were able to bear a more extensive invasion.

As to the theory that the admission of cold air into the lungs has a tendency to excite pneumonia, I do not think that is sustained by either clinical observation or experimental research. I certainly do not regard tracheotomy as a number of times for other obstructions than croup, and have known of its being done by others, with no such precautions as we ordinarily take with these little children, and yet not even a general bronchitis has been caused. There have been several tracheotomized vagrants about the city, one of whom had phthisis, that seemed to suffer very little from their exposures.

I have here a letter written by a patient whom I tracheotomized for Dr. Charles F. Stillman, over six years ago, for chronic laryngitis. He is still wearing the tube, as appears, with very little discomfort. It seems to be a settled conviction with those who hold the pneumonitis theory, that when their patients get this complication a fatal result is not long in following, and that a number of the first recoveries from this alleged condition. To me such a diagnosis would carry with it a comparatively favorable prognosis, inasmuch as quite a percentage of recoveries take place from secondary pneumonias in other infectious diseases. Other reasons why this secondary lesion is not pneumonia might be assigned, especially a consideration of the course of the disease and of the physical signs attending it; but after all the question is, "What do we find at the autopsy?" Steiner says: "Pneumonia is a much rarer complication of croup than is commonly supposed. Sometimes it occurs in a lobular, less frequently in a lobar form. In seventy-two autopsies I found the former variety only eight times, the lobar diffuse pneumonia only six times; hence I am surprised that some writers regard pneumonia as one of the most frequent complications of croup." How much these fourteen pneumonias had to do with causing death, the author does not say. In ten autopsies made by Dr. J. O'Dwyer on the bodies of infants that died with croup, all the cases having been treated variously by tubing the larynx, and two of them later by tracheotomy, pneumonia was found in three instances. In one it had preceded the croup and was the cause of death. In one it complicated the croup and was a factor in causing death. In the third there was not sufficient infiltration to influence the result. In private practice it is very difficult to obtain autopsies on the bodies of children that have been sub-jected to tracheotomy, and hence I have had an opportunity of attending only seven post-mortem examinations. In only one of these was there pneumonia, and that was limited to the upper lobe of the right lung. In the other cases there were present in the lungs, chiefly, extensive bronchial croup, scattered areas of collapse, and consequences vesicular and interstitial emphymas. If the children could live long enough, I suppose the collapsed portions would be succeeded by pneumonia.

During the last three years I have saved nearly one-third of the children that I have operated on for croup, not on account of any new and especially valuable treatment that I have adopted, but because there has been less tendency to late complications than after tracheotomy into the bronchi. The course of the disease varies in different epidemics, and from time to time in this city, where it seems to be endemic. In my first experience with diphtheria it was rare to have croup complication. Steiner says: "In North America the implication of the bronchi seems to have been noticed very frequently, while in England during recent epidemics it has been strikingly rare." This comparative exemption of the bronchi from membranous deposit may serve to explain, in a great measure, the remarkable success from tracheotomy which Dr. Smith has quoted from abroad.

**Tracheotomy.—**Tracheotomy for croup is said by many to be a simple operation, and quite free from danger. The reasons that have been applied to this are true. One is that the operation is not so desperate as it is true. But, generally, as Dr. Leale says, it is not only a difficult operation, but one attended with great immediate danger to the life of the patient. The operation itself has been so often described that I will only say a few words in regard to some practical points connected with it.

I prefer to operate below the isthmus, because (1) the caliber of the trachea is greater at that point than above, and (2) because I can subsequently explore the interior of the trachea better in case of obstruction or other trouble; and (3) I believe there is less danger of permanent injury to the larynx, especially if the tube is to remain in a long time. On the other hand, I do not favor opening the trachea lower down than necessary. The superficial incision should not reach nearer than within half an inch of the sternal notch, which is an important landmark during the operation. For nothing is to be gained by having the tube reach a half-inch further down in the trachea, and when the opening is too low, on account of the anatomical relation of the trachea to the carotid sheath, the chances of temporary asphyxia are made to fit either accurately or comfortably. Besides, there is danger of wounding the innominate artery in this very low operation, as has already happened. Lastly, the anterior mediastinum is frequently opened into in very low operations, producing mediastinal emphysema, sometimes mediastinal abscess. This emphysema I have twice found at autopsies and referred to before. I believe if the admission of air into this space ceases as soon as the operation is completed, little harm is done, unless other matters also escape into it, as blood and pus from the tracheal opening. But if continued, on account of a large incision in the trachea, a comparatively small tube, and a close suturing of the superficial soft parts about the tube, it might become a source of embarrassment to the thoracic organs. Emphysema of the superficial cellular tissue of the neck can always be prevented by seeing that the tube extends well into the trachea and that the soft parts are not closed too tightly around the tube. This seems to be quite a common accident. After the tracheotomy is made, if desired there is ordinary time and opportunity for examining its interior, and extracting any loose pieces of membrane that may be present; but it is a fruitless and dangerous task to attempt to swab out a trachea lined with adherent membrane as one would a foul gun-barrel. Such membrane is not likely to do harm, even in the way of obstruction.
I was glad to hear Dr. Lange give the weight of his opinion in favor of using a tube after the operation. If these instruments fit properly they cannot do harm. I have already referred to patients who have worn them for years. The most suitable are those made of silver, consisting of a double canula, the external fenestrated, and the inner tube placed six inches to the outer half being attached to the outer extremity. I lost one child, as I believe, that was progressing favorably, by having in use at the time a non-fenestrated canula. While the mother, alone with the child, was cleaning the inner tube the outer one became suddenly obstructed, and the child immediately suffocated. Had there been a fenestra above, this accident might have been avoided. A tube is easily managed and keeps the way open as far as it reaches. As a rule, children breathe better when it is in place than without it, even although the superficial part of the wound be widely separated by inflammatory process, and the tracheal opening be enlarged by excision of a portion of the anterior wall. In the absence of a tube the same accident is likely to happen as was met with by both Dr. Lange and myself, namely, the mechanical closing of the opening by a twist or bend of the neck. In my case the child would certainly have died within a few minutes more had it not been relieved.

After-treatment.—It would no doubt materially increase the number of recoveries after tracheotomy, a complication, one especially skilled in the management of these cases, could be kept in continuous attendance until convalescence should be fully established. I have lost four children by suffocation from obstruction of the tube, and two of them would almost certainly have recovered but for this accident. In most of the cases that I have operated on during the last four years, no matter what has been given until after the establishment of convalescence. In nearly all, stimulants in the shape of brandy, whiskey, or champagne, have been taken freely. Milk has formed the principal article of diet. Iron, cod-liver oil, and hypophosphites have been given later. Locally, so far as membrane of the wound, saucers, or nose was concerned, I have done substantially nothing. If scirr discharges from the nose or wound were producing exoriation of the contiguous parts, I have tried to keep the offending parts clean. Whenever I have had harsh and obstructed breathing I have used simple steam or lime-water spray.

They do good by liquefying the inspissated mucous-purulent secretions in the variousous membranes moist, and so palliate the symptoms. I do not believe steam, whether simple or that evolved from slaking lime, is of much practical value in dissolving croup membrane. I have been a party to the treatment of at least twenty cases of croup with lime-steam, and I have yet to see the first recovery. The only apparent solvent effect on membrane that I have ever observed by the use of lime-water in croup has been in a few cases of large children, where I have been able to spray or pour it into the trachea by the teaspoonful, repeating the operation in one case every hour, nearly for thirty-six hours. It seemed, in two cases at least, to gradually relieve the secondary dyspnoea. With lactic acid my experience corresponds to that of Jacob, that is, I saw one child apparently benefited by its use several years ago, but none since, although I have seen it used many times.

After the tube is permanently removed it is not necessary to either suture or strap the wound. A little pad of marine oaukum or other clean and porous material placed under the chin will sufficiently protect it until heals, which will require but a few days provided the child has recovered from the disease.

DR. VAILLE.—Dr. R. C. Newton writes that Dr. Vaille, to whom he referred in an article (Medical Record, Jan. 19, 1884), is still living, although retired from practice.

SYPHILIS AND LOCOMOTOR ATAXIA.

By LEONARD WEBER, M.D.

NEW YORK.

PATHOLOGISTS have not succeeded as yet in demonstrating a syphilitic sclerosis of the posterior columns of the cord, but clinically, the question of a causal nexus between syphilis and tabes has assumed considerable importance. The number of observers who believe in a syphilitic origin of many cases of tabes is large, probably larger than those who deny such origin, although the latter have among them many of great authority and experience. The question being far from settled, the practitioner has the privilege as well as the duty to contribute his mite of experience in a matter of such clinical significance.

In former years, the search for syphilitic lesions of the central nervous system in the dead body was limited to the brain, and the cord was generally forgotten, or rather neglected, on account of the difficulty and loss of time which is met with in its dissection. Although Romberg, Wunderlich, Virchow, and others spoke of syphilis as an etiological factor in tabes, already thirty years ago, no modern clinician was so emphatic in pronouncing his belief that syphilis may produce an ataxia of its own, as A. Fournier, 1876. The proofs of his assertion are mainly statistical; he does not deny that syphilitic tabes may be typical and atypical, and that it has no pathognomonic symptoms. But from a diagnostic point of view he lays great stress upon the types incompletes, the irregular forms of syphilitic tabes, and distinguishes:

1. The lumbar or exclusively spinal type, in which the cerebral nerves are not affected.

2. The cephalic type, where the cerebral nerves participate.

3. The ophthalmic or amaurotic type.

It is hardly necessary to say that we meet with Fournier's types incompletes in ordinary tabes as well as that of syphilitic origin, but his experience that tabes may occur in cases where there are other specific lesions of the nervous system, or may follow the latter, is an important observation.

Grasset and Vulpin, Férot and Liredoy, hold similar opinions; William A. Hammond mentions syphilis as a very probable cause of tabes, and Hutchinson repeatedly speaks of syphilitic ataxia.

Within the last four or five years the Germans have given much attention to the pathological connection between syphilis and tabes, and Berger, 1878, and Erb, 1879, were the first, I believe, who studied the question clinically. Berger is convinced that many cases of tabes are of syphilitic origin; Erb believes that constitutional syphilis often creates a predisposition to tabes, and accepts Fournier's tenet, that in all cases of tabes, whether syphilitic or non-syphilitic, a specific treatment should be employed. The question of syphilitic localization in the cord in such cases, or of the presence of a specific sort of sclerosis, he leaves for future pathological research to decide. I conversed with Erb a few weeks, before he published his first paper on the subject in Deutsches Archiv für Klin. Med., xxiv., 1879, and perceiving the clinical importance of the matter, I have since written up the history of cases which I have had in my practice, and inquired into their bearing upon this question.

Erb's views, though supported by a formidable array of statistics, were not received with great favor at the International Medical Congress, held in London in 1881, and the evidence of the importance of physicians who took part in the discussion of his paper did not coincide with his own.

Again, at the meeting of neurologists and alienists at Baden-Baden, in June, 1883, Erb reports another hundred cases of tabes in the etiology of which all important factors have been examined into, and has found no di-

1 Read before the New York Academy of Medicine, at its meeting on March 9th.
rect hereditary influence in typical tabs, and that a neurotic disposition has but little to do with it, the majority of the patients having been previously in rather robust health. But syphilis he finds the most important cause; 91 of the patients had over twenty-five and syphilis respectively. 9 only had neither, 69 developed symptoms of ataxia in the first fifteen years of syphilitic infection, 15 between sixteen and twenty years thereafter, the others still later. The same or nearly the same results are given in the statistics of Fournier, 93 per cent.; Rumpf, 66 per cent.; Voigt, 81 per cent., and G. Fischer, 72 per cent. Of 22 of the former's cases had chronic and syphilis, respectively, only 22.75 had syphilitic antecedents. In 3 only out of 109 cases of locomotor ataxia, rheumatic influences were thought to be the only cause. Sexual excess and trauma had but little influence in producing tabs, according to Erb. Myosis, and particularly the Robertson pupil, as well as the paralytic affections of the muscles of the eye-ball—symptoms that occur by themselves mainly in syphilis—also speak for the syphilitic character of tabs. Tabetic women frequently have a syphilitic history. Erb finally says, "tabs is probably a syphilitic affection, the development and local area of which are determined by predisposing causes." Prof. O. Siegmund, a firm believer in syphilitic tabs, and says that it is particularly apt to develop in those individuals who have suffered much from specific cutaneous lesions. Why syphilitic exanthemata and ulcerations of the skin should be followed by tabs any more than non-specific exanthemata and chronic ulcerations, which occur so frequently, I fail to see. Among those who explain tabes as caused by convulsions, of syphilis and tabs, or hold their opinion in reserve, we find Moxon ("Guy's Hospital Reports," Series iii., vol. xvi., 1871) ready to deny the etiological influence of syphilis in tabs, as he has not been able to find a trace of syphilitic lesion in 17 autopsies of cases of posterior degeneration of the cord. Lancereaux, in his well-known work, says in 1873, treating with syphilitic myelitis, but not of syphilitic degeneration of the posterior columns. Westphal, in a discussion on the subject (Berl. Klin. Woch., p. 141, 1880), says that the autopsies of tabetic individuals, as well as the statistics within his reach, militate against the etiological connection of syphilis and tabs. Again, in a sequel to a paper on the subject (Archiv für die ges. Neurol. Kran. Geb., 1873), he comes to the conclusion that no sufficient pathological nor clinical proofs have as yet been brought forward to make the etiology between syphilis and tabs certain, or even probable.

M. Rosenthal (Wien. Med. Presse, 1881, Nos. 3, 6, 7, and 9) is as decided as Westphal in his opposition, and finds that the opposing party have used the statistics to suit their own particular views. Among his cases of tabs with a syphilitic history he cites seven in which the symptoms of specific myelitis were greatly improved by specific treatment, while the clinical features of ataxia remained as before. He maintains that the therapeutic results in typical tabs after syphilis are as unsatisfactory as in cases of ataxia due to other causes, and therefore cannot be the direct cause of posterior sclerosis. That diffuse spinal syphilis may give rise to ataxic symptoms he does not consider unlikely.

In looking over the statistics of tabs in the course of syphilis we are surprised by the enormous difference in the percentage reported by the various authors. Here we have Fluckingham: 36 per cent.; W. R. Birdsell: 9.5 per cent.; Westphal: 14.6 per cent.; M. Rosenthal with 18 per cent.; O. Berger, 20 per cent.; Remak, 21 per cent.; Gowers, 70 per cent.; G. Mayer, 70 per cent.; Fournier, 80 per cent.; Erb, 88 per cent., and in his last report with 93 per cent.; A. Reumont ("Syphilis and Tabs," 1881), 68 per cent. It is easy to see that the inquiry as to syphilis in the anamnesis of tabetic cases has not been as rigid as might have been. It is quite certain that specialists like Fournier, and physicians practising at certain watering-places where a good many syphilitic patients come for treatment—like G. Mayer, Voigt, and others—will have a much higher percentage than other practitioners. Erb's and Gower's high figures would show that they have been particularly searching in their inquiry into the antecedents of their tabetic patients, and were satisfied to attribute the spinal disorder to syphilis when present in the history of the patient. These statistics prove one thing beyond a doubt, that syphilis occurs frequently in the anamnesis of ataxia, and corroborate the fact which is more and more appreciated—that syphilis in ataxia is very common and that in luetic persons serious lesions of the central nervous system occur, which probably would not have developed if they had not had the syphilitic cachexia.

Siegmund (Wien. Klin. für Syph., p. 33, 1878) having of all observers probably the largest material at his disposal, gives the statistics of cases of syphilis observed in his work. Of 2,407 cases of ataxia, 394, or 16.4 per cent., go to show that the disease is on the increase relatively and absolutely; and he is constrained to say that syphilis is the worst of all diseases afflicting humanity, because the most insidious—poisoning the present and tainting the future generations—a statement in which I fully concur after an experience of more than twenty years in practice among all classes of society, and the importance of which for practical purposes was recognized in the discussion of an interesting paper read before this Academy by Dr. Sturgis about two years ago. We are not satisfied with the history of any serious case unless accompanied by a thorough test of the patient's urine, and the practitioner who, in chronic and puzzling cases, is not on the alert to make a look-out is very liable to lose cases, and will not carefully try to eliminate it by getting a true statement of the facts from the patient, or by tentative therapeutic measures, will often meet with unpleasant surprises where he least expects it. If, therefore, we rank syphilis among the important predisposing or inciting causes of tabs, we shall not be going out of the truth. I should not like to leave this part of the subject without saying something about the influence of masturbation upon the central nervous system, when its practice is begun at the age of puberty and continued for one or more years. There are some who make light of its effects upon the system, and believe that the same are psychical only. While I do not deny that the influence of masturbation more or less serious mental disturbances, particularly in those with neurotic taint, its hurtful effect upon the cord and sympathetic can be plainly seen in those cases of mal-nutrition and neurasthenia in the adult, in which the early indiscipline has been acknowledged, and our examination failed to disclose other influences.

Of more importance than the loss of semen appears the debilitating influence of the frequent sexual orgasm in the masturbator, as well as the frequent nocturnal emissions, which persist for a long while after he has discontinued the vicious habit, in exhausting the cord and brain, and by excessive irritation and subsequent malnutrition creating a predisposition not only to functional also to organic disease of either or both. This consideration explains to me why the female masturbator
may suffer from the effects upon the spinal cord as well as the male, while regret and shame of being guilty of a contemptible act, increased by the impotent rage of not being able to overcome the passionate desire, prepare the way for the development of mental depression, or some form of psychosis.

When have been in practice, at all events, a few cases of locomotor ataxia, in the history of which masturbation in early youth was found to have been the foremost cause.

A disease as widespread and of so baneful an influence upon the constitution as syphilis, cannot fail to show itself often in the etiology of disorders of the nervous system. Reumont, for example, found among 3,400 cases of syphilis, 498 (44 per cent.) with affection of the nervous system. In my own experience I believe to have been of specific origin, showing again how important it is, from a theoretical point of view, to examine as to syphilis in all cases of initial tabes, for the reason that our therapeutic efforts are almost always nil, when they have reached the ataxic stage, no matter what their cause may have been. My own cases of syphilis observed through a period of twenty years, do not show many instances of specific disease of the cord or brain. My cases of tabes constitute so far but a small number; yet syphilis, as an important etiological factor, occurs in the history of some of them, and I believe that it certainly creates a predisposition to locomotor ataxia, but does not act as directly as a syphilitic disease.

From a clinical standpoint, tabes often presents so complex a picture of regular and irregular symptoms, that great difficulty may arise in deciding which of them depend upon specific lesions of the cord.

Charcot, Erb, and other authors, from numerous facts observed of late are led to the conclusion that the typical form of tabes is not caused by disease of the posterior columns alone, but that the neighboring parts of the lateral columns and the posterior gray horns are also affected. If this be true for the typical it is the more so for the atypical cases, which are more often seen in syphilitic patients than the former, and in which various lesions may be found both in the cord and meninges.

Virechow, as long as eighteen years ago, in his "Onkologie" vol. ii., p. 438, says: "The entire and probably pretty large domain of the simple irritative processes incited by poisoned blood and otherwise, has not yet received satisfactory explanation as to its effect upon the central nervous system; observations that have only commenced; it is hardly doubtful that some cases of tabes are syphilitic in origin, and that syphilis holds good to-day as a great extent. However, foreign observers have furnished sufficient proof of late that cardiac hypertrophy and arteritis in chronic nephritis are due much more to the irritative action of the poisoned blood than to the diminution of the area of small blood-vessels in the diseased kidney. Now, in sclerosis of the posterior columns we have a chronic form of inflammation, hyperplastic in character, either occurring primarily in the connective tissue of the medulla or of the leptomeninges and adventitia of the pia-vessels. I think it quite probable that in constitutional syphilis the irritative action of the syphilitic blood may start such inflammation when other conditions are favorable to its development.

At the last annual meeting of the American Neurological Association, in June, 1883, Dr. Mills, of Philadelphia, said that, in comparing the inflammatory changes he had seen in the spinal meninges as well as the cord with the symptoms in the early stages of certain cases of locomotor ataxia, he became persuaded that posterior sclerosis in other cases is syphilitic in origin. Similar views were held by other members present.

The more we learn of tabes, the more the conviction is forced upon us that pathologically and clinically it is rather of protean form. There is the typical primary posterior sclerosis, the most terrible form, and as untractable to-day as years ago, when Romberg first drew its gloomy picture, generally uninfluenced also by specific treatment when there is a combination with syphilis.

A second and frequent form of tabes, I believe, is caused by slow atrophy of the medullary nerve element and slow proliferation of connective tissue, characterized by initial asthenia and gradual loss of muscular tone and power; but tabes without diminution of sensibility may be of the type of reflex; various rheumatoid pains, often recurring, but neither severe nor of long duration; paraesthesiae about the rectum, bladder, and sexual organs, and painful sensa-

There is no appreciable ataxia in such cases, and the patient can stand and walk pretty straight, with eyes closed, but not as well as healthy persons.

To the objection that such cases are simply aggravated neurasthenia, depending upon functional disorder of the cord, I would answer that spinal neurasthenia, unless hereditary, concerns persons who have previously been healthy, and frequently become so again by timely and proper treatment; while the individuals above described never get normal health and strength again, but are generally led into senectus proterce by gradual spinal atrophy.

In my experience this form of spinal trouble occurs mainly in adults between thirty and forty years old, with history of irregular nerve and liver disease in the age of puberty. It is of very slow growth, apt to remain stationary in its main features for years, and amenable to galvanic and hydraulic treatment. Such patients are apt to succumb more easily to intermittent acute diseases, because they have but little reserve force. As a third form we would designate the irregular and mixed nys-

Charcot and other observers have insisted that the spinal cord and its medullary connections, the disease of which the syphilitic and other cachexias, metal-poisoning, trauma, and disease of the spinal vertebrae are important elements. It is mainly in these atypical cases where a temporary or even permanent cure of the tabetic trouble is often effected by specific treatment, when syph-

It has also been observed of late that in many cases of syphilis the outbreak of constitutional disturbance is preceded by considerable diminution or abolition of the patellar tendon-reflex, showing how apt the syphilitic poison is to affect the cerebro-spinal organs. That Romberg's sign is one of the most constant and regular in tabes is accepted by all observers, and that the absence of tendon-reflex is not an absolutely constant symptom has been proved by O. Berger and H. Fischer (Med. Centralblatt, 1879, No. 4); but nearly all are agreed that Westphal's sign is fully as important in the diagnosis of posterior degeneration of the cord, if not more so than Romberg's.

Prognosis.—The prognosis of tabes of syphilitic origin
is relatively favorable when the syphilis is not of very long standing, when the tabetic symptoms are irregular and yield promptly to specific treatment; relatively unfavorable when the opposite conditions prevail. Benedict says that in cases of syphilis of the central nervous system he has often succeeded in ameliorating or removing the spinal symptoms while the cerebral trouble remained either stationary or continued its progress. Reumont and other observers have had similar experience.

Treatment.—The therapeutic results have thus far been far better than the opposite conditions prevail. Benedict says that in cases of syphilis of the central nervous system he has often succeeded in ameliorating or removing the spinal symptoms while the cerebral trouble remained either stationary or continued its progress. Reumont and other observers have had similar experience.

In comparing the results of the treatment of cases of syphilis I had in the first ten years of my practice with those from the last ten years I find them to be better in the latter than in the former. Not only was the time required to make the syphilitic latent shorter, but the relapses were less frequent and less severe and better manageable. I attribute this better success to my discarding the giving of mercury or the proto-iodide of mercury by the mouth, and holding instead the inunction-cure of the indigous syphilitic sore, a method which has since been practised by the physicians in Aachen (Germany), and at Hot Springs (Ark.), in this country. I venture to predict that any one who will follow this method of treating fresh cases of constitutional syphilis systematically and without regard to the patient's whimsical objections to the troublesome cure he has to undergo, will have the satisfaction of effecting a quicker, better, and permanent cure than by following the other method of giving the medicines by the mouth. That there are syphilitic patients who will not bear mercurial treatment, inasmuch as they are afflicted with scrofulous or other diatheses, or show such an idiosyncrasy that they will get stomatitis and sativation at the very commencement of the treatment and work is put an end to their cure, is small indeed. I have also met with cases which I could ply with mercury by the mouth or by the skin to any reasonable extent without healing the syphilitic lesions, nor yet observing any of the constitutional effects of the drug. Not infrequently we meet in old cases of syphilis with sudden and alarming symptoms from the central nervous system. It would be fatal here to lose time by instituting some methodical plan of cure, while large doses of the iodides promptly given and often repeated may be found of eminent service.

The number of cases of syphilis of which I have kept a record amounts to 134, 110 of them men and 15 women. None of them has been less than four years under observation, most of them from ten to twenty years. It would be trespassing upon your time and patience to read the history of these cases to you; but I should like to give the details of a single one, not for the bearing it has upon our subject, but because it is the only case that I have ever seen of syphilis occurring twice in the same person.

M. S., American, thirty-eight years of age, liquor-dealer, came to me first in 1864, with chancre and indolent inguinal buboes, followed by general and well-marked roseola, and specific lesions of mouth and throat. By a course of mercurial treatment and the iodides his syphilis became latent within two years, and, to my surprise, he remained free from all symptoms three years thereafter. In 1869 he came to me again with a venereal sore on his penis, the base of which was somewhat hard, and was followed in due time by a train of constitutional symptoms like the first chancre (in 1864), but milder in form; they yielded to the usual specific treatment in about two years. But from 1873 to 1880 he suffered from time to time from various neuralgias of cerebro-spinal nerves and gastrointestinal affections, which were relieved by specific treatment.

Of the 134 cases, 18 had symptoms of specific lesions of the central nervous system, i.e., 13.5 per cent; 8 of them of the brain alone, i.e., 6 per cent; 5 of the brain and spinal cord together, i.e., 3.7 per cent; 5 of the cord only, i.e., 3.7 per cent. Two of the 3 cases died of cerebral syphilis, the others are still alive but not cured. Of the 5 cases of syphilitic affection of the cerebro-spinal axis, 2 have succumbed to the disease, 3 still live. Of the 5 of spinal syphilis, 1 died of syphilitic paraplegia, 4 live and are relieved by treatment.

Of tabes I have records of 17 cases.

Case I.—G. K., German, thirty-seven years of age, single, merchant, under observation from 1866 to 1866 with the characteristic symptoms of locomotor ataxia, typical, complicated by diabetes mellitus. Died rather suddenly of diabetic coma, 1867. No syphilitic history.

Case II.—H. B., American, sixty-five years of age, married, merchant, under observation from 1869 to 1879. Typical case of tabes involving the brain about 1874, and ending with dementia paralytica and death in 1876. Venereal excesses were acknowledged in this case, and syphilis was strongly suspected.

Case III.—G. K., German, thirty-eight years of age, married, clerk. Typical case of the ataxic type, with a steady progress of over 10 years, beginning in 1871; uninfuenced by treatment; present condition unknown. Etiology: rheumatic influences, no syphilis.

Case IV.—G. S., German, fifty-four years of age, married, merchant. Typical case of tabes of the lumbar of twenty-four years' duration. No syphilis.

Case V.—H. H., German, forty-seven years of age, German, married, horse-dealer. Typical case of tabes of the lumbar type, almost stationary for fifteen years. Contracted syphilis after having had tabetic symptoms for some years. Etiology: rheumatic influences.

Case VI.—A. K., German, thirty-nine years of age, single, merchant, under observation from 1878 to 1881. Typical case of tabes. Etiology: hereditary predisposition and severe rheumatic influences. No syphilis proven.

Case VII.—J. d' A., German, forty-four years of age, married, tobacco-dealer, under observation from 1870 to 1884. Atypical case of tabes of the lumbar type, non-progressive. Rheumatic influences and hard work.

No syphilis.

Case VIII.—L. G., German, thirty-two years of age, married, clerk, under observation during 1874. Atypical case. No syphilitic history. Early masturbation the predisposing cause.

Case IX.—H. F., German, forty-two years of age, married, merchant, under observation from 1878 to 1883. Typical case; died in March, 1883, of complicating cardiac disease. Causes: early masturbation, later on venereal excess and rheumatic influences. No syphilis.

Case X.—A. H., German, fifty-four years of age, under observation these fourteen years. Lumbar type, slowly progressive, almost stationary of late. Causes: mainly venereal excesses. No syphilis.

Case XI.—M. S., German, forty-two years of age, married, under observation from 1879. Atypical case of lumbar spinal type. Rheumatic influences only.

Case XII.—L. H., German, forty-five years of age, married, merchant, seen in 1881. Atypical case of the
lumbar type, slowly progressive. Early masturbation and
poor case venereal excesses.
Case XIII.—E. V., American, forty-two years of age,
marrried, merchant, from 1883 to 1884. Typical case of
the cerebro-spinal type. Etiology: syphilis and rheu-
matica influences. Improvement by specific treatment.
Case XIV.—F. B., German, thirty-six years of age,
single, mechanic. Atypical case. Seen in 1879. No
case elicited.
Case XV.—F. C., Italian, forty years of age,
marrried, merchant, from 1882 to 1883. Typical but
slowly progressive case of the lumbar type. Had syphilis
about twenty years ago of a mild type, and has been
guilty of venereal excesses for many years. Specific
treatment had no effect, but improved by galvanic and
hydraulic treatment.
Case XVI.—A. M., American, thirty-eight years of
age, single, notary, from 1883 to 1884. Typical case of
eight years’ standing. Early masturbation, and
later on prolonged physical exertion. No syphilis.
Some improvement by galvanic and hydraulic treat-
ment.
Case XVII.—J. W., fifty-five years of age, Ger-
man, married, tradesman. Typical case of tabes, in-
volving finally the entire cerebro-spinal organ, and ter-
minating in dementia paralytica, of which patient died
a year ago. No doubt that syphilis was the principal
cause in this case.
Of the above 17 cases syphilis was certainly the
principal predisposing cause in 3, i.e., 18 per cent.
and in 2 more of them it has probably been an important
etiological factor.
Conclusions.—First.—There is not sufficient evidence
to show that syphilis may be the direct cause of the
formal type of locomotor ataxia, i.e., posterior sclerosis
of the cord.
Second.—There is proof, and plenty of it, that syphilis
produces such a lesion in the spinal cord and its menin-
gles readily, if not as frequently, as in the brain. These
lesions may be, and often are, followed by symptoms of
(atypical) tabes. They are generally relieved by prompt
and energetic specific treatment, but rarely cured.
Third.—Experience has shown me that the tendency
of the syphilitic virus to produce lesions in the nerve-
centres occurs the sooner, the less its action is interfered
with by judicious and prolonged treatment, although old
cases of syphilis are, ceteris paribus, more apt to de-
velop symptoms of neurosis than those of more recent
date.
Fourth.—As it has been shown by all observers that
syphilitic lesions of the central nervous system once
established are very rarely cured, and in most cases we
have additional reason to insist upon timely and
long-continued treatment. It is also our duty to im-
port such information of the nature of the disease to
the patient as will lead him to keep a strict and judicious
watch over himself, and have suspicious symptoms at-
tended to as early as possible.
Final.—I believe a properly graded injection-cure with
uqnguement hydragry in most cases of syphilis to be
the best means of reducing the disease to early and
harmless latency.

THE "BUBBLE TEST" FOR ALBUMEN.—Dr. H. La-
throp, of Cooperstown, N. Y., writes: "In reply to Dr.
Neal’s inquiry in your issue of January 6th, I wish to
say that Professor J. K. Mitchell, of Philadelphia, in his
clinical lectures of thirty years ago, frequently called
attention to the characteristic of albuminous urine re-
ferred to by him; and also remarked that if poured
rapidly from a phial the whole interior would be occu-
pied by large bubbles, which would continue a longer
or shorter time as the albumen was more or less abundant.
As an early symptom it is often convenient in the hurry
of general practice; but should scarcely be relied upon
as an infallible diagnosis."

PRACTICAL OBSERVATIONS ON THE HUMAN EAR AND ITS DISEASES, WITH ILLUSTRATIVE CASES.

By SAMUEL SEXTON, M.D.,
AURAL SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY.

I.—THE EXTERNAL EAR.

(Continued from Vol. xxiv., p. 444.)

Significance of the configuration of the auricle.—Much importance has been assigned by writers, both ancient and modern, to the size and configuration of the auricle, and the angle of its attachment to the head. Especially have alienists been led to believe that idiots and imbeciles possess in many instances anomalously developed ears; but while this, to a certain extent, is undeniable true, the subject brings up the question of the ear’s morphology, and, therefore, the discussion be-
longs more properly to congenital defects of the exterior ear.
That the external ears of some perfectly sane in-
dividuals are not ornate in character is also quite true,
but peculiar ears cannot always be regarded as significant
of mental conditions, since the insane themselves are
found to possess ears which are, sometimes, even more
perfectly developed.

The observations of physiognomists in regard to the
significance of the ears in determining the character of
persons seems to hold true to a certain extent, but my
own views, founded on observations among people of
different nationalities, are that the auricle maintains
a very constant configuration in individuals of similar
physiognomic development, irrespective of the time of
birth. From a large clinical experience, however, I cannot
resist the corollary that between a disordered brain—and
perhaps other diseased organs as well—and the ear’s
diseases there exists very often a seeming correlation by
means of which the ear’s ‘complex physiological,
and the theory lends plausibility to some very interesting
suspects on the part of ancient writers, to which allusion
will directly be made.

Charles Darwin, in his untiring search for evidences of
the truth of evolution doctrine, of which he was himself
the most able of all its advocates, availed himself, in
pointing out the morphological correspondence between
man and monkey, of the frequent occurrence of an ir-
regularity in the superior border of the helix of the ear
of man corresponding with the more unvarying pointed
ear in some species of monkeys. This cannot, however,
in man, be construed to indicate the existence of any
mental defect.
The physiological functions of the exterior ear, espe-
cially of the pinna.—Those special functions of the ex-
terior ear, the collection of undulatory sound move-
ments approaching the conductive mechanism and the
regulation of drum-head tension, which have been al-
ready considered, cannot become too familiar to the
mind, since the drum-head comprises the power, when
set in motion by sound-waves, on which normal hearing
depends, and its efficiency is impaired by greater or
less extent by abnormalities of the exterior parts.
The nervous relationship of the exterior ear.—Upon
a knowledge of the relations of the ear with other parts
by means of the nerves, and a study of the modus oper-
andi of the phenomena sometimes thus brought about,
we may more clearly understand the etiology and pathol-
ogy of the diseases to which the organ is subject, and
consequently adopt a rational mode of treatment.
The knowledge we now possess respecting reflex action in
general has been of slow growth, the result of repeated
clinical observations conducted side by side with physi-
ological experiment, and although still incomplete it has
come to be recognized by many as one of the important
causative factors in a large number of the diseases affect-
ing different parts of the body.
In order to understand this sympathetic influence on
an organ so richly supplied with nerves as is the ear,
it will be necessary to consider the subject some-
what in detail. Attention, then, will first be given to the influence probably exerted on the exterior ear through the action of the sympathetic nerves. An exceedingly instructive example, although perhaps less impressive because of its frequent occurrence, is thus offered by the familiar phenomenon of vascular engorgement in the auricle from the play of the emotions, some persons experiencing "burning of the ears" quite as frequently as others are found to "blush" under certain mental impressions; and, indeed, both phenomena sometimes manifest themselves simultaneously. In contemplating these occurrences we are at once greatly impressed with the profuseness of the blood supply of the external ear, as well as with the abundance of its vaso-motor nerves, and it is owing to this fact that mental excitement or nerve-transmitted disturbances from regions remote from the ear may, through reflex action, give rise with such quickness to aural flushing. It was doubtless owing to the observation of these and probably other phenomena in the past that led to the asseveration that the ear possessed attributes of greater interest even than some of its other known functions. Thus in ancient times was the belief entertained that sexual limitation was attainable through ablation of the pinna, and the authors of these ear-operations dimly lighted days, therefore, sought to prevent the perpetuation in the dimly lighted days, therefore, sought to prevent the perpetuation of these operations by cutting off the ears of their criminals lest they should transmit their traits to their own unfortunate offspring. 1

The Scythians, who were imbued with this belief, had recourse to bleeding behind the ears as a means of inducing sterility; and in more recent times Ambrose Paré in his book on military surgery, as he is fondly called, mentions in his work that the pain caused by the tearing of the ears of criminals was another method by which they were prevented from being reborn.

The external ear's relation to the brain.—It is a well-attested fact that the auricle, especially in lunatics, is sometimes the seat of grave lesions consecutive to or accompanying impairment of the mental functions; in other words, a disordered mental state assumes, under certain circumstances, a causative relation to aural disease. Clinical and physiological research has combined in furnishing a vast amount of confirmatory evidence respecting the interesting relations that exist between the brain and the ear. Among the earliest, if not the very first, indeed, to avail himself of the physiological knowledge then existing upon this subject was I believe, Dr. Achille Foville, who suggested the sympathetic origin of disease of the external ear. Foville, in a paper 2 published in 1859, thus alludes to the experiments of M. Bernard, who found that a predisposition to malignant tumors of the ears could be brought about in animals by subjecting them to section of the great sympathetic.

Subsequently, Dr. Brown-Séquard, in speaking of the production of cerebral symptoms as a consequence of injuries to the auditory nerve, says: "I have found that in batrachia the slightest wound of the auditory nerve suffices to produce the following phenomena: 1, a peculiar state of the limb of the opposite side; 2, marked hyperemia of the skin, both lasting during the life of the animal. This nerve in batrachia is almost as sensitive as the fifth pair." 3

This author believes, also, that the auditory nerve has the power, reversely, by reflex action to produce convulsions, vertigo, and other symptoms of disturbed cephalic functions. Thus cold injections thrown into the ear or sudden sounds are liable to give rise to these phenomena in all nervous or feeble persons. And, inasmuch as these symptoms may all occur in healthy brains, they can only be regarded as sympathetic or reflex, and as excited by lesions of the nerve of hearing. Still pursuing this line of inquiry, M. Brown-Séquard at a later date 4 draws attention to the remarkable fact that dry gangrene of the ear commonly occurred on section of the restiform bodies. The precise part of the restiform body excited in order to produce hemorrhage and abscess was the nub of the calamus scriptorius. It is a well-known fact that the hypoglossal nerve and the fifth pair take their origin in the neighborhood of the calamus scriptorius. The writer pointed to the strict analogy which exists in a great number of cases between the phenomena determined experimentally in animals and those which are observed clinically in man, thus confirming the observations of Foville above cited. Other curious researches have also been made by M. Brown-Séquard. Thus he has noted changes in the shape of the ear in animals born of parents in which such a change was the effect of a disease of the ears. Furthermore, hemorrhage and dry gangrene of the ears occurred in animals born of parents in which these ear alterations had been caused by an injury to the restiform body near the nub of the calamus. The animals on which these experiments were made were guinea-pigs.

The external ear's nervous relations with regions other than the brain's have received but little attention; yet the suggestion was thus going on, other observers in the field of clinical medicine were not behindhand in availing themselves of the significant suggestions thus thrown out. About this time Mr. Hilton, Surgeon to Guy's Hospital, was afforded an unusual opportunity to study a case which further confirmed the belief of physiicans in the intimate sympathetic relationship between the nervous centres and the ear.

The case which seemed to support the hypothesis of this important factor in some of the affections to which the ear is subject, and in which Mr. Hilton studied the precise distribution of the sensitive nerves supplying the exterior auditory apparatus, occurred in a man in which the auricular branch of the second cervical nerve had been divided. He found that when pricking with a needle over the whole auricular surface in this case there was complete loss of sensation over the posterior and inferior portion which is supplied by this nerve, while the superior and anterior portion, which is supplied by the fifth cervical nerve, retained its sensibility. The functions of the fifth cranial nerve, a branch of which supplies the superior portion of the auricle, are, perhaps, much more liable to disturbances than are those of the second cervical nerve, and we may thus find an explanation for the nutritive changes in the auricle in subjects of hematemesis auris during impairment of the mental functions. The nutritive changes in diseases of

Progress of Medical Science.

Neuralgic Accompaniments of Lesions of the Pharynx.—Dr. Hack, of Freiburg (Deutsche Med. Wochenschr.), delivered a lecture recently on neuralgic accompaniments of pharyngeal lesions. His attention was first called to the subject in connection with a patient on whom he had performed various cauterizing operations of the nose, on account of obstinate migrane and pains in the nape of the neck, and who, having been cured of those, came complaining of pains between the shoulders, and of a peculiar burning and tickling in the throat. He himself suggested that the throat should be burned for the cure of the pain, as his nose had been for the pains in the neck. The only lesion in the throat was a marked hyperemia, and Dr. Hack, not considering himself justified in having recourse to cauteryization for so slight an ailment, tried various remedies without any result, until he was at last persuaded to use the galvano-cautery. The pain between the shoulders at once subsided, and also the peculiar feeling in the throat. In another case that came under his care, the pain was in front, above the clavicles, and in the pharynx a little granulating tumor was visible, and bleeding on compression. The destruction of the tumor by the galvano-cautery, the pain over the clavicles completely disappeared, to return again with a slight return of the growth, which was easily removed in the same way. In a third case, hypertrophy of the inferior turbinate bone had caused stoppage of the nose and hyperemia of the pharynx, with which was associated a peculiar sensation in the clavicles, which vanished in the same way when the hypertrophy was overcome. The neuralgic pains appear to accompany slight pharyngeal affections more often than severe ones, and always those which are hypertrophic in character rather than the atrophic. The neuralgia is sometimes in the form of sudden, sharp pains, of lightning rapidity; sometimes more diffused, and "neumatic" in character. Their cause must remain to a great extent hypothetical, but it probably depends on the termination of the nerves in the pharyngeal mucous membrane.

Phosphorus in the Treatment of Rachitis.—Dr. Kassowitz recommends phosphorus in small doses in rickets. He gives it in solution in cod-liver oil (1 to 1,000) in doses of one or two teaspoonfuls a day. Under this treatment he claims that the disease rapidly subsides. The fontanelles close, the softened bones become firm, the attacks of laryngitis and stridor are less frequent, and the general condition is much improved. He regards rachitis as due to an abnormally increased vascularization of the osteogenous tissues, which increase is controlled by minute doses of phosphorus. —Centralblatt für Chirurgie, January 26, 1884.

Diet in Tuberculosis.—In the Berliner Klin. Wochenschrift Dr. Bidder, of Berlin, concludes three articles on the relation between the alkalies of the food and the etiology of tuberculosis, by advocating a diet as free from potash salts as possible, but rich in common salt, as being a soda salt. He argues that the latter renders the tissues unfavorable to the development of the bacilli of tubercle, and that in young patients with tuberculous processes going on in the bones, joints, lungs, lumps, etc., half a gramme to one gramme of common salt should be given three or four times daily with the food. He recommends the liberal use of sodium benzoate, as a substitute of sodium bicarbonate; sodium benzoate of soda may be substituted in doses of 3 to 7 grammes. Indeed, the latter salt (known to be useful in the summer diarrhea of children) is highly relished; it is aromatic in taste, and increases the appetite. Bidder thinks, moreover, that the well-known injurious influence of iodide of potassium upon tuberculosis or scrofulous processes is probably due not to the iodine but to the potash, which is replaced by soda in the stomach. The diet
should contain an excess of albumen, of fat, and of salt in the cases mentioned. The article concludes by a reference to rickets, in which a connection with tuberculosis is attempted to be proved. Rickets is said to be due to an excess of potash salts in the food as one cause of it.

The Fever of Growth.—This affection, first described by Bonilly, in 1850, is characterized by a fever pursuing a specific course, and accompanied by pain and tenderness in the epiphyses of nearly all the long bones, and is followed by a very rapid growth of the individual. It may occur at any time between the fifth and twenty-first year. It is occasioned by excessive exercise, as long walks, standing for a considerable time, fattiging gymnastic exercises, swimming, etc. Bonilly distinguishes three forms of the disease: 1. acute, with rapid course, the most common; 2. acute, but more protracted than the first; and 3. chronic or relapsing (trainante). Fever and tenderness of the bones are common to all these forms. The pain occupies the "juxta-epiphysial" zone, and is most commonly located in the lower ends of the femora, though all the long bones are not infrequently affected. The joints are not involved as a rule, though sometimes serous effusions, more especially in the knee, may occur. The disease often forms its course in from twenty-four to thirty-six hours. The second variety may be of several days' duration, and may even be accompanied by typhoid symptoms, but its termination is always by a rapid return of temperature to the normal. The chronic form is characterized by a succession of attacks running along for weeks and months. The progression is not uniform, but relapses are common. Quinine should be given during the attacks, and in the intervals all fattiging bodily exercises should be avoided, while attention is directed to a building up of the general condition. The following case of growing fever is reported by Dr. Guiller: A child of five years old of leprous constitution was taken suddenly ill with convulsions, high fever, and pain in all the extremities. There was tenderness over the epiphyses of the femur, tibia, and humerus on either side. A slight improvement on the next day was followed by an increase in all the symptoms in the evening. Under antipyretic treatment the fever subsided on the third day. After five weeks the child was able to leave the bed, though she was still very weak. During that time the height increased two and one-half inches.—Centralblatt fälr Chirurgie, January 26, 1884.

Gonorrhoeal Arthritis.—Dr. F. Kammerer reports in the Centralblatt fälr Chirurgie, January 26, 1884, two cases of joint inflammation following gonorrhoea. The first case was that of a man, thirty-two years of age, who fell and sustained a compound fracture of the leg, necessitating amputation. Shortly after the operation the patient complained of pain in the knee of the other side. The joint became rapidly swollen, and was so exceedingly painful that it was decided to draw off the fluid. A large quantity of a sero-purulent fluid was removed, which was found to contain numerous micrococci exactly resembling the organisms found by Neisser in gonorrhoeal secretion. The patient denied having had gonorrhoea, but examination showed a reddened meatus and a slight urethral discharge. The fluid reaccumulated in the joint and was again drawn off, but this time contained no micro-organisms. The second case was in a woman, twenty-two years old, suffering from gonorrhoea. The knee was painful and greatly swollen. The fluid was removed on the fifth day, but no micrococci were found. In two other cases of gonorrhoea, no micrococci were found. (Centralblatt fälr Chirurgie, September 15, 1883.) The same organisms were found in the effused fluid. Kraske, Brieger, and Ehrlich have each reported cases of gonorrhoeal urethritis in which, however, they could discover no kammereria. Notwithstanding these negative results, Kammerer regards his first case and the two reported by Petrone as proving almost conclusively that the joint affections in gonorrhoea are due to the migration of bacteria from the urethra. This migration takes place through the channels of the blood circulation. Petrone, indeed, found the characteristic micro-organisms in the blood itself. The absence of the cocci in some of the recorded cases might be explained by the time at which the examination was made, since in all the cases in which they were found the fluid was withdrawn very soon after the exudation had occurred. Kammerer suggests that the organisms die very shortly after the inflammation is excited, as in other pathological processes dependent upon the presence of micrococci the organisms are always found in greatest numbers at the commencement of the disease.

Operations upon Abdominal Cysts.—Dr. J. Landau (Centralblatt fälr Chirurgie) advances his method of treating abdominal cysts as possessing the advantage that a multiplicity of cysts, or the presence of adhesions, do not give rise to difficulties in operating. The plan adopted by him is to make a vertical incision through the integuments over the cyst as high as the border of the ribs, an exploratory puncture having first been made. The peritoneum is then to be fixed to the abdominal wall by sutures. The rent in the peritoneum is then closed forward by an assistant, a fine canula is inserted to evacuate the fluid. The distended cyst becomes flaccid, and can be drawn outward; its slackened walls can then be fixed by sutures to the integuments. The remaining fluid can then be emptied, or is expelled by the respiratory action; none can escape into the peritoneal cavity. The cavity of the cyst becomes obliterated by granulation.

Bromiform.—In a communication addressed to the Vienna Medical Society, at its session on January 11, 1884 (Wiener Medicinische Wochenschrift), Dr. von Horoch presented some facts concerning the anesthetic value of bromiform. This substance, analogous in composition to iodoform and chloroform, is an oily, transparent, liquid, of an agreeable odor and sweetish taste. It is sparingly soluble in cold water, but dissolves readily in warm water and in ether, has a specific gravity of 2.9, and boils at 151°C. The drug was given to animals by inhalation, subcutaneous injection, and by the mouth. In all the experiments it was shown to possess remarkable anesthetic and hypnotic properties. The anesthesia produced by inhalation could be maintained for any desired length of time without producing any unpleasant symptoms in respect either to respiration or the action of the heart. The primary stage of excitement was less marked than is the case when chloroform is administered, and there was no nausea nor vomiting. When employed in a one per cent. solution it possesses strong antiseptic properties. Very profound and long-continued narcosis is produced by subcutaneous injection. In a rabbit an injection of fifteen minims caused a deep sleep for forty-eight hours. Dr. v. Horoch employed bromiform also in man. It was used in three cases of surgical operation, one a double osteotomy, without any unpleasant effects being produced. Professor Albert stated that the anesthesia observed after inhalation of bromiform was very similar to that produced by chloroform. However, however, are less transient, the narcosis is longer continued, children when under the influence of bromiform will, upon awakening, eat with relish, but fall asleep again immediately. In other respects its action seems to be somewhat less powerful than that of chloroform, especially as regards the heart and respiration, upon which it appears to have no depressing influence. Of very noticeable, however, which it possesses is an irritant effect upon the mucous membranes. The conjunctiva and the nasal and laryngeal membranes are all considerably irritated when bromiform is given by inhalation. This effect, Professor Albert suggested, might possibly be obviated by mixture with some other substance.
THE REFORM OF THE MEDICAL SERVICE ON PASSENGER STEAMERS.

Already a bill is before Congress, introduced by General Slocum, which aims at establishing the reform of the medical service on passenger steamers, so earnestly advocated by this journal. The full text of the bill has not yet reached us, but we are satisfied from the abstract in hand that, subject to certain modifications, the measure is one meriting the gratitude of the public and the cordial support of the medical profession. It enacts that vessels carrying passengers to the United States shall have on board a second or assistant surgeon whenever the number of passengers and crew exceed six hundred; to which might well be added the compulsory employment of a competent dispenser, and for every three hundred passengers at least one hospital steward and trained nurse. It further provides that there shall be two hospitals—one for men and the other for women—each to be eighteen square feet for every fifty persons on board. This clause needs alteration. Assuming the height between decks to be about seven feet, and allowing for displacement by the patient's body, bed, and the necessary fittings, a hospital of eighteen superficial feet would scarce allow one hundred cubic feet for respiratory purposes—manifestly insufficient for even one healthy person.

On the other hand, when the passengers and crew amounted to fifteen hundred persons, as is quite usual on the larger steamers, this clause would require that 1,080 square feet of deck room be assigned for hospital purposes. The commercial capability which in face of repeated warnings maintains a system equally disgraceful and disastrous deserves small consideration at the hands of Congress, and none from us; at the same time we are prepared to respect every interest involved, and we wish to demand no more than is absolutely necessary for the health of passengers and the protection of the communities among whom they are about to commingle.

With this view we would suggest the following:

That every steamer carrying from twenty to one hundred passengers, not more than twenty-five of whom shall be under twelve years of age, shall provide two hospitals, located upon the main or upper deck, and toward the stern of the vessel, each of which shall contain not less than 350 cubic feet of clear breathing space; and that for every additional fifty females, or twenty-five children under twelve years of age, 250 cubic feet shall be added, up to a maximum of 2,500 cubic feet; and that for every additional fifty males over twelve years of age, 50 cubic feet shall be added, up to a maximum of 1,000 cubic feet. It should also be insisted on that this space be left entirely at the disposal of the medical officer, and devoted to no other purpose than the accommodation of the sick. The bill further provides that the medical officer shall act as sanitary inspector. In this we entirely coincide; but it is well to remember a point constantly insisted upon by Dr. Irwin, and without attention to which this clause would be simply a dead letter. So long as the surgeon is employed and dismissed as at present, in the interest of the shipowner, he can never be an efficient sanitary officer. It not infrequently happens that upon these crowded steamers the health interests of the passengers comes into direct opposition with the money interests of the owners; and wherefore the purpose of United States law declaring the ship surgeon a sanitary inspector, unless it is prepared to protect him in the discharge of the functions pertaining to that office?

PROFESSOR HUXLEY'S PLAN FOR A CONJOINT EXAMINING BOARD.

It would be a great surprise to American readers to find such a subject as medical legislation discussed in popular monthlies. In England, however, this is being done, and it must be inferred that the matter in that country has a more than technical interest. In the recent issues of the Nineteenth Century and of Blackwood's Magazine the medical bill now before Parliament has received extended criticism at the hands of Professor Huxley and of an anonymous Conservative writer. As the situation of medical affairs in England resembles somewhat that in this and other States, our medical statesmen can possibly learn something from a study of the progress of medical reform across the water. The United States has about one hundred and twenty, England nineteen licensing and teaching bodies. It is desired by the great mass of the profession in both countries that the licensing bodies should be made fewer in number, and that they should be independent and free from any possible bias.

To secure this end the Parliamentary bill creates three Boards of Examiners—one for England, Scotland, and Ireland respectively. These Boards will establish a minimum qualification, and prevent the present practice of students who fear to fail in England going to Scotland or Ireland. This is the main and most radical feature in the Parliamentary bill.

Professor Huxley is the stalwart opponent of this plan, and defends his views with much plausibility in the Nineteenth Century. He has a scheme of his own, which is, he thinks, very simple and will suffice to secure all the reform needed. It consists, so far as the point under consideration is concerned, of having conjoint medical examiners appointed, representing no college, who shall examine the students and sign the licenses in connection with the professors in the schools.

A similar scheme applied in this State would be the creation of a medical faculty whose members should have the power to attend the college examinations and sign the diplomas with the professors. This is a step in ad-
vance of the plan proposed in the so-called "College Bill," and its practicability is at least worthy of consideration.

At the first glance it certainly seems a physical impossibility for such a faculty to do the work proposed. We have thirteen or fourteen colleges in New York State, and the majority of the Commencements occur within the same fortnight. The conjoint examiners, therefore, must divide up in order to do their work properly. Very great care would also have to be exercised in order to prevent undue influences affecting the judgment of the gentlemen who would thus assist in the examinations. Finally, it has to be remembered that probably the majority of the twelve hundred graduates from New York colleges will not settle in this State, while, per contra, a considerable number of physicians who do settle here are graduates from institutions elsewhere.

RED HAIR AND PSYCHICAL STATES.

MEDICAL science progresses. It is pleasant to feel that the phrases which are usually uttered with platitudinous ease can sometimes be strenuously emphasized in the exalted conviction of their far-reaching significance. The world has revolved many thousands of times, blowing the torch of science into a continually brighter blaze. But not until the present year did the illuminating rays of scientific incandescence show to inquiring man the exact psychical significance of red hair.

Let our readers think that we are trifling, we beg to say at once that in Virchow's Archives, Bd. 95, Heft 2, 1884, Dr. C. Reinhard, of the Friedrichsberg-Hamburg Insane Asylum reports facts which break a new path in science, and throw an auroral light upon the history of red-headed men.

In April, 1880, there was brought to the asylum in question an idiot boy aged eleven years. He was microcephalic, with small brow, large mouth and ears, light yellow hair and dull expression. He could not speak nor understand a word, though sight and hearing were normal. The legs and arms were atrophied andcontractured.

This interesting creature was subject to periodical changes in his mental or rather emotional condition. For about a week he would be very excitable, crying, grunting, restless, and sleepless; his face would become red and turgid, the pulse fuller and the skin warm. This condition would gradually subside and he then entered a stuporous state.

Now it was very soon observed that during the states of excitement the hair changed from a light yellow to a golden red. On the other hand, in the stuporous state it changed back to yellow. This phenomenon was frequently and carefully observed, says Dr. Reinhard, and all sources of error excluded. There were no dyes or washes used, the hair was not falling out, and it was the same hair which underwent the periodical change in color.

Here, then, is an authenticated fact, showing that emotional excitement reddens the hair, while quietude and sleep tones down the primary color to a neutral tint. May one not suggest that isolation, repose, somnolence, and self-restraint will be better for a red-haired man than hair-dyes?

We should add that the patient subsequently died in his yellow hair. The autopsy revealed atrophy of the anterior horns of the spinal cord, microcephalia, hyperostosis cranii, and wide convolutions, while the cortex cerebri was of a pale green color. As green is the complement of red, the deep significance of this last finding will be apparent. We will not dilate upon it; however, lest it be thought that Dr. Reinhard used a serious publication like Virchow's Archives in which to utter things frivolous and trifling.

THE VALUE OF TARSOTOMY IN THE TREATMENT OF TALIPES.

The operation of tarsotomy in inveterate club-foot has hitherto attracted but little attention in this country. A discussion took place recently in the Surgical Society of Paris upon the value of this operation in cases of inveterate talipes. Beauregard related several cases of old club-foot attended with great deformity, in which, after all other measures had failed, he performed osteotomy. Excellent results were obtained, the wounds healed readily and without any serious accidents. In the discussion which followed, despite the favorable issue in the cases cited, the great majority of the surgeons present declared themselves emphatically against the operation in children. Palotillon quoted the dictum of Guiain, that there is no deformity of this kind, except in talipes of the adult, which may not be corrected by means of tenotomy, syndesmotomy, and apparatus. Many, however, were of the opinion that tarsotomy is necessary in the case of adults afflicted with congenital club-foot, and it is probable that should the operation ever win for itself an established position, it will be reserved entirely for these inveterate cases, more conservative measure being sufficient for the relief of any deformity of this nature in children. Some of the most enthusiastic advocates of the procedure—Boeckel, Rydygier, and others—proposed, indeed, to operate upon children as well as adults. They thought to recognize two forms of club-foot, a tendinous and an osseous one. The former, they asserted, was curable by the ordinary methods of manipulation, tenotomy, and the like. But for the correction of the latter osteotomy was necessary. In spite of these views held by an enthusiastic minority, the ruling opinion of continental surgery seems to be that while we have in tarsotomy an operation of undoubted value, its general adoption in the treatment of club-foot, to the exclusion of more conservative and milder measures, especially in the case of children, would mean retrogression rather than advancement.

THE NEW BANTINGISM.

A little green-covered book, entitled "Corpulence and its Treatment on Physiological Principles," is being extensively distributed among the news-stands of this and other cities. It is written by Dr. William Edbens, and translated and "adapted for popular reading" by an ingenious and philanthropic physician of this city. It is always a matter of much delicacy if not danger to lay before the public a new curative method. For one must be sure the method is right, sure the public will understand it, and confident that if tried by the laity it will do no harm, since, of those sufferers that read, not
two per cent. go to their physicians, nor one per cent. to the translator.

Dr. Ebstein's method of treating corpulence has been generally noticed in medical journals and must be somewhat familiar to the profession. It is based, as he says, upon physiological principles, which are, first, that superfluous fat must be got rid of very slowly; second, that the anti-fat regimen must be kept up all one's life; third, that this anti-fat diet should contain considerable fat, a moderate amount of proteids, and very little starch and sugar.

The main novelty in Ebstein's plan (for everything else has been said before) is the addition of fat and decrease of proteids in the diet. This difference in diets can best be seen in the following table made by Professor Voit (Centralblatt f. Klinische Medicin, No. 8, 1884):

<table>
<thead>
<tr>
<th>Diet of</th>
<th>Albumen in grms</th>
<th>Fat</th>
<th>Carbo-hydrates</th>
</tr>
</thead>
<tbody>
<tr>
<td>Healthy workman</td>
<td>118</td>
<td>56</td>
<td>500</td>
</tr>
<tr>
<td>Physician</td>
<td>127</td>
<td>89</td>
<td>262</td>
</tr>
<tr>
<td>Banting</td>
<td>173</td>
<td>7</td>
<td>81</td>
</tr>
<tr>
<td>Ebstein's diet</td>
<td>102</td>
<td>85</td>
<td>47</td>
</tr>
</tbody>
</table>

The prevailing theory of physiological chemists now is that the fats of the body are derived largely from the proteid or albuminous bodies through partial oxidization of the same. Feeding with starch, sugar, or fat increases the fat in the body because these foods are easily oxidized. By consuming a large amount of oxygen the albumen receives less and breaks down into fat instead of more completely oxidized products like urea and its allies. In fine, carbo-hydrates and fats protect the albumen and cause fatty deposits therefrom.

Ebstein accepts this theory in all respects except that he denies the protective power referred to, so far as regards fatty food, and says it does not favor the deposit of fat out of albumen.

It appears to us that as yet Ebstein has furnished no arguments in experiment or experience, which prove his view. And, furthermore, so distinguished an authority as Professor Carl Voit has published an argument in which he denies that Ebstein's treatment is based on physiological principles.

While no one will refuse, therefore, to give Ebstein's method of treating corpulence a fair trial, or will deny the value of his clinical results, it is not yet time to announce that we have a new and surer remedy for corpulence "based on physiological principles."

THE QUESTION OF MIDWIVES.

The New York County Medical Society did well to refuse an endorsement at the present time of the bill to establish a college of midwifery. The profession here has had an unpleasant experience with such institutions, and is not ready just now to give its support to them.

Because one college of midwifery has turned out badly, however, it does not follow that we must educate no midwives; nor should physicians look upon this class as one not adapted to our American civilization. Experience through many years and in many countries has shown that midwives exercise a useful function in society. If American doctors denounce and try to exclude them from recognition, the action will be attributed to selfish motives and a trades-union spirit.

Midwives, carefully trained and, in particular, taught early to recognize complications and abnormal labors, and to call in help on such occasions, will be useful adjuncts to the profession, and will furnish a needed service to the poorer classes.

Midwives do and will exist. The medical profession had best, therefore, see that they be properly licensed and educated, so that they may be made more skilful and responsible. This, we believe, our County or State Society will in time undertake to do.

A NEW HONOR TO PROF. FORDYCE BARKER.

The many personal friends of the distinguished president of the New York Academy of Medicine, Dr. Fordyce Barker, and the profession generally, will join us in congratulating him on the eve of his receiving another high honor from abroad. The Edinburgh University, on the occasion of its tercentenary anniversary, has decided to confer a limited number of honorary degrees upon distinguished foreigners. Dr. Barker has been invited to attend the convocation and receive the degree of L.L.D. from that university. He sailed accordingly on Wednesday last.

No honor which this ancient university can confer will be more worthily bestowed or more honestly earned. The profession of this city and country have more reasons than one for being proud of the subject of this rare distinction.

News of the Week.

THE BILL TO REGULATE MEDICAL PRACTICE in Maryland has been killed.

MEDICAL TRAMPS AND MEDICAL CONFIDENCE MEN.

—We are constantly hearing of men, claiming to be doctors, who are travelling around the country and swindling the profession by obtaining money under false pretences. It is so easy to avoid these swindlers by refusing to help them under any circumstances that we are tired of calling attention to the fact. A physician who has to work hard for his money ought not to be ready to part with it to the first beggar who drops into his office with the story that he has lost his pocket-book, his railroad ticket, his satchel, or his check-book. If such a man has friends at home he can obtain money-orders by telegraph, and if he has none such at home he does not deserve any abroad. The moment a strange man asks for money because he is a suffering doctor, that moment he should be looked upon as a pretender, a fraud, and a swindler. Every sensible medical man knows this, but is willing to be gullied notwithstanding. We are aware that doctors are generally soft-hearted, but there is no reason why this qualification of tenderness should find expression in any higher organ of their economy.

Dr. James A. Stewart has been appointed Health Commissioner of Baltimore, and entered on his office March 1st, in place of Dr. George W. Benson. Dr. James McShane has been reappointed Assistant Health Commissioner.
The Latest Trick in Professional Advertising in this City is to write, or have written, a biographical sketch of one's self for some obscure family paper, pay for an extra edition, and have specimen copies of the same distributed upon the thoroughfares. Of course, it is not to be presumed that the principals have anything directly to do with the matter. And even if they had, free personal advertising is not in such bad odor as before the distinguished editor of the Association journal published his very liberal views on its propriety. It is, in fact, another way of publishing professional cards, announcing specialties and office hours. Medical colleges, dispensaries, public and private, do it for the good of the suffering poor, and why should individual doctors be debarred of a like privilege when they wish to help themselves? It amounts to the same thing in the end. The only pity is that the young and struggling doctor, who is anxious to earn his bread by "the sweat of his brow," does not dare to let the people know of the fact that he is willing and ready for business. The only way left to him, apparently, is to hire a room in a tenement house, start a private dispensary, make himself the chief medical adviser thereof, and advertise with the laudable anxiety of helping the sick poor, who are so notoriously neglected in this great city. It is not much more difficult to start a dispensary than it is to found a medical college, and, considering the need for both not only here but elsewhere, there are abundant opportunities for using printer's ink legitimately and profitably. The other method, of trying the biographical scheme, is not to be thought of by men who have no reputation and who are not old hands in the business. This requires experience as well as everything else.

Medical Vienna.—At the meeting of the Royal Society of Physicians of Vienna, on March 9th, Professor v. Basch made a communication upon the subject of the "Innervation of the Intestine," based upon experiments made by Drs. Fellner and Ehrmann. These showed that the longitudinal and circular fibres of the muscular coat have each inhibitory and motor nerves. The vagus sends motor fibres to the circular muscles and inhibitory fibres to the longitudinal muscles. The splanchnic, on the other hand, is the motor nerve for the longitudinal fibres, and the inhibitory nerve for the circular fibres. At the meeting of the Vienna Doctoren-Kollegium, March 3d, Professor Schnitzler read a paper on the "Therapy of Tuberculosis," but presented nothing new.

Medical Berlin.—At the meeting of the Society for Internal Medicine, on March 3d, Dr. Bernhardt reported a case of spontaneous hydrophobia. Dr. Pedell showed a case of stenosis of the larynx after typhus. Dr. Gutmann reported a case of diaphragmatic hernia in a man aged forty-two years, not diagnosed until after death. Among 290 cases, only six times has the diagnosis been made. Some general remarks upon the symptomatology and physical signs were made.

Medical Paris.—At a meeting of the Académie de Médecine, March 11, 1884, M. Mercier read, in his name and that of M. Garrigou-Desarès, a note upon the "Treatment of Strictures of the Eustachian Tube by Electrolysis." The operation consisted in passing a fine silver sound into the Eustachian tube, and a small olive-shaped electrode into the external auditory meatus. A feeble current is then passed, the sound is gradually pushed on, and the stricture disappears. In the Société de Chirurgie, at its meeting March 13th, a discussion took place upon the pathology of spina bifida. M. Lannelongue showed that some cases were due to cicatrical adhesions, others to arrest of development. M. Terrier reported a case of Battey's operation for hysteria. M. Vulpius presented a patient with a nasopharyngeal polypos of extraordinary size, and asked advice as to the question of operating. Intratracheal injections of Piaza's solution had been made without doing any good. The galvano-cautery and ligature of the carotid were measures suggested.

The Chicago Medical College held its Twenty-fifth Annual Commencement on March 25th, graduating a large class.

A Chair of Pathology has been created at the University of Cambridge, and a Professor will be elected in May.

Edinburgh University and Its Tercentenary.—On April 17, 1884, the University of Edinburgh celebrates its third centennial anniversary. On this occasion the chief institutions of learning throughout the world will be represented by delegates. Several American colleges are included in the list. It is to be remembered that the fame of Edinburgh is very largely due to the excellence of its medical teaching. The roll of university professors includes the name of Charles Bell, of whom, says Science, the story is told that when he visited the class-room of Roux in Paris, Roux dismissed the class, saying, "Sufficient, gentlemen: you have seen Charles Bell." Another university professor was Sir James Y. Simpson, whose bold introduction of chloroform as an anesthetic is world-renowned. When a Scotchman was presented at the court of Denmark, the king said, "You come from Edinburgh? Ah! Sir Simpson was of Edinburgh." Simpson himself said he was more interested in having delivered a woman without pain than in having been made physician to the queen. At an earlier date the fame of William Cullen was wide-spread. Among the teachers of non-medical sciences, the names of Black, John Playfair, Robert Jameson, David Brewster, Edward Forbes, James D. Forbes, and Wyyllie Thomson are those which come first to mind; while in mental and moral science the Scotch philosophers, Dugald Stewart, Thomas Brown, and Sir William Hamilton, are not likely to be forgotten. A part of Edinburgh's medical fame is due also to its "extra-mural" teachers.

The English View of an American's Pedestrian Fret.—We can hardly understand the astonishment and interest which the English press exhibit over the fact demonstrated by Weston, that the body can sustain itself under severe work better without alcohol. To Americans, who drink a great deal of water, this fact has long been a commonplace.

The Medical Press and Circular goes off in the following strain: "Never, in the history of the Temperance movement, has the value of abstinence from alcoholic or
other artificial aids been so signally demonstrated as during the past four months, when, without any preliminary training, the pedestrian Weston has, for one hundred successive days (excluding Sundays and Christmas Day) walked fifty miles a day, until, on Saturday evening last, he completed the number—five thousand—which he had undertaken to accomplish in the time specified.

"During the final week, when the walking took place in London, at the Victoria Coffee Palace, a complete and exhaustive series of observations were made by Dr. Edwin C. Green, delegated by the Medical Temperance Association for that purpose. The sphygmograph, clinical thermometer, dynamometer, and spirometer were all made to contribute their valuable revelations. The food and excreta were weighed, as was Weston himself—his height being taken before and after each day's walk. The urine, in view to the amount of urea, phosphates, etc., being estimated, was sent daily to Mr. A. Wynter Blyth. The results will be published in detail in due course; but it may here be stated that they were in the main eminently satisfactory. The vital capacity was not, perhaps, quite so great as we were prepared for, and the grip was what might have been expected from the pedestrian's comparatively slight physique. But the clinical thermometer and the sphygmograph proclaimed that the temperature and the pulse—both unerring indicators of abnormal states of health—were perfectly natural; indeed, the tracings with the former were typical of the most perfect health."

The Women's Medical College of Philadelphia held its annual Commencement on March 13th, and graduated a class of twenty-six.

The German Cholera Commission will soon go to Goalpara and Darjeeling, in India, to prosecute further studies. They will then return to Germany, but expect to be again in India next winter.

Quintuplets.—Dr. Reeves, of Wheeling, West Va., vouches for the following (Columbus Medical Journal): A married woman, living in Moundsville, West Va., gave birth to five children—two boys and three girls. They were perfectly formed, and weighed from four pounds to two ounces. Only one of the number weighed four pounds, while the remainder ranged from two ounces up. They were still-born. The mother at last reports was doing well.

Limiting the Height of Houses.—A bill has been introduced into the State Assembly, of which one section reads as follows: Sec. 2. Such height, measured from the sidewalk line, and taken in all cases through the centre of the façade of the house to be erected, including attics, cornices, and mansards, shall not exceed seventy feet upon all streets and avenues not exceeding sixty feet in width, and eighty feet upon all streets and avenues exceeding sixty feet in width. The bill has been favorably reported upon. It resembles in the main the law in Paris.

A Bill to Regulate the Practice of Medicine and the Sale of Medicines in Utah was passed by the Legislature, but vetoed by the Governor, at the solicitation, as we are informed, of certain patent-medicine men.

Investigating the Tenements.—A bill has been introduced into the State Assembly appointing a commission to investigate and report upon the tenements and "slums" of New York City.

The New York Neurological Society held its annual meeting on April 1st, and elected Dr. Wm. J. Morton, President; Dr. E. C. Wendt, Secretary.

The Number of Medical Diplomas Given in France and Germany.—While the United States generously bestows some three or four thousand medical diplomas yearly upon its laboriously educated students, in France there were granted, in 1883, only 662 diplomas; of these 465 were granted in Paris, the remainder in the five provincial schools. In the same year the number of diplomas conferred in the German Empire was 692.

The College of Physicians and Surgeons of Chicago held its annual commencement on March 11th, and graduated a class of fifty-two.

The Rhode Island State Medical Society held its regular quarterly meeting at Providence on March 20, 1884.

The Indiana Insane Asylums.—We are constantly reminded that reform progresses slowly, especially as concerns the proper medical care of the insane. Recent despatches state that a great deal of indignation has been excited over the reported condition of insane women in the county poor-houses throughout the State of Indiana. The Secretary of the State Board of Health and the Superintendent of the Insane Asylum have been making a survey of these poor-houses, and the condition of things is terrible. Superintendent Fletcher states: "If one could tell half the truth about the poor-houses of Indiana, and the treatment of the women in them, the insane and the idiotic, I believe the women of Indiana would move upon them and tear them down. There is a fine opening for reform, and if you will awaken sentiment on the subject you cannot fail of doing great good."

Three Students of the Harvard Medical School, who last week passed their examinations, are not happy. One wrote an excellent set of papers, the other two copied them word for word, and the examiner ranked them at 98 per cent. He remarked, however, that as the three papers were identical this gave the three but about 33 per cent. each, and as 50 per cent. is required for a diploma, all three were plucked.

Bills Before the New York State Assembly.—The following bills were favorably reported this week: Incorporating the New York Cancer Hospital. Incorporating the Good Samaritan Dispensary in New York. Legalizing all medical degrees and diplomas granted by the United States Medical College in New York. The bill making the Health Officer of New York a salaried officer was reported adversely.

Against Female Physicians.—At a largely attended meeting of the Philadelphia County Medical Society, April 4th, a proposed amendment to the constitution, permitting the admission of female physicians to membership, was defeated by a vote of 79 yes and 48 nays, it requiring a two-thirds vote for the passage of the amendment.
THE SIMS MEMORIAL FUND.

To the Medical Profession and Others throughout the World:

The great achievements of Dr. J. Marion Sims call for some more lasting testimonial than obituary and eulogies. To him medical science is indebted for much brilliant and original work, especially in gynecological surgery. Those who have been benefited by his teachings and new operations, and such as have had the direct advantage of his skill are among the first to recognize and acknowledge this debt.

To him is due the honor of giving the first strong impulsion to the study of gynecological surgery in America. It is believed that the medical profession everywhere, the vast number of women who owe their relief from suffering directly to him, and those who realize the benefits he first made possible, will gladly unite thus to honor the man through whose original and inventive genius such blessings have been conferred upon humanity.

At the suggestion of many friends, therefore, the subjoined committee has been organized, and it is proposed that a suitable monument be erected to his memory in the city of New York.

To this end the active co-operation of the medical profession and the many other friends of Dr. Sims throughout the world is respectfully solicited. Contributions of one dollar and upward may be forwarded to the journal which has been constituted the treasury of this fund—The Medical Record, New York.

Reviews and Notices.

The book before us is said to embody the results of twenty-six years' hospital and private practice experience, as well as several years' laboratory study. It tells us, in plain and unmistakable language, what Dr. Millard thinks about nephritis, and the way in which he treats patients afflicted with the various forms of that frequent and largely fatal disease. Beginning at the very start, he says that the chapters on treatment mention most of the methods and remedies recognized by the profession as potent to afford relief or work a cure in diseased conditions of the kidneys. New ideas are conspicuous by their absence from this portion of the book. Turning thence to the first portion of his treatise, we find the evidence of an original mind that has attempted to elucidate the complex histology of the renal organs and their still more complex pathology. Dr. Millard's views on both subjects being borrowed from, or largely influenced by, the teachings of Heitzman, are at variance with what the profession has generally recognized to represent the actual condition of things. It is certainly refreshing to read anatomical and pathological statements that are not mere repetitions of what has been already well said by previous writers. The discriminating physician and pathologist will not fail to read with interest the opinions expressed by Dr. Millard, even if he discovers that he cannot accept them in place of his own. To those who are able to compare self-generated experience and matured opinions on the subject of nephritis with the author's somewhat peculiar views, the work may be confidently recommended.

As for the novice in medicine, be he student, recent graduate, or inexperienced practitioner, he will do well to choose along with this work some of our standard textbooks for his guide in the attempt to understand the subject of Bright's disease.

DIE DIPHTHERIE. IHRE Entstehung, VERSEKUNDE, UND BEHANDLUNG. By Dr. C. G. Röthe, Altenburg. Leipzig: Ambr. Abel, 1884. DIPHTHERIA: ITS ORIGIN, PREVENTION, AND TREATMENT. By Dr. C. G. Röthe. Dr. Röthe is an intelligent practitioner of large experience. He is, besides, thoroughly familiar with the literature of his subject. It is not surprising, therefore, that he should have written a valuable and concise treatise on diphtheria. He wastes no space with purely theoretical disquisitions. His book gives us a very fair idea of the actual state of our knowledge concerning diphtheria.

EXCESSIVE VENERY, MASTURBATION, AND CONTINENCE. The Etiology, Pathology, and Treatment of the Diseases resulting from Venereal Excesses, Masturbation, and Continence. By Joseph W. Howe, M.D., late Clinical Professor of Surgery in Bellevue Hospital Medical College, Visiting Surgeon to Charity and St. Francis Hospitals, etc., etc. 8vo, pp. 299. New York: Birmingham & Co.

This is a very judiciously written book on a much hackneyed subject. The name is viewed from the standpoint of a practical surgeon of large experience, and is thoroughly discussed in all its bearings. The author has the faculty of generalizing his points, which proves of immense service to him in writing a book of this kind, and shows in marked degree his qualities as a successful clinical teacher. His facts are clearly presented, due prominence is given to the statistics, and the conclusions are rational and logical. In fact, the author shows himself a master of the subject in all its various details. The causes, diagnosis, and treatment of the various disorders that marshal themselves under the general term of excessive venery are very instructively presented. Very curious experiences are detailed, especially such as bear upon mental influences as connected with the use or abuse of the sexual act. In matters of treatment, the author takes the usual rational courses now so generally admitted—local and general. He has much faith in electricity in many obstinate cases of impotence and spermatorrhexis; but, contrary to the experience of most surgeons, he does not advise the steel sound, save in cases of neurepsia of the neck of the bladder. His confidence in special medication is quite pronounced, if not overdrawn. This, however, is excusable, in view of the number of admirable prescriptions which appear in different parts of the work. Altogether, this book is an admirable one for such as desire to study the subject of which it treats in all its varied bearings, and to obtain points of treatment based upon the large and varied experience of the author.

The present edition of this standard work is considerably enlarged compared with former ones. Several new illustrations have been added. The book maintains its high standard of completeness and excellence, the additions are of value, and prove that the author "has done all he finds himself able to do," which is saying a great deal. As might be expected, his line of work drifts more strongly toward dental operations, so understood, than to the higher surgery of the oral region. This is no disparagement to the skill and originality of the author as a surgeon, but gives us a good reason for saying that the work is especially adapted to the wants of the progressive dentist. One of the most interesting parts of the book to surgeon and to dentist is the description of the author's method of using the dental engine in operations upon the jaws properly. Dr. Garretson has shown in many ways the future possibilities of that instrument in precision of application and in certainty of results, as compared with the ruder method of breaking a way through bone by the "lion forceps" for the removal of morbid growths, or for the cure of diseases involving the harder structures of the jaws. The work is well printed, and in every way a creditable production.

For military surgeons and all those interested in the treatment of gunshot injuries and the other accidents of warfare, this little collection of cases will have an undoubted value. The average practitioner, living among people of peaceful proclivities, will care very little for such collections of surgical cases.

The first edition of this little book appeared many years ago, and it has been out of print for some time. The new issue is full up to date, and will be welcome to many on whose shelves now lingers the old edition. It will be more especially serviceable to our British cousins, as the recent issue of our own Pharmacopoeia contains adequate information concerning most of the drugs and preparations mentioned in the "Extra Pharmacopoeia."
NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 20, 1884.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

LOCOMOTOR ATAXIA AND SYPHILIS.

DR. LEONARD WEBER, read a paper on the above subject (see p. 370).

The President, in opening the discussion, directed attention to the light shed on diagnosis by the results obtained from the use of certain therapeutic agents. He gave briefly the history of three cases, in which ataxic symptoms were well marked; no evidence could be obtained of syphilis beyond the fact of exposure, except in one, and in that instance the patient had been perfectly well, apparently, for many years, and yet there was an extraordinary improvement under the influence of iodide of potassium and bichloride of mercury gradually carried up to the tolerance of the posterior columns of the spinal cord, or a syphilitic affection.

He thought that the effects produced by remedies should not be lost sight of while studying the relation which exists between these two diseases.

DR. R. W. AMIDON thought that but little could be added to the paper of the evening, but he wished to put himself on record as opposed to the view that typical locomotor ataxia, or sclerosis of the posterior columns of the spinal cord, is a syphilitic affection.

The speaker then referred to the statistics given in Dr. W. R. Birdsell's paper, of carefully selected cases; that, in all others, in which syphilis could be traced distinctly, and of 44 cases of locomotor ataxia collected from the clinic for nervous diseases at the College of Physicians and Surgeons, and at the Manhattan Eye and Ear Hospital; only 9.5 per cent. gave a history of syphilis.

Heretofore the conclusions, with reference to causal relation existing between the two diseases, had been based upon statistical data entirely. It was well known how unreliable such data were, and the fact that the percentages varied, as stated in Dr. Birdsell's paper, varying from 9.5 to 88 per cent., and further, as seen by Dr. Weber's paper, from 1 to 96 per cent., Dr. Amidon regarded as sufficient to render statistical deductions worthless.

With reference to deductions drawn from treatment, he had never seen a case of sclerosis of the posterior columns of the cord, as stated in Dr. Birdsell's paper, varying from 9.5 to 88 per cent., and further, as seen by Dr. Weber's paper, from 1 to 96 per cent., Dr. Amidon regarded it as sufficiently rendered statistical deductions worthless.

With reference to deductions drawn from treatment, he had never seen a case of sclerosis of the posterior columns of the cord, as stated in Dr. Birdsell's paper, varying from 9.5 to 88 per cent., and further, as seen by Dr. Weber's paper, from 1 to 96 per cent., Dr. Amidon regarded it as sufficiently rendered statistical deductions worthless.

It was true that syphilis was very apt to produce disease of the connective tissue, and it was also true that the lesion in locomotor ataxia, or sclerosis of the posterior columns, was secondarily a connective tissue disease. Dr. Amidon thought all authorities agreed that primarily there was a lesion of the contents of the nerve-tubules themselves, which was followed by disease of the connective tissue, resulting in cicatricial contraction of the parts involved. The course of the disease was also against the idea that locomotor ataxia was a progressive and slow, while the course of most late secondary and tertiary syphilitic diseases was rapid. What experience Dr. Amidon had had in the treatment of the disease, as well as what he had derived from consulting authorities, and in the study of the pathological anatomy, had been in one direction—namely, against the view that sclerosis of the posterior columns of the spinal cord, or true locomotor ataxia, was syphilitic in nature.

Dr. R. W. TAYLOR said he was already on record as an opponent of the theory, founded on statistics, that locomotor ataxia was caused by syphilis, and was very glad to observe the cautious manner in which Dr. Weber handled the subject. As was well known, perhaps, Duchenne first suggested a causal relation between syphilis and locomotor ataxia, inasmuch as he had found the two diseases associated in a number of cases, but he did not assert that such a relation existed.

It was Fournier who first placed syphilis as a cause of locomotor ataxia, and in one of his lectures said that in thirty-six cases, twenty-four of the patients were syphilitic. Dr. Taylor thought the large proportion thus reported by Fournier could be accounted for readily, on the reasonable supposition that if a man ever had syphilis and had locomotor ataxia, he certainly went to Fournier for treatment.

One reason given by Fournier for the frequent association of the two diseases, was its occurrence in the tertiary period, or as he termed it, the third year; but in America syphilis was not seen in the tertiary period in the third year of its existence. Dr. Taylor also thought that the symptoms described by Fournier, such as loss of sexual power, etc., differed entirely from the symptoms seen in the course of typical locomotor ataxia.

Again Fournier was almost alone in the statement that treatment was useless.

Turning to cases reported by Erb, Gowers, Broadbent, and others, it would be found on close inspection, that in all of them syphilis was reminiscent. Dr. Taylor also reviewed the statistics published by a large number of observers, and said he believed that they exhibited sufficient disparity to cause grave doubt concerning the existence of a causal relation between the two diseases.

With regard to the pathological anatomy of syphilis of the nervous system, it had been well studied under the following heads: (1) Changes affecting the blood-vessels; (2) hyperemia; (3) connective tissue infiltration, and (4) gummatous infiltration.

When in the course of the above syphilitic lesions, they were scattered ill patches, and frequently asymmetrically. Further, syphilitic lesions of the nervous system were apt to be of meningeal origin. Besides, Westphal and Goven had reported autopsies made after locomotor ataxia, with and without syphilis, and precisely the same changes were found in both classes of subjects.

Dr. Roentgen's cases was, that in a number of the men who are put down as syphilitic had begun perfectly healthy children before they suffered from any of the symptoms of locomotor ataxia; and just here Dr. Taylor asked the pregnant question, Can we say that in those cases the tabes was due to syphilis?

DR. W. R. BIRDSALL thought that, at the time he reported his collection of cases, referred to by Dr. Weber and also by Dr. Amidon, no similar report had been made in this country; and while he found only 9.5 per cent. of the cases of locomotor ataxia, seen at Dr. Seguin's clinics referred to, associated with unquestionable syphilitic history, he thought the statistical argument should not be ignored entirely. Nor did he think that, from the whole number collected, 523 cases, anything like an average could be reached; certainly not from the number which any single observer had reported.

An important fact to be borne in mind when studying Erb's cases, was that that observer did not make any distinction between chancroid and chancroid.

If it should be found that the two diseases have been associated in a larger number of cases, Dr. Birdsall thought we should be extremely cautious before saying there was no connection between the two affections. So far as the proof of any connection between the two
diseases was concerned, he was of the same opinion as those who had already spoken. He was in accord with the conclusions given by Dr. Weber, although he did not have the pleasure of listening to the first part of his paper. Buzzard had recently called attention to the fact that gummatous affection might disappear and the secondary meningitis continue, which might account for the prominence of the sclerous found on final examination. Dr. Birdsall regarded true locomotor ataxia as synonymous with posterior spinal sclerosis.

Dr. E. L. Kevles thought the syphilitic element in these cases should not be ignored entirely, and while he did not believe that simple sclerosis of the posterior columns of the cord, locomotor ataxia pure, could be caused by syphilis, it was entirely possible that meningal lesions might progress into parts of the spinal cord and be attended with ataxic symptoms. He had seen two or three dozen syphilitic cases, perhaps, with ataxic symptoms, and was inclined to attach some weight and value to pre-existing syphilis as an active factor in the induction of such lesions as would produce ataxic symptoms. In one or two cases the ataxic symptoms had been distinctly relieved by anti-syphilitic treatment, the iodide in large doses, and mercurial instillation. He did not believe, however, that either remedy alone was necessarily effective. His general view of the therapeutical results in these cases was that some patients could be relieved, none could be cured, and that the therapeutical result fell entirely within the realm of experience.

Dr. A. McLane Hamilton thought that much confusion had arisen from the different use of terms by different observers, and it was readily seen, while studying the literature of the subject, that a great variety of conditions had been recorded as locomotor ataxia. In pure classical locomotor ataxia, posterior spinal sclerosis, he had not found more than twelve per cent. of the cases with a history of syphilis.

In the disorderly cases, where there were head symptoms, etc., syphilis played a very important part.

So far as treatment was concerned, he had used mercurial instillation with good results. The use of the iodide of potassium, however, in very large doses—two or three hundred grains daily perhaps, given in mildly alkaline water, had benefited some patients very much indeed.

Dr. F. N. Otis thought that the experience of Erb and Fournier, each well known and eminent in his special work, could hardly be discarded, and therefore he spoke with great hesitation concerning disallowing the claim that syphilis was a common cause of spinal lesions. His knowledge of syphilitic disease had been such as to make him incline to the opinion that locomotor ataxia might be more readily produced as some syphilitic troubles are than in any other way, regarding it as a disease of the connective tissue, which acts exactly as we know syphilis does, and in the same rotation. For example, in the syphilitic testicle, there appeared first gummatous material, which was capable of changing into connective tissue, that contracted and destroyed the function of the organ.

There was nothing known of the pathology of tabes which could shed any light upon its etiology. As Erb had said, we must wait, and perhaps an intelligent explanation will yet be reached through histological investigations with reference to the lymphatics.

In the mean time personal experience and statistics must be our guide, and we cannot afford to say that the experience of men whom we know have capacity to give these investigations value is of no avail.

Dr. Otis then related a case which illustrated that our belief sometimes rests upon the possibility of the patient being benefited by anti-syphilitic treatment. He had also had three cases in which the patients had been very greatly benefited by this kind of treatment. He felt convinced that no case, if early obtained, should be passed by without the benefit of a thorough trial of mercury and iodide of potassium; and until some scientific knowledge on the subject could be obtained we should be guided by experience.

Dr. E. C. Spitzen, on invitation, took part in the discussion, and said that one important set of facts had been ignored. Syphilis, in the secondary period, undoubtedly affects the central nervous axis, as during the fever of the secondary period tendon reflex is abolished, if syphilis in the secondary period was capable of so affecting the central nervous axis as to abolish tendon reflex, why might it not, during the tertiary period, affect it in the way of producing locomotor ataxia?

- Syphilitic meningitis differs in no respect from ordinary meningitis; nor is endarteritis peculiar to syphilis. It was only the gumma, then, that could be regarded as characteristic not of the existence of syphilitic meningitis, nor syphilitic hemorrhage, etc. According to his own experience, syphilis had been an essential etiological factor in about two-thirds of his cases of locomotor ataxia. He had had three cases occurring in women, in which there was a well-defined cause other than syphilis, and besides, no trace of syphilis case could be obtained in their histories. While the statistical argument was usually a weak one, it had been so handled in connection with these two diseases as to leave no doubt that syphilis preponderates among those who suffer from locomotor ataxia. He thought the question of etiology was almost identical with that of general paralysis of the insane, a question which has been very often discussed, and it seemed to have been established that syphilis preponderates among those who suffer from that disease.

The Academy then adjourned.

SECTION IN OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN.

Stated Meeting, March 27, 1884.

ALEXANDER S. HUNTER, M.D., CHAIRMAN.

THE TREATMENT OF DIPHTHERITIC GROUP.

This subject was brought before the Section by Dr. J. Lewis Smith in a paper read February 26, 1884, and its discussion was made the special order for this evening.

Preliminary to the discussion proper, Dr. W. H. Welch, on invitation, briefly described the anatomical characters of diphtheritic croup, and said, that as the present discussion related chiefly to the treatment of the disease it would be out of place for him to do more than to give a brief outline of the pathological characters. As part of the confusion regarding the pathology of diphtheria and croup is due to a failure to distinguish between the anatomical use of the terms diphtheritic inflammation and croupous inflammation, and the clinical significance of the terms croup and diphtheria. Every pseudo-membranous inflammation of a mucous membrane is called by pathologists either a croupous or a diphtheritic inflammation, without regard to the cause of the inflammation. An essential condition of such pseudo-membranous inflammations appears to be a destruction or a profound alteration of the epithelium covering the mucous membrane. This destruction or alteration of the epithelium may be only in small patches, or it may involve the greater part of the epithelial covering of the affected mucous membrane.

The false membrane differs in its constitution in different cases, and particularly according to the situation of the inflammation. In some cases the false membrane consists of a coagulated exudate from the blood, and then the process is called croupous inflammation.

In other cases the false membrane is composed wholly or in part of a portion of the mucous membrane itself, which has undergone a kind of coagulation, and then the process is a diphtheritic inflammation.

A croupous membrane contains fibrillated fibrin, often not differing from that found in inflammations of serous membranes, or that resulting from coagulation of liquor
sanguinis. It also contains a greater or less number of leucocytes, and these may undergo a hyaline metamorphosis or coagulation necrosis, and matted together form an integral part of the false membrane. The membrane rests usually in some part of its course, either upon the membrane proper of the mucous membrane or upon necrosed epithelial cells. Croupous membranes as a rule are readily stripped off from the subjacent mucous membrane. Pseudo-membranous inflammations of mucous membranes, such as the trachea, covered with cylindrical epithelium, resting upon a thick basement membrane, and supplied but not always, of the croupous variety.

In diphtheritic inflammations either the epithelial cells or the superficial layers of the corium of the mucous membrane have been converted into a peculiar glistening hyaline substance, with little or no trace of cell structure, and arranged usually in the form of an irregular and coarse network. When the false membrane is derived from the epithelial covering of the mucous membrane and occupies the situation of this epithelium the process is called a superficial diphtheritic inflammation by Ziegler, or less happily by Weigert, a pseudo-diphtheritic inflammation. When the false membrane is composed also of a part of the cornium of the mucous membrane the process is a deep diphtheritic inflammation. Most of the organs of the mouth and soft palate are of the superficial diphtheritic variety. During life they are closely adherent, but at the autopsies they are often readily detached.

Diphtheritic membranes may contain ordinary fibrin as well as the hyaline or coagulated substance derived directly from the tissue of the mucous membrane. The change in the tissue giving rise to the former substance is described by various names, such as fibronid or diphtheroid degeneration, coagulation-necrosis, and hyaline metamorphosis. The hyaline material seems to be produced, at least in great part, by a direct transformation of the cells and tissue-elements. This material, although it is believed by some to be produced by a fibrinous coagulation of cell-substance, differs from ordinary fibrin in several respects. It is much more refractive, and is much more resistant to the action of acids and of weak alkali than is fibrin. It also reacts differently toward various staining dyes. In addition to fibrin and hyaline material the false membrane may contain mucus, red blood-corpuscles, leucocytes, intact epithelial cells, and bacilli.

The mucous membrane beneath a croupous or a diphtheritic membrane is more or less infiltrated with emigrated white blood corpuscles, and sometimes contains hemorrhages. Peters, working under v. Recklinghausen's direction, has recently called attention to foetid of hyaline degeneration in the mucous membrane beneath the pseudo-membrane. Such foci are found mainly in the superficial layers of the mucosa. The hyaline degeneration involves, first, thrombi formed in the blood-vessels and the lymphatics, next the walls of the blood-vessels, and finally the adjacent connective tissue and inflammatory products.

The distinction thus drawn between croupous membranes and diphtheritic membranes is a histological one. It usually, but not necessarily, corresponds to the macroscopic distinction adopted by most writers that croupous membranes are loosely adherent, and diphtheritic membranes are closely adherent to the subjacent mucous membrane. There are some writers who do not see any use in distinguishing between croupous and diphtheritic conditions for they regard all these membranes which are sometimes croupous, sometimes diphtheritic, and sometimes fibrinous inflammation. The distinction which has been drawn, however, seems a useful one, even if its application in individual cases is not always easy, a difficulty, indeed, with most of our classifications in medicine.

Diphtheritic and croupous inflammations of mucous membranes may be produced by a variety of causes, of which the special poison of the disease diphtheria is only one. The false membranes produced by the special poison of diphtheria have nothing about them, so far as we at present know, which distinguishes them from false membranes produced in the same situation by other causes. Most pathologists do not accept the view of Klebs, that in diphtheritic membranes micro-organisms exist, which can be distinguished by certain characteristics from similar organisms in decomposing fluids and in other places. The presence of bacteria in the diphtheritic membranes, and, what is of more importance, in the lymphatics and lymph-spaces of the affected mucous membranes, and in internal organs in diphtheria, has been often observed, and the observation is of interest and importance; but it cannot be said that diphtheria is at present one of the strongholds of the germ-theorists. Most of the arguments urged by the opponents of the germ-theory can be presented with especial plausibility as regards the existing observations of bacteria in diphtheria. One's position with reference to the existence of specific micro-organisms as the cause of diphtheria, will therefore depend upon his attitude toward the germ-theory in general. Dr. Welch believed that such organisms do exist in diphtheria, but their special characteristics are not known, they have not been satisfactorily isolated by fractional cultivation, and attempts to produce them in artificial media have not yielded uniform and clear results.

Dr. John H. Ripley then read the paper of the evening (see page 367).

Dr. A. G. Gerster, on invitation, opened the discussion, and said he had performed both the high and the low operation, and regarded a long slender neck as most suitable for the latter. He had performed tracheotomies in 22 cases, the children varying in age from ten months to nine years; 4 patients recovered and 17 died. In most of the cases the high operation was performed. The cause of death in ten cases was extension of the previous inflammation downward; in 5 cases sepsis; in 1 case acute edema of the lungs, pneumonia having preceded the operation; and in 1 case death was caused by asphyxia, the father having blown a teaspoonful of powdered alum through the tube into the trachea. He fully agreed with Dr. Ripley that true pneumonia is not common as a complication of croup of the larynx. Croupous bronchitis, however, was very commonly the cause of death. Dr. Gerster thought it possible to select cases in which it was very much to be feared that Paquetin's cauerty, at one time recommended as a means of avoiding hemorrhage, and had found the operations far from bloodless.

Dr. A. R. Robinson agreed with Dr. Ripley concerning the place for opening the trachea, and also that a fenestrated silver tube should always be used.

He then spoke especially concerning the time at which the operation should be performed in order to best avoid the complications which might influence the result unfavorably. The amount of blood-poisoning could be closely estimated, as a rule, by the situation of the membrane and the area affected. If upon the parts covered with squamous epithelium, as the anterior part of the throat or the back part of the tonsils, the operation would not be so great danger, when the membrane was situated upon the upper, posterior part of the pharynx, and in the nose. But, whether great blood-poisoning was present or not, the symptoms went on without great elevation of temperature. When laryngeal diphtheria existed, however, pharyngeal and nasal diphtheria were present in nearly every case. There were then, the same conditions in large diphtheria as in the other divisions, and besides the stenosis and its results, if it continued, which accompanied the formation of a pseudo-membrane in that locality.

He based his argument for the early operation upon the dangers attending the stenosis, which were suffocation, lack of proper supply of air to the pulmonary circulation, collapse of the brain, and the sooner the child the sooner the closure occur. Besides the dangers from stenosis, there were those from exten-
sion of the membrane to the trachea and bronchi, which was more likely to occur if those parts were in a cat-
tarrhal condition. The longer the stenosis existed the
nearer was the approach to collapse, and an edematous
condition of the alveolar walls and broncho-pneumonia.
The important question was, whether tracheotomy should
be performed before these pathological conditions devel-
oped or after they were on the road to broncho-pneu-
monia.

The immediate effect of the operation was to produce
shock, more or less, and if the child was very weak, it
might be sufficient to cause death to occur upon the
table.

The dangers after the operation were also from blood-
poisoning, descent of the membrane, and from catarrhal
pneumonia.

From these liabilities and dangers Dr. Robinson
argued that, in cases requiring the operation, the earlier
tracheotomy was performed the less the danger from de-
scent of the membrane or the occurrence of broncho-
pneumonia. That death occurred from broncho-pneu-
monia complicating diptheria had been established by
statistics. He believed it to be important, after the
operation, to administer such remedies as added force
to the cardiac action and thereby increased the activity
of the pulmonary circulation, as for example, digitalis.
The inhalation of a warm, moist air, he regarded as an essen-
tial, and to secure this he kept a sponge moistened with
water in the room. Dr. Ripley as to the great importance
in keeping the inner tube clear, and to do this properly, and also see that the patient had necessary attention, constant medical attendance must be given until the period of danger has fully
passed, say forty-eight hours. Do not allow the tempera-
ture to rise above 102° F., and it could be controlled by
ice bags. Dr. R. believed that Dr. Ripley was unwise in
accept any statistics made up from cases in which the
after-treatment had not been thoroughly attended to; for
example, those cases in which the physician saw the
patient only once or twice a day. He thought that in his
four fatal cases out of thirteen operations, two of the
patients died from lack of attendance.

Whether or not the operation should be performed, he
thought should not be a question. If it was evident that
the patient would die no one had a right to perform
tracheotomy, as the patients did not suffer, although the
symptoms were apparently very urgent. The principal
objection to operating under such circumstances was the
effect it had in preventing others from allowing trache-
otomy to be done in cases where it afforded the best
hope of recovery.

A slight stenosis of the larynx in a child two years old would call for the operation
much earlier than the same amount of stenosis in a child six, eight, or ten years of age.

Dr. Fanning referred to the administration of pow-
dered alum, in draught doses, every fifteen minutes, as sug-
gested by Meigs and Pepper, until it produced vomiting,
and perhaps the necessity for an operation could be
avoided by throwing off a cast, and thus relieving the
stenosis.

Dr. J. H. Fruitnight spoke of the beneficial effects
produced in some cases by the use of inhalation, particu-
larly of lime-water in combination with liquor potassa,
as recommended by Dr. Smith.

The discussion was continued by Dr. S. M. Roberts,
and then closed by Drs. Ripley and Smith.

Dr. Ripley asked Dr. Robinson how many cases of
pneumonia complicating diptheritic group he had seen
at autopsy.

Dr. Robinson said he had not seen any, and that his
statement was founded upon the statistics of other ob-
servers.

Dr. Ripley said he based his statement, concerning
the occurrence of pneumonia, upon autopsies which he
had seen, of which there were seven, and he had records
of each clinical history. So far as children having bron-
chial croup was concerned, and dying of pneumonia
three or four days afterward, it was not true, so far as his
experience went, and further, the children might die with
high temperature without any pneumonia whatever.

Tympianitic percussion was the rule in laryngeal, and
also in bronchial stenosis. At autopsy, in such cases, the
lungs were pale, bloodless, occupied a larger space
than normal, and did not collapse on opening the thorax.
That was the rule, so far as he had seen. There was
excessive dilatation of the air-vesicles.

Those who operated early would have better results
than those who operated later, because they would oper-
ate upon some patients when the operation was not essen-
tial to recovery. So far as congestion of the lungs was
concerned, occurring in patients with laryngeal stenosis,
he believed he had refuted that theory by the evidence
afforded at autopsies.

He had performed tracheotomy for croup a hundred
times, and had rarely seen bronchial croup present,
even in the later periods of the disease. He believed it
to be almost impossible for Dr. Robinson, or any one,
to tell when the operation was absolutely useless, and
Dr. Robinson had admitted that he had operated when he
suspected the child would die, but recovery took place.
Dr. Leale also had had reported a case of like character.
Further, of the bad-looking cases, quite as good a per-
centage had recovered as among any other class with
reference to its being a simple operation. Dr. Ripley was
willing to do this with Dr. H. Here were two operations
upon the table in tracheotomy than from any other operation which is performed. He was in most
hearty accord with what Dr. Robinson had said concern-
ing the importance of skilled attendance after the opera-
tion.

Dr. J. Lewis Smith said he looked upon emetics with
a great deal of suspicion, and should not feel inclined to
recommend either alum or turpeth-mineral in the treat-
ment of diptheretic croup. With regard to inhalations,
as soon as the patient was hoarse they should be begun,
and in many cases, if followed up faithfully, true dip-
theritic croup could be averted. He had no doubt con-
cerning the benefit to be derived from inhalation of alka-
line solutions, especially turbid lime water with two per-
cent. of liquor potassa, and administered with a metallic
point having a large opening.

The Section then adjourned.

A Means of Limiting Injections to the Anterior Portion of the Urethra.—According to Guyon the urethra is divided by the sub-pubic sphincter into two portions, an anterior and a posterior. Fluids injected in the ordinary way, if the meatus be not closed, do not pass this internal sphincter, but neither do they reach all portions of the anterior urethra. If the meatus be held closed over the point of the syringe, the injection bathes all the surface of the urethral membrane, but at the same
time it is forced up into the posterior portion and thus
often serves only to increase the extent of the gonorrhoeal
inflammation. In order to obviate these difficulties, and
to ensure a thorough cleansing of the anterior portion of
the urethra, while avoiding the danger of extending the
inflammation to the posterior portion, Dr. Aubert em-
ploys the following simple procedure (Lyon Medical,
February 10, 1884): He takes a piece of rubber tubing
about four inches in length, and of a calibre very much
less than that of the urethra. This is oiled and intro-
duced into the canal, and the nozzle of the syringe being
attached to its free extremity the injection is passed
through it. The fluid is thus introduced deep down into
the anterior portion of the urethra and flows outward
alongside the tube. It washes out the anterior portion
very thoroughly, but unless great force be employed in
the injection none of the fluid passes into the posterior
portion.

OUR LONDON LETTER.
(From our Special Correspondent.)

THE UNIVERSITY OF LONDON AND ITS MEDICAL DEGREES.

London, March 24, 1884.

The promulgation of some fresh regulations at the London University suggests a few remarks on the shortcomings of that institution. Originally established in Gower Street as a mere teaching body, in a few years it vacated the buildings there erected and moved westward, where in turn it became, under a new charter, merely an examining body. The institution then became known as University College, and still continues as a teaching body with numerous faculties. The basis on which the present University of London was started was to give a degree to any one who could pass the examinations. So far as regards the medical examinations, this understanding has not been carried out, and they are fenced in with numerous vexatious regulations.

There are two preliminaries to be passed—one in arts and one in science. These two examinations combined are as hard or harder than a pass B.A. at Oxford or Cambridge. The scientific preliminary is becoming more and more an examination in pure science, without reference to the wants of medical students. For instance, the chemistry given is not medical chemistry, but general scientific chemistry. Nearly half the questions in some years have been on such subjects as the extraction of metals from their ores, the chemistry of silicon compounds, and similar bodies of non-medical interest, gaseous chemistry, and various theoretical parts of the subject.

The same remarks apply to the syllabus of each of the other subjects, viz., botany, zoology, and physics.

As regards the later examinations they are too heavy. Too many subjects are examined in at once, and the consequence is that many students fail to pass. Then all the examinations—except the matriculation examination—are only held once a year. There are eleven medical schools in London for men, and the London School of Medicine for Women. It might be thought that these would send a large contingent of graduates yearly to the university. What are the facts? The annual entries at the London schools are over six hundred in number. The number of medical graduates at the London University a year is (taking the average of the last ten years) about 170. It is evident that some deduction must be made, for a few graduates a year come from Provincial, Irish, and Scottish schools. Taking it, however, at forty, this means that out of every fifteen students only one succeeds in graduating. And this in London—our chief centre of medical study. With all the boundless resources of our large London hospitals, and all the teaching power that two hundred medical teachers—many of them of world-wide reputation—have to offer, less than seven per cent. of London students succeed in graduating at the London University. Being the only British university which offers to students a medical degree without exacting a term of residence within its own colleges, it might have been thought that in London, at any rate, it would draw a large contingent of graduates. But it is not so.

It is not, in fact, the University of London, but, as it has well been termed, the University in London, i.e., it is simply an examining body located in Burlington Gardens. The standard it fixes is unreasonable. Of those who do graduate a large proportion have been plucked at some stage, and many of the obstetricians in London have formerly been plucked, and there is scarcely one of our metropolitan hospitals but has on its staff one or more members who have been plucked at the London University. I could mention half-a-dozen instances in a moment, and could easily make out a list of "killed and wounded" that would astonish your readers. It would, however, be invidious to mention names. I may just remark that it is not alone the idle and incapable who do not succeed. I have known several cases where men who obtained a medal or exhibition at one examination have failed at a subsequent one; others in which unsuccessful candidates have subsequently won scholarships and medals, and one or two instances in which candidates have, on a second trial, taken the first place and gold medal in the very subject in which they were rejected only the year before.

Such being the state of things it is not to be wondered at that many of our leading teachers deliberately advise their pupils to avoid the University of London, and go elsewhere for a degree, or else remain satisfied with a diploma. It must not be inferred that there is any unfairness to individual candidates, though certainly in the rules and practical parts of the examinations there is room for a little difference in the severity of the task set different candidates; for instance, at the Medical Board examination in 1882, one candidate was given a case of exophthalmic goitre to diagnose in which the symptoms had disappeared under treatment and the patient was about to be discharged from the hospital. The candidate failed to make out the case and was plucked. If this occurred exactly as I heard it, it seems hard, at least, if not positively unfair. Moreover, some of the examiners are not particularly nice in their manner with candidates. Professor Rutherford, when examiner, was by no means a favorite, and among the present examiners neither Dr. Mathews Duncan nor Professor John Wood were very over-efficient. I am told that the latter examiner is very deaf, which is, to say the least, rather awkward for candidates.

OUR PARIS LETTER.
(From our Special Correspondent.)

THE DISCUSSION ON THE PATHOLOGY AND PROPHYLAXIS OF Puerperal FEVER.

Paris, March 11, 1884.

After the learned discussion that has taken place at the New York Academy of Medicine, on the pathology and prophylaxis of puerperal fever, your readers may be interested to know something of the most recent literature of the subject as enunciated by French authorities at the various learned societies, in their clinical teachings and in their published works.

Dr. Sirkéy, of Paris, in a recent speech, solemnly hinted that the obstetrician, yet has had considerable experience from having devoted much of his time and attention to puerperal affections at the Lariboisière Hospital, to which he has been attached since 1858—first as an intern and then as physician—at which there is an important service of accouchements. Here a considerable number of parturient women passed under his observation; his opinion and experience on the nature of puerperal fever will therefore be of some value, and this he gives in an interesting work he has just published, entitled: "Clinical Studies on Puerperal Diseases." As among our American confères, there are on this side of the Atlantic two principal currents of opinion entertained as to the nature of puerperal fever: the one representing it as an essential fever generated and propagated after the manner of other infectious diseases, while the other attributes its origin to an unknown agent, but whose effects are always marked by appreciable lesions having their starting-point in the alterations in the lymphatic vessels or veins of the uterus. The former has few supporters among the present generation of obstetricians, while the latter theory is at the present time, represented at the Paris Maternity. Professor Tarnier, surgeon to the institution, scorns the idea of essentialism in puerperal fever, while Dr. Her-vieux, the physician, is a fervent believer in it. That the
puerperal poison is a morbid entity after the fashion of typhoid fever, small-pox, cholera, etc., is a theory more fallible developed in a work by Dr. H. H. H. W. on the subject.

In a recent clinical lecture at La Charité Hospital, Professor Hardy warned his hearers of the dangers of the use of salicylic acid in the treatment of typhoid fever, adding that in this affection there often existed a latent myocarditis which contra-indicated the administration of sympathines of the heart. Professor Hardy grounded his fears on a fatal case which lately occurred in his ward. The case was that of a female patient who was the only one to whom he had ever administered salicylic acid in typhoid fever. She died suddenly, and was the only patient he had lost in this way. Whether it was a mere coincidence or not he could not say, but from the increasing number of accidents that have occurred with this drug caution is necessary.

Dr. Sirédy has been elected member of the Paris Academy of Medicine in the Section of Medical Pathology.

NATURE VS. SCIENCE IN OBSTETRIC PRACTICE.

To the Editor of The Medical Record.

Sir: It has been quaintly said, that one engaged in the practice of medicine "is either a doctor or a fool at forty." If this be true, then I am somewhat of a doctor, for I have been conspicuously acting the fool for nearly twenty years. I have been a "doctor" that I tell it in Goshen, and to publish it in the streets of Askelon.

For thirty-three years, Mr. Editor, I have been actively engaged in the general practice of medicine. Indeed, one-third of a century. All of this time, except three years, in this immediate vicinity, a beautiful inland city with a resident population of about three thousand. The community is composed of the usual elements,即 white and black inhabitants. This place is pleasantly located upon an elevated plateau six hundred feet above the sea level. The dwellings of the white population are well ventilated, the yards and grounds are large and commodious. The hygienic surroundings of the colored people not so favorable, often four or five crowded into one small room. Conditions auspicious for the development and spread of infectious and contagious diseases, among which we see practically demonstrated the probably infectious nature of phthisis pulmonalis, verifying in a limited degree, the theory of Prof. Koch as to the contagious or infectious nature of consumption. This by way of digression. But to the main issue. Now, Mr. Editor, I am writing this letter with the hope of enlightening your readers for any allusion to self, as what I have to say of myself is done in no spirit of egoism, but to acquaint you somewhat with me and to assure the profession that I speak as one of them, and that I give out no uncertain sound. In the winter of 1848 and 1849 I attended my first course of medical instruction at the University of New York, and under the obstetrical direction of Professor Gunning S. Bedford. The winter of 1849 and 1850 I was at the University of Pennsylvania, and there had the teaching of that eminently conservative man, Professor Hugh L. Hodge. In April, 1850, I received a medical diploma from the university. Since that time I have had as a life-work the general practice of medicine. I can safely say I have been the personal attendant of five hundred cases of obstetrics. In all of this time I have never had the case of a woman in labor to die undelivered. When but a tyro in the profession, I was forcibly impressed with the truth, as expressed by the original and logical Blundell, that "no woman in labor should ever die without being delivered." I have never used the antiseptic forceps, but be sure and leave them in my office. The result has been, the forceps still in the office, and I have succeeded thus far without their use. In my own practice I have had three cases of craniotomy. I have
assisted professional friends in four other cases. I hope, for woman's and for conscience sake, never to have another. An advocate for the forceps, perhaps, may say the forceps ought to have been used. In most of the cranioamy cases the child was dead. I have had five well-defined cases of puerperal peritonitis, four cases of puerperal meningitis, two cases of puerperal eclampsia, no cases of endometritis, and one case of pelvic cellulitis. I lost one case of eclampsia after delivery, and the only case I ever lost within the parturient month.

Is this record too good for publication? Criticised as it may be, it is nevertheless true. This is written not in a spirit of boasting, but in thankfulness. In the practice of medicine, faith; knowledge of the subject (to this extent art and science are of great necessity), and then be gifted with patience and sound common sense. A good maxim, "Hasten slowly." In ordinary or natural labor there is but little to do, or that should be done. Some manual aid is all that is usually necessary. The process of labor being purely natural, then meddle some mischief before and after delivery can only work harm. From the teachings of modern scientific obstetricians, the whole process of human delivery is abnormal; and the unfortunate woman should be dealt with as though she had undergone a capital surgical operation. With this new idea the astonished mother is confused. She is made to ascribe refutations as to the error of the theory. God is too merciful, and God thought nature too conservative to command the human family to "be fruitful, multiply, and replenish the earth" at such a tremendous risk as "advanced obstetric science" tells us is involved in the effort of human delivery and its subsequent results. Is parturition attended with so much danger? No. New York City and other cities in the Middle and Eastern States as some of our medical writers tell us? Then we gladly invite her people southward, to a land beautified with roses in December, with orange fields and queenly magnolias; a land genial in climate, hospitable in home; with a people refined and cultivated, and where her women can accomplish their grand mission work, giving birth, without feeling fear and realizing that they must pay as a forfeiture their own precious lives. If the statements made by some be half true, no woman in sound mind would voluntarily consent to become a mother. Indeed, the terror becomes so appalling that even the physician would shrink from the duties of the lying-in chamber. The present state of the art is such that the public accept and practise the obstetric art as taught by the advanced thinkers, or be considered obsolete, behind the age, as negligent and incompetent? I believe I know that the profession, outside of certain localities and favored circles, will not consent to such a decision. I am glad to tell you, Mr. Editor, that there is no necessity for such an ado for our lying-in women in any part of this State with which I am acquainted.

If it were so, sad would be the fate of our parturient women, not one in the thousand could be furnished according to modern obstetric demands, and only one in the thousand financially able to compensate a medical attendant. No royal fees here. Very few of the population independent, the majority poor and porter; many of them not ready money enough to pay for the boracic acid the doctor needs for his bath, leaving out German Cologne and Lubin's Extracts. New Yorkers may need all of this grand lying-in preparation and precaution, and if so I am glad their pecuniary condition is so good that they will not be ashamed to afford it, and then to pay their professional attention in princely style, furnish their wardrobes to repletion, to say nothing of bodily disinfectants and handkerchief extracts. All physicians, even with us, recognize the general necessity in all cases of bodily cleanliness, comfortable apartments, and ordinary hygienic attention.

Many of our women among the poorer classes, especially with the blacks, have not even ordinary comforts. Often but one bed for the family; scanty supply of clothing; poor diet. No disinfectants but water, sunlight, and a bountiful supply of oxygen, furnished free to us all in our wholesome air. Yet under such adverse circumstances it is a remarkable event to hear of a woman dying in the parturient month. Why this difference? Had our women more vigorous constitutions? Are our physicians less meddlesome? Do the city doctors take their cases out of the hands of nature and make them their own cases? If this be true, no wonder then the record tells of such fearful havoc. There is a grand underlying principle which should control every medical man, whether in surgery, obstetrics, or in the practice of medicine, that nature, the vie side, the dynamic force, is a grand conservator, and has an important, yes, a necessary part to perform in every cure, an enabling force in the recovery from all the ills "which frail human flesh is heir to." This is a God-given capacity, and in every human body that tends to resist disease and, when assailed, to recover, in many instances without medical help.

Professor Forbes left a valuable legacy to the profession in his little volume, "Nature and Art in the Cure of Disease." I fear that some of our city doctors make trouble in their obstetric practice because they assume to be wiser than they are, and find a way to displace a knowledge may be dangerous. I know that this is a day of great progress, rapid movement. Time and space seem nothing, almost annihilated, things of the past.

Science with a Samson-like tread moves apace. It is proper that the medical profession should keep well abreast with the age; but the doctor must not become materialistic and relegate everything, even the human body, to cold, abstract science. This human body is a divine temple, not simply matter, but a grand, complex organism, and somewhere enclosed in it a jewelled aspiration that seeks an immortality. In his zeal for reputation the doctor must not overlook the bounds of prudence and, when this poor human body is in suffering, make new difficulties and more complications, then sound a fog-horn, an alarm-bell, that others may recognize them as advanced thinkers, profound physicians, skilful experts, teachers of other but more conservative men. In conclusion, Mr. Editor, let me say to you and to others, that I write in no vindictive spirit, but for the elimination of truth. I am willing to "render unto Caesar the things that are Caesar's: and unto God the things that are God's." The day will come when they should be done though the heavens fall." The chaff is mine, burn it; the wheat, if any, is yours, and belongs to the profession.

W. J. GAUTIER, M.D.

TUSKEGEE, Ala., March 15, 1884.

THE NEZ PERCES ON THE INDIAN RESERVATION Dying Out.—Dr. Woodward, an intelligent young physician employed by the Government, resides among the Nez Perces, and divides his time between them and the Poncas. He has charge of the commissariat and a general oversight of affairs. In reply to a question put by a reporter, he said: "Their fate is inevitable. They are doomed. They must dwindle down and become extinct. And this is not only true of them, but it is true of other Indians. Look at the Pawnees. When they came here in 1875 they numbered 2,630; they now number 4,191. The Nez Perces came three or four hundred years ago, numbered 360. I came here in 1881 from Nebraska, and we brought one hundred head of horses. In four months thirty-six of them died. I take my quinine almost as regularly as I take my meals. Malaria, pneumonia, and consumption are their prevailing diseases. Last year I gave them over a hundred ounces of quinine. There are but three young children among them."
Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from March 23, 1884, to March 29, 1884.

HAMMOND, John F., Colonel and Surgeon. Now in New York City on sick leave of absence, will, after the expiration of his sick leave, await orders in that city. S. O. 70, par. 8, A. G. O., March 26, 1884.

GANDY, Charles M., First Lieutenant and Assistant Surgeon. Assigned to duty at Fort Brady, Mich., as Post Surgeon. S. O. 56, par. 6, Headquarters Department of the East, March 22, 1884.

Official List of Changes in the Medical Corps of the Navy, during the week ending March 29, 1884.

GREEN, E. H., Passed Assistant Surgeon. To the Greely relief steamer "Thetis."

BRYAN, J. H., Passed Assistant Surgeon. Resigned. To take effect April 10, 1884. Leave of absence till that time, and permission to leave the United States.

RUSH, C. W., Passed Assistant Surgeon. To the Naval Academy.

D. B. Ward, of Greensboro, Ala., sends us the history of a peculiar case of gun-shot injury. An infant of eight months was accidentally shot in the forearm, a charge of bird-shot lacerating the extensors, splintering the bones and elbow-joint. The infant recovered from the shock. Twenty-four hours after the injury Dr. Ward amputated the arm just above the elbow. The operation had to be performed without intelligent assistance, but the patient made an excellent and rapid recovery.

TAURET'S MERCURIC IODIDE TEST FOR ALBUMEN.—Some mistakes have been made in giving Tauret's formula, which is as follows:

| B. Hydarg. bichlorid. | 0.35 |
| Potas. iodid.        | 3.32 |
| Acid. acetic.        | 20  |
| Ag. destillat.       | q. s. ad 100 |

M. The precipitate of peptones or alkaloids, if present, is dissolved by heat. It is not necessary to acidulate the urine first.

OSMIC AND PEROSMIC ACID.—A correspondent inquires the difference between osmic and perosmic acid. The terms have been used interchangeably by the German writers. The formula is Os O2.

INFLUENCE OF THE OVARIANS IN THE DETERMINATION OF SEX.—Dr. Richard Neale writes to the British Medical Journal: "Among the many theories regarding the determination of sex, is one broached or supported by Mr. Thomas Tuckey, that the right ovary is for males, and the left for females. On the 5th instant I delivered a lady, upon whom left ovariotomy was performed, in January, 1883, of a male child. Dr. Hamilton, in the Lancet, page 191, records a case where two males were born after the removal of the right ovary, the patient having borne two female children previous to the operation. These cases refute the ovular theory."

SOUTHERN MEDICAL COMMENCEMENTS.—The blood courses warmly through the veins of our Southern brethren; even college commencements are an excitement. Witness: "After Dr. S.—'s address the audience was again entranced by the beautiful music of one of the most delicious medleys this paragraph slinger ever heard. Suffice it to say that it began with ' Dixie' and ended with 'Auld Lang Syne' " As for the orator of the evening, "He glanced with a rapid but penetrating gaze upon the tremendous forces which are centralized in the present era, when science, literature, and the arts are scattering their jewelled trophies in the pathway of the aspirant for fame or fortune, etc."
Original Articles.

SOME REMARKS ON
THE ACOUSTIC PHENOMENA PRODUCED BY
THE FLOW OF FLUIDS IN TUBES,
AND ALSO UPON THE SITE AND MECHANISM OF CARDIAC
FUNCTIONAL MURMURS.

BY A. BRAYTON BALL, M.D.,
VISITING PHYSICIAN TO ST. LOUIS AND BELLEVUE HOSPITALS, NEW YORK.

RENEWED interest in the subject of functional cardiac murmurs has been awakened recently by a discussion of certain controverted points in the Edinburgh Medical Journal and the British Medical Journal. The object of the present paper is, first, to review briefly the more important experiments which have been made during the past half century, to determine the acoustic conditions of cardiac murmurs; and, secondly, to present the main points of the controversy alluded to.

Laennec, as is well known, made the singular blunder of supposing that the bellows-murmur heard over the heart and arteries was due to spasm of their muscular structure, and not to the motion of their fluid contents. "On many occasions," he says, "I have been struck with the complete resemblance of the sound produced by muscular contraction and that of the bellows-sound. In resting the ear upon a pillow, if we contract the mas- seter muscles, or rather if we contract and relax them alternately, we give rise to sounds precisely like the bellows-sound of the arteries. In the following experiment the resemblance is more perfect still: If we place the stethoscope upon one of the condyles of the humerus of a person whose arm is supported by an assistant, and then cause the individual to bend and extend the arm gently, we perceive a sound exactly similar to that produced by the raising and lowering of a pair of bellows." Objections to this theory led Dr. Corrigan, of Dublin, to reinvestigate the subject in 1829, and to him we are indebted for the discovery of the most frequent factor in the production of cardiac murmurs, viz., obstruction in the blood-channels. Corrigan held that the movement of the column of blood in health differed from that of an ordinary current, the blood being propelled as in a pipe, while in an ordinary current "the particles that constitute the body of the stream move at different rates, those at the centre with the greatest velocity, and at varying degrees of rapidity as they recede from it, or may meet with obstacles: a compound motion is thus produced, a movement of the whole mass forward, and with it an irregular motion of the constituent particles within themselves, and against the side of the conduit or channel. In the living body in rude health, the arteries being always quite full and equally distended, and the heart's action being regular, the blood cannot assume the motion of a current, but must ever move in the way already described. If you may means the regularity of the heart's motion be interfered with, or the full and equal distention of the arteries obstructed, the motion of the blood becomes that of a current, and at the same instant bruit de soufflet et frémissement catale become evident."

"It occurred to me," he continues, "that I might be able to put my views to the test of direct experiment. One end of a length of small intestine was attached to a pipe, and a current of water of considerable force allowed to run through it. While the intestine was kept full and tense, the finger laid upon it received no sensation, any more than if it were laid upon a portion of the same intestine containing fluid at rest; but constriction being made at any part, then immediately below the narrowed part where the intestine was no longer tense, and where, for the reasons already gone into, the motion of the fluid became very different from that through the upper portion of the tube, a sensation was felt precisely resembling frémissement catale. No similar sensation was felt above the constriction. The same thing took place with the sound heard by the stethoscope. While the intestine was tense, no sound, or a murmur exceedingly indistinct was heard; but any part being constricted, so as to produce an alteration in the motion of the fluid, a very loud bruit de soufflet immediately became evident."

Two important facts were demonstrated by this experiment; first, that the main factor in the generation of the murmur is an obstruction to the flow of the fluid; and second, that the sound becomes audible, not at the seat of constriction, but in the dilated part beyond. In 1853 Félix Savart published the results of a series of brilliant experiments, which appeared to throw much light upon the mode of causation of these murmurs. Savart showed that when water is allowed to escape through a circular orifice in the bottom or at the side of a vessel, the emerging column forms a sonorous liquid vein ("veine liquide sonore"); which presents certain remarkable peculiarities. Below the opening the fluid descends for a time in a transparent column, gradually decreasing in diameter until it reaches its point of maximum contraction. Beyond this point the vein becomes turbid, and alternate swellings and contractions are noticed. When illuminated by successive flashes of electric light these alternations in diameter are seen to be produced by the resolution of the vein into liquid spherules, which, as they descend, change their form gradually from that of prolate spheroids with their longest axis vertical to that of oblate spheroids with their longest axis horizontal. The quivering motion produced by these changes, when it is forcible enough, generates an acoustic murmur. The sound, or the acoustic phenomena, are observed whether the fluid escape into the open air or pass from

a constricted into a dilated part of a tube. Savart's fluid vein has played an important part in the interpretation of cardiac murmurs, but the claim that it is the efficient cause has not gone unchallenged, as will appear later.

In France the clue afforded by Savart's experiment was applied by Chauveau, in 1855, in his investigation of vascular murmurs by experimentation on horses. His conclusions were substantially the same as those obtained by Corrigan. He found that the murmur was generated beyond the constricted part of the vessel, and was carried forward in the direction of the current; but he also demonstrated the fact that the chief element in the production of murmur was the rapidity of the current, and that the size of the orifice was important only in so far as it influenced the rate of flow. The same causal relation he found to be true also of the quality of the fluid. Still, Chauveau regarded a certain amount of constriction or dilatation in the vessel as essential, and as presupposed by the very existence of a murmur. Indeed Savart's theory, which he accepts, does not provide for the occurrence of murmur except in this condition. In 1854, four years, therefore, before Chauveau's article, and apparently without Chauveau's knowledge at the time he published the results of his own investigation, Heysius, of Leyden, made another contribution to the study of the subject, viz., a new explanation of the vibratory motion of the fluid in the dilated part of the tube. His theory, it will be seen, differs essentially from that of Savart, and resembles, in many points, that already presented by Corrigan. In order to make the motion of the current visible he mixed powdered amber with the fluid, and then found that when the column of liquid passes from the constricted into the dilated part of the tube the central portion of the fluid preserves, in the main, its original direction, while the lateral portions form eddies (tourbillons) in a direction opposed to that of the general current.

These tourbillons, or lateral eddies, Heysius supposes are produced in the following way: The stream as it enters the dilated part encounters on both sides fluid particles, which are pursuing their course more leisurely, and are drawn into the current by the force of the molecular cohesion between the individual particles. This process will take place naturally with most activity near the point of entrance, where the rapidity of the current is greatest, since the cohesive attraction diminishes as the stream becomes slower in its expansion to fill the dilated part of the tube. Fluid particles are thus being constantly withdrawn from the triangular spaces a c e and b d f in the lateral side of the entering column of fluid, and as this withdrawal is greatest near the point of entrance, a reverse current is established toward the part where the loss is going on most actively. In confirmation of this explanation Heysius found that there was a marked diminution in the lateral pressure on the sides of the entering column as compared with that in the general current.

That the murmur is due to vibrations in the fluid, and not to vibrations excited primarily in the tube-wall by friction, Heysius proved by producing murmurs in glass tubes in place of the flexible tubes used by previous investigators—in tubes, therefore, in which, by reason of their smooth surface and rigid material, vibrations could not be produced readily by friction. He also confirmed the observation of Corrigan and Chauveau, that the murmur is heard loudest in the dilated part of the tube, and not at the point of constriction, where the friction is, of course, the greatest.

The friction theory—that is, the theory that the acoustic vibrations originate in the wall of the tube—has, however, not been without its advocate. Thus Weber, in 1855, denied the possibility of the production of murmurs in fluids on account of the comparative incompressibility of the latter, and held that the acoustic vibrations were produced in the tube-wall in the same way as the strings of a violin respond to the pressure of the bow. "As the violin-bow," he says, "must be pressed with a certain force upon the strings, and be drawn over the same with a certain rapidity in order to produce a tone, so a certain pressure and a certain rapidity are necessary to produce a murmur in the friction theory has been shown already in part, and need not detain us now, as the full proof will appear from the experiments of Nolet, to be mentioned later. Weber's chief contribution is his discovery of the important fact that with a sufficiently strong current murmurs may be generated even in a tube of uniform diameter, that is, in a tube in which there is no transition from a constricted to a dilated part of the tube—a condition regarded as essential by previous investigators. Heysius failed to discover this fact, apparently because, as Nolet points out, his apparatus was not adapted to supply a current of sufficient rapidity to produce a murmur, except dilatation in the tube afforded the presence of a favorable conditions.

Marey, in 1863, regards the murmur as originating in the vibrations of the fluid, but expresses no opinion whether the acoustic phenomena are due to the "fluid vein" of Savart or to the tourbillons of Heysius.

In 1871, Thamm reviews the subject in the light of his own experiments, and confirmed Heysius' theory that the vibrations originate in the fluid, and not in the tube-wall as Weber supposed. He found, also, that murmurs could be produced in tubes of uniform diameter by increasing the rapidity of the current, and that, therefore, changes in the lumen of the tube are not essential to the development of acoustic phenomena. In tubes of uniform diameter he saw that when the current was sufficiently rapid only the particles of the central portion of the fluid pursued parallel directions, while the peripheral portions described irregular curves in a reverse current.

In 1871, Nolet, of Leyden, made a thorough investigation of the subject. Like all previous observers he found that the murmur was heard loudest beyond the constricted point; but he had also, though less dis...
tinctly, on the near side of the constriction. Over the site of the constriction the murmur was inaudible, and this fact Nolet regards as irreconcilable with the supposition that the murmur is produced by friction and vibration of the tube-wall. Moreover, were this the explanation, the murmur should be modified by the material of which the tube is composed, which is not the case, as the murmur is produced without regard to the character of metal or glass tubes, as well as in tubes with distensible walls. For these reasons he concludes that the cause of the murmur is to be sought in the fluid itself.

The question as to the nature of the sound-producing vibrations in the fluid, Nolet admits is not so easily settled, but accepts the "fourth" theory of Heyen, that of the electric effect on the fluid, and finally on the fluid. He affirms his explanation with great orthodoxy. That the "fluid yam" of Savart is not the cause of the murmur, he thinks is proved by the following considerations:

1. In tubes of uniform diameter. Recent experimentation has shown beyond question, that in a tube of uniform diameter a murmur may be produced if the current be sufficiently rapid. In such a tube the condition necessary for the formation of a fluid vein obviously exists only in the escaping column at the extremity of the tube. If the murmur originated here, and not in the course of the tube itself, the roughness or smoothness of the internal surface of the tube-wall ought to have had an effect on the rapidity with which the current is necessary to produce the sound, whereas the contrary is the case. In rough rubber tubes less rapidity is necessary than in smooth ones, while in metallic tubes much greater rapidity is required. Moreover, in tubes of uniform diameter the murmur has the same intensity throughout the whole length of the tube. If the murmur were produced by the outflowing stream, the intensity of the sound should diminish in proportion as we recede from the point of outflow.

2. In tubes with changed diameter. If a broad rubber tube be joined to a narrow one of considerable length, the extremity of which dips into a vessel containing water, and the current be regulated so as to produce a strong murmur on the distal side of the constriction at the junction of the two tubes, scarcely any murmur will be heard where the narrow tube enters the water. If the outflowing stream were the cause, the murmur at this point should be just as strong as elsewhere in the course of the narrow tube.

Nolet found, moreover, that in rubber tubes of uniform diameter the current-rapidity necessary to produce a murmur was not very much greater than the normal velocity of the blood as it passes through the aortic orifice; the latter rate being estimated at 1,548 millimetres per second, while the requisite velocity in rubber tubes was only 2,607 millimetres per second. Although this experiment cannot be applied without some reservation to the explanation of the so-called anemic murmur in the aorta and pulmonary artery, it is at least highly probable that mere rapidity of current plays a more important part in the production of such murmurs than has been commonly supposed. Changes in the lumen of the blood-channels undoubtedly favor the generation of acoustical phenomena, and such changes are the main factor in securing the requisite velocity in most cases of cardiac organic murmurs; but it is no small gain to our knowledge that in anemic murmurs we are not compelled to assume the existence of abnormal alterations in the lumen of the blood-channels, as is implied in the acceptance of Savart's theory. In anemia there are special conditions favoring the unusually rapid flow of the blood, such as the small quantity of blood in the circulatory system and the irregular action of the heart, particularly during periods of excitement. Chauveau supposed that in aortic and pulmonary murmurs of anemic origin there was a relative dilatation of these arteries as compared with the heart cavities, which had diminished in size to accommodate themselves to the lessened quantity of blood. We now know that in cachetic conditions there is a tendency to dilatation rather than to contraction of these cavities. Nolet's experiments enable us to explain such murmurs without hypothetical relative changes in the diameter of the blood-channels.

In our remarks upon the site and mechanism of cardiac inorganic murmurs we shall confine ourselves mainly to the question involved in the interpretation of the temporary murmur heard in cachetic conditions in the second and third intercostal spaces so far to the left of the sternum as to render doubtful the origin of the sound in the pulmonary artery. The following case will serve to bring the points at issue more clearly before us.

An elderly female, aged 65, from Ireland, servant, was admitted to my service in St. Luke's Hospital October 30, 1883, suffering from chlorosis. Had an attack of tertian intermittent fever in the winter of 1883. For several months has been very anemic, and subject to palpitation and dyspnoea on exertion. Never had rheumatism or any pulmonary affection. On admission patient presents the typical appearance of chlorosis: well-marked panniculus adiposus, pronounced palor of skin and mucous membranes; palpitation and dyspnoea on exertion; menstruation regular, but scanty; no cough; pulmonary physical signs normal; no enlargement of liver or spleen; examination of urine negative; apex of heart beats in fifth interspace half an inch to right of middle line, not obliterated; part of the heart felt heard at apex, or in axilla, or at angle of left scapula, or in the aorta or carotids. In the second intercostal space, one and a half inch to the left of the sternal border, is seen a distinct pulsation, over which can be heard a soft systolic bellows-murmur, perceptible also in the third space, but shading off rapidly in all directions, and heard with distinctness only in a region of about two or two and a half inches in diameter. The greatest intensity of the murmur was found by repeated examinations to be situated exactly at the point indicated. Well-marked venous hum heard over internal jugulars, especially on the right side of the neck. Under the free use of iron, patient's health rapidly improved, the anæmia disappeared, the murmur gradually became fainter, and finally vanished completely about a week before her discharge on December 5th. She was seen again two months afterward, and no trace of the murmur was then audible.

The not infrequent occurrence of a murmur in this situation, with tolerably sharply defined limits, and unaccompanied by murmur elsewhere, did not escape the observation of the late Mr. W. J. Latham, in his admirable clinical lectures, published in 1845; he gives the following description of a murmur, which corresponds in its situation and general character with the one under consideration:

"Fancy a line," he says, "drawn from the left side of the sternum along the upper edge of the second costal cartilage, and continued an inch along the second rib; and another line drawn from the sternum along the lower edge of the third costal cartilage, and continued one inch along the third rib. Between these two lines a space is included, in the whole or in part of which a murmur is often audible coincident with the systole of the heart, when no such murmur can be perceived either in the precordial region, or in the course of the aorta, or in the carotids, or in any part of the arterial system, but here and here only. It is a gentle bellows-murmur, quite obvious to the ear and unmistakable in its character.

"Of such a murmur, often audible in this situation exclusively, I am certain as a matter of fact, and certain, too, of its very remarkable accompaniments. I have associated it with phthisical prostration, or with phthisical or consumptive, or in those who were too justly suspected of being so. I cannot say in what proportion of the phthisical it occurs; but I am continually meeting with it." Latham has apparently no doubt that the pulmonary

tery is the point of origin of the murmur, but confesses his ignorance whether "it becomes such in consequence of its own disease or by reason of pressure or impediment reaching it from the diseased being." Although the reticulum itself, or by consolidation of the lungs, the generation of cardiac and arterial murmur was well recognized even in his day, Latham appears to have had no suspicion that this definitely located murmur could be produced by this cause. The situation of the murmurs, so far to the left of the sternum led him to conclude that the murmurs was caused either by a morbid condition of the reticulum itself, or by consolidation of the lungs, conduct- ing the sound to some distance beyond the valves.

A murmur in this situation was subsequently noticed in many cases of mitral regurgitation in connection with an apex murmur by Skoda, Meyer, Bamberger, Gerhardt, and others. Meyer explained the murmur in the second intercostal space in these cases by supposing that the acoustic vibrations reached the walls of the pulmonary artery; but if solid media were the means of conduction the sound ought to be heard rather in the aorta, because the fibrous ring to which the mitral valves are attached connects them with the aortic orifice, and not with the pulmonary ostium. Bamberger's theory, that the murmur is due to dilatation of the valves has given rise to many controversies. As far as is excluded by the fact that the murmur in the pulmonary area is not found in mitral stenosis, where the same condition is also present. In 1868 Naunyn, 1 in a brief and very modest article, advanced a new explanation, which immediately attracted wide attention, and in Germany, at least, has since been accepted very generally as providing the explanation of the murmurs in the pulmonary area with regurgitation though the mitral orifice. Naunyn maintained that in mitral regurgitation not only the left auricle, but its appendix as well, is dilated, and that the latter not infrequently, under such circumstances, winds round the pulmonary artery, and comes into contact with the chest about one and a half inch to the left of the sternum, where an actual impulse can be seen if the impact be forcible enough. The conduction of the murmur of mitral regurgitation to the point indicated may easily be accounted for, therefore, provided the approach of the left of the chest-wall would be proved. To satisfy himself on this point Naunyn thrust his hand into the axillae, perpendicularly to the chest-wall, at the point where the chest descends, and on the left side, found that they entered the appendix of the left auricle where it bends around the pulmonary artery. It is implied in this statement that the appendix was in more or less close proximity to the thoracic parietes, but no details on this point are given. The importance of fuller information in this particular will be seen later.

Among English writers Balfour, 4 of Edinburgh, was the first to apply Naunyn's observation to the interpretation of inorganic murmurs. The essential points of Balfour's theory of this class of murmurs may be briefly stated as follows: He regards the distinction made by Walaseh, and since followed by most writers, between hematic and dynamic murmurs, not only in the pulmonary, but in the mitral area, as essentially invalid. He adheres to this classification the true murmurs of anemia are invariably basic, and originate in the aorta and pulmonary arteries. The anemic murmur is, therefore, an arterial, as distinguished from a true cardiac murmur, which is generated within the heart itself at either or both of the auriculo-ventricular orifices. That temporary systolic murmurs do occur in the latter situation, independently of lesions recognizable after death, has always been recognized; but they were regarded as etiologically distinct from murmurs of hematic origin, and a separate class was, therefore, erected for them, viz., that of dynamic mur- mus, in the interpretation of which many ingenious hypotheses have been advanced. This distinction, which has been the source of endless perplexity, Balfour pro- posed to do away with completely, and to explain all the murmurs of inorganic origin by the direct or indirect results of the cardiac or pulmonary diseases. He thus leaves the class of diseases which are not infrequently accompanied by cardiac functional murmurs—in chlorosis, which may be regarded as a type of anemic affections, as well as in febrile disorders, such as typhus, enteric fever, erysipelas, etc.—the defective nutrition noticed in the musculature of the body in general produces also a flabby and relaxed condition of the valves, through which the temporary establishment of patency of one or both of the auriculo-ventricular orifices. This valvular insufficiency may result either from a simple dilatation of the ventricular cavity; or the papillary muscles, which, as Friedreich 1 has shown, are specially subject to atrophy and degeneration, may become weakened so as to be unable to close the auriculo-ventricular valves; or, as Macalister 6 supposes, the enfeebled base-muscles, instead of squeezing the ostia into something near their systolic shape and size, preparatory to the complete closure by the valves, may do their work incompletely, and thus the valves may prove inadequate because "they are asked to close bigger orifices than usual; but not because the valves have been made larger by dilatation." A mechanism by which the complete closure of the valves is prevented, the result, in the left cavities of the heart, where dilatation usually takes place first, is to raise the blood-pressure in the left auricle and pulmonary artery, and thus to produce the accentuated second pulmonary sound, which Balfour regards as the earliest indication of functional dilatation of the pulmonary artery, or the presence of a large systolic murmur. As the dilatation is not so readily in the direction of the current producing them, the systolic muscular generated at the mitral orifice will be transmitted to the dilated left auricular appendix, and thence to the chest-wall in the second intercostal space, an inch and a half to the left of the sternum. Whether a murmur at this early period of dilatation is heard also at the apex depends partly on the intensity of the sound generated at the mitral orifice, and partly on the condition of the right ventricle. If this cavity be also dilated, the murmur at the apex may be obscured by the revolution of the heart on its longitudinal axis during the process of dilatation, and the interposition of the right ventricle between the ear and the apex. Before losing tricuspid hear is heard also a systolic murmur when the tricuspid area is heard in the tricuspid area. Still later, purely hæmical murmurs are developed at the aortic and pulmonary orifices, as a result of the larger waves of watery blood thrown into the arteries by the now irri- tably acting heart. Murmurs, which are either primarily or secondarily due to impoverishment of the blood, therefore arise at all the four orifices of the heart. The order of their development may not be always that just described, but, as a rule, the intracardiac murmurs due to dilatation precede the arterial murmurs of more direct hæmical origin. It will be seen, therefore, that, according to Balfour's theory of functional cardiac murmurs, the systolic muscular murmur is generated unconditionally in the pulmonary, or rather auricular area, as he prefers to term it, is generated at the mitral orifice, and not in the pulmonary artery as has been commonly supposed; but it is equally apparent that his theory rests upon the assumed correctness of Naunyn's observation as to the part played by the left auricular appendix in the production of the murmur. This main position has recently been vigorously assailed by Dr. Russell, 6 of Edinburgh. He maintains that there is no clear evidence that the left auricular appendix ever approaches near to—with less touches—the anterior chest-wall. Anatomical facts, he insists, are opposed to such an hypothesis, and the difficulties are increased by

the cardiac dilatation which occurs in anemia. "The origin or root of the appendix is overlapped in part by the pulmonary artery, so that the movement of the appendix has to traverse a course equal to the diameter of that vessel. Any increase in the diameter of the artery from increase of its contents will thus place the appendix deeper in the chest; and the distance it has to travel toward its assumed destination is further increased by others coming its root upward. During dilatation of the appendix its movement is mainly a downward one, following the base of the ventricle as it contracts during systole. Doubtless there must be also, as Sibson points out, a certain amount of forward movement, but this can only be inconsiderable." "It is further recognized that, in debility, owing to dilatation of the left ventricle, the left is displaced outward and backward; a change occurs, which may be regarded as a rotatory movement of the heart round its longitudinal axis, and this must be conceded as having a displacing effect on the auricle analogous to what it has on the ventricle of the same side." Furthermore, there is good reason to suppose that in dilatation of the appendix the current takes place more transversely than longitudinally.

In a later article Dr. Russell says: "The fact of cardiac dilatation is accepted by the advocates of this [Balfour's] theory; we have, therefore, only to learn from post-mortem observations, made with the heart in situ, the changes which occur in the relations of the various parts of the cardiac muscular wall in this condition. It will, I submit, be found that in less degrees of dilatation the conus arteriosus occupies the second left space, that the same space is occupied by the pulmonary artery, and that the left limit of the vessel is from one to one and a half inch from the top of the sternum. In greater degrees of dilatation the conus arteriosus occupies the inner angle of the space formed by the aortic arch, the pulmonary artery, and the origin of the pulmonary artery is under the second rib. In both degrees of dilatation the left appendix is invisible from the front, and is deeply buried behind the root of the pulmonary artery and adjoining ventricle." In proof of these statements Dr. Russell records his post-mortem examinations in three cases of progressive pulmonary dilatation, in which the heart was, in each instance, over a quarter of an inch in diameter, and one of "surgical kidneys," in a case of which the heart was, notwithstanding the presence of various degrees of dilatation, the left appendix was either invisible or could be seen only on profile view when the left wall of the pericardium had been drawn outward. Upon these points Dr. Bryom Bramwell says: "Sibson has shown that, in the large majority of cases in which he has examined, the greater part (in 25 of 45 cases) or the whole (in 14 of 45) of the artery bore to the left of the sternum, and presented itself behind the upper costal cartilages and their spaces, from the first cartilage to the third space, and further, that the average breadth of the vessel in Pirigoff's five front views of the healthy heart was an inch and a quarter. I see nothing improbable, therefore, in a pulmonary murrmur having in many cases its point of maximum intensity considerably to the left of the sternum." In confirmation of Dr. Russell's statement that the appendix of the left auricle is usually invisible from the front when the right cavities of the heart are dilated, as Balfour admits the case is chronicosis, Dr. Bramwell adds: "I have had several opportunities of verifying this statement during the past season, two of the cases being typical examples of pernicious anæmia. In none of these cases was the appendix much dilated; indeed, in one of the cases of pernicious anaemia it was considerably smaller than usual." In his reply to Dr. Russell Dr. Balfour claims "that

chest-wall the appendix lay, or what were its post-mortem appearances as to dilatation or actual size, we are not informed. Even with these serious defects Naunyn's observation was eagerly accepted, without confirmation by more scientific investigation, and upon this insecure foundation Balfour erected a most attractive theory for the interpretation of this class of murmurs—attractive because it appeared to bring order out of the confusion which was admitted to exist upon the subject. As it is, the Scotch verdict of "not proven" is all that can be claimed even by his most ardent supporters.

By way of exclusion, therefore, we are compelled to seek the origin of the murmur in question in the pulmonary artery. The chief difficulty in the acceptance of this interpretation, viz., the situation of the maximum intensity of the murmur, so far to the left of the sternum, has been removed in great measure by the observations of Russell and Bramwell, that in cardiac dilatation the pulmonary artery may ascend and be transposed laterally so as to occupy the region which is the site of the murmur. Balfour's objects to the pulmonary theory on the ground that there are in chlorosis no causes of murmur analogous to those produced by the dilatation of the left auricle, is beside the point. If the pulmonary murmur would certainly be accompanied by an aortic murmur also, and the latter would, of course, be propagated along the course of the aorta, and more or less distinctly into the carotids. In this objection he entirely overlooks the fact that the existence of an aural murmur, in the absence of the more pronounced conditions of which he insists so strongly, presupposes conditions in the pulmonary artery which do not exist in the aorta. A certain amount of dilatation may be supposed to accompany the increased pressure in the pulmonary artery, and this change in the diameter of the vessel may be all that is required, in connection with the rapid flow of anemic blood, to produce the sound on which the diagnosis is based. In the aorta, where there are no conditions to change the lumen of the vessel, a murmur may not make its appearance until later, when the necessary rapidity of the current is secured by the more irritable and forcible action of the left ventricle.

Not satisfied with his destructive criticism of Balfour's theory, Dr. Russell advanced an ingenious hypothesis of his own, to the effect that the question is one in regard to compression of the pulmonary artery by the dilated left auricular appendix. This theory concedes a dilatation of the left auricle and appendix; but Dr. Russell seems to be in doubt whether such dilatation is due to "the incomplete emptying of the left auricle during its weakened systole and consequent imperfect relief to the left ventricle, due first to the certain amount of regurgitation, or to both causes combined." If regurgitation be admitted, conditions for the production of murmur at the mitral orifice are present at this orifice, and Balfour's theory, therefore, must be regarded as not entirely unsupported, even although the difficulties as to the transmission of the murmur to the second interspace be not quite explained. If, on the other hand, the dilatation of the auricle and appendix be due merely to incomplete emptying of the left ventricle, it is not easy to see how, in the early stage of chlorosis—the case we are considering—the tension in the left appendix can be raised so as to exceed that in the pulmonary artery. Balfour, in reply to Russell on this point, says: "It is absolutely impossible that the left auricle can ever so compress the pulmonary artery." Our limits will not permit us to consider the mechanical problems involved in this proposition, and discussed at some length by Drs. Balfour and Russell, in their somewhat acrimonious controversy. It is, moreover, unnecessary to do so, if we exclude mitral regurgitation, there is no demonstrable cause leading in the circumstances of auricular dilatation for producing the requisite degree of tension in the left appendix. But even if we admit a certain degree of mitral reflux as aiding the process of dilatation in the appendix, Russell's argument from the greater power of the left ventricle as compared with the right, is inconclusive, as Bramwell points out, because the reflux current at the mitral orifice is opposed by the valves and the contractile force of the left auricle, whereas the only obstacle to the power of the right ventricle is the blood-pressure in the pulmonary circulation. "The right ventricle, though much weaker, is acting (considering when the tricuspid is said) at an immense advantage, and undoubtedly propels a much larger quantity of blood into the pulmonary artery than the left ventricle propels (in any ordinary case of mitral regurgitation) into the left auricle." 1

It will thus be seen that the theories of Balfour and Russell present serious difficulties. A dilated left auricular appendix plays an important part in both. In one the near approach to, or contact of the appendix with the chest-wall is unproved; in the other, the compression of the pulmonary artery by the left auricular appendix implies a degree of tension in the latter which can hardly be supposed to be present even with extreme dilatation of the auricle, much less with the slight degree of dilatation which is usually found. In view of all the evidence before us, the conclusion seems to be justified that the murmur in question, in all probability originates in the pulmonary artery, but there is less certainty as to the causes which determine the occurrence of the sound in the pulmonary artery rather than in the aorta, and give it a localization so far to the left of the sternum. It is possible, however, that a small current in anemia, possibly a slight diastolic change in the pulmonary artery may be all that is required to produce a murmur. And, finally, the situation of the greatest intensity of the murmur—from one to two inches to the left of the sternum—may be accounted for by the upward and lateral transposition of the pulmonary artery by the cardiac dilatation.

ACUTE LOBAR PNEUMONIA WITH THE FORMATION OF ORGANIZED INFLAMMATORY PRODUCTS WITHIN THE AIR-PASSAGES AND VESICLES.

By FRANCIS DELAFIELD, M.D.

NEW YORK.

I HAVE recently seen, both during life and after death, two cases of acute lobar pneumonia of a character entirely new to me.

Case I.—Male, aged thirty-nine, laborer, admitted to the Roosevelt Hospital on December 29, 1883.

December 24th.—The man came to the out-patient department of the hospital, saying that he had been vomiting for several days.

December 25th.—He was attacked with pain in the side, chill, dyspnea, and fever; and crepitant rales were heard over the right middle lobe.

December 29th.—The man is somewhat intoxicated. His face is flushed, tongue coated and dry, pupils small, mild delirium. Consolidation of the middle lobe of the right lung. Urine, sp. gr. 1.007, albumin.

December 30th.—The mild delirium alternating with stupor continues. The lower lobe of the right lung has become consolidated.

January 1, 1884.—The dulness and bronchial voice and breathing continue over the middle and lower lobes of the right lung, the same physical signs, with subcrepitant rales, can now be heard over the upper lobe of the left lung.

January 2d.—The patient is now in the typhoid state: brown, dry tongue, active delirium, involuntary discharges of urine and feces.

January 4th.—The left parotid gland has become swollen and painful. The patient remained in the same typhoid state and died on January 8th. The course of

---

1 British Medical Journal, June 30, 1883.
the temperature, the pulse, and the respiration can be
seen in Fig. 1.

The entire duration of the disease was fourteen days
and a few hours.

The physical signs of consolidation of the lungs were
well marked. The cough was infrequent and the expec-
toration scanty. The temperature was not high, the
breathing was but moderately accelerated, and the pulse
was not rapid until the last day of the disease. The
most marked symptoms were the delirium, stupor, pro-
stration, and typhoid condition.

At the autopsy the only morbid changes were in the
pia mater, the spleen, and the lung.

The pia mater was infiltrated with serum and with new
connective-tissue cells.

The spleen was large and soft. The lower lobe of
the left lung was small, dense, partially atelectatic, of red
color, mottled with small gray patches. The bronchi
were somewhat congested. The pulmonary pleura was
coated with a little fibrin. The middle and lower lobes
of the right lung were consolidated, but diminished in
size. The pulmonary pleura was coated with a little
fibrin. The pulmonary artery and vein were injected with
blue gelatin. The consolidation of the lungs was
effected, as in ordinary lobar pneumonia, by plugs of in-
flammatory material within the air-passages and vesicles.
In ordinary lobar pneumonia these plugs are so large as
to distort the air-vesicles, and in this way the hepatized
portion of lung is increased in size. In this case, how-
ever, the plugs were small, not large enough to fill the
vesicles. This small size of the plugs enabled one, in
sections, to see plugs within air-passages sending out
processes into the communicating air-vesicles. Some
of the plugs were composed of ordinary reticulated fibrin
and pus; in others the fibrin ran more in straight lines
and was stiffer, so that the plugs were of irregularly tri-
angular shape, only touching the walls of the vesicles at
their angles. Many of the plugs were composed of a
homogeneous basement substance, in which were im-
bedded fusiform, polygonal, round, and oval cells. In
some of these plugs are large blood-vessels with thin
walls, into which the blue injection has run. This new
tissue does not look like an outgrowth from the walls of
the vesicles but like tissue formed within their cavities,
and only touching their walls at some points. Some of
the plugs are composed partly of new tissue, partly of
fibrin and pus. The walls of the air-vesicles show a
complete blue injection of the capillaries; and some of
them are thickened and infiltrated with round cells.

Case II.—Female, forty-five years of age, admitted to
Bellevue Hospital November 27, 1883.

On November 17th she was exposed to the weather
for a long time. Soon after she came home she was at-
tacked with a chill, fever, headache, and prostration.
The next day she had a cough with brownish sputa,
 dyspnea, and was obliged to go to bed, where she has
since remained.

November 27th.—The patient looks seriously ill. Her
face is flushed, she is dull and apathetic, tongue coated
and dry, pain over right lung, dyspnea, cough, and abun-
dant mucous-purulent sputa. Over the upper lobe of the
right lung there is dulness and very distinct bronchial
voice and breathing. The patient soon passed into the
typhoid state and died on December 5th. The tempera-
ture and pulse are shown in Fig. 2.

At the autopsy no lesions were found, except in the
upper lobe of the right lung. This lobe was consoli-
dated, but not enlarged. There was a little fibrin on
the pulmonary pleura. The cut surface of the lung had
the gross appearance of a smooth red hepatization moll-
ted with numerous minute white dots, which corresponded
to plugs in the air-vesicles.

Minute examination shows a diffuse interstitial growth
of connective tissue, most marked around the vessels and
in the septa, but also involving the walls of the air-ves-
icles. These walls are symmetrically thickened and in-
filitrated with round cells.

Within the air-passages and vesicles are plugs compo-
sed of a homogeneous basement substance, in which are
embedded round, oval, fusiform, and polygonal cells.
There is also a well-marked growth of epithelial cells
adherent to the walls of the vesicles and detached from
them. In a few vesicles coagulated fibrin and pus-
cells were found. The plugs only partly fill the vesicles
and touch their walls at but few points; they can be
seen to project from the air-passages into the communi-
cative vesicles.

Both these cases were characterized by the excessive
development of prostration and typhoid symptoms. Ex-
cept for the physical signs, they looked like patients with a continued fever.

The anatomical changes which existed in these lungs I have never seen described. In broncho-pneumonia and in phthisis the air-vesicles may be filled with organize
dized tissue instead of with fibrin and pus; but a diffuse
lobar pneumonia, running an acute course, with the pro-
duction of organized tissue in the air-spaces, is something
very unusual.

Drawings of these lungs will be published in the next
number of my "Studies in Pathological Anatomy."

PRACTICAL HINTS REGARDING THE METH-
ODS OF EXAMINATION EMPLOYED AS
AIDS IN THE DIAGNOSIS OF NERVOUS
DISEASES.

By A. L. Ranney, M.D.,
Professor of Applied Anatomy in the New York Post-Graduate Medical
School and Hospital.

(Continued from page 315.)

In progressive muscular atrophy the "bird-claw" appear-
ance of the fingers attracts attention at once. When
the muscles of the arm and forearm are badly wasted
the limb hangs at the side in a helpless way, "as if it
were tied to the body by strings." If the muscles of the
lumbar region be attacked the belly becomes slightly
prominent and tense, and the back is strongly arched
in order to balance the trunk. A line dropped from the
shoulders falls behind the hips as the patient stands
erect. If the abdominal muscles are atrophied the
belly falls forward to a marked extent, and the back
is arched in such a manner by the healthy lumbar mus-
cles that a vertical line from the shoulders passes through
the sacral region. The mus-
cles of the lower limbs are
seldom so severely wasted as
to prevent the patient walk-
ing.

In hysterical paralysis the patient (usually a young
woman) is often confined to
the bed. Todd has de-
scribed the facial appearance of this class of patients as
characterized by "a remark-
able depth and prominent
fulness with more or less thickening of the upper lip, and
by a peculiar drooping of the upper eyelid." Sometimes
the muscles of the limbs are flaccid, while in others the
legs are stiffly extended and the feet are turned inward.
The nutrition of the muscles is generally good, and
marked atrophy is seldom present.

In cerebro-spinal sclerosis the face first attracts atten-
tion by the stupid and vacant expression, the half-open
mouth, an oscillation of the eyeballs (nystagmus) in some
instances, and a contracted state of the pupils in many
cases. The speech is liable to be of a "drawing" charac-
ter, and the tone of the voice monotonous. The head is often turned slightly to one side during attempts
at walking, or perhaps is drawn a little backward—a
point which is explained by Bramwell as an effort on the
part of the patient to prevent unsteadiness of the head
by an artificial stiffness of the neck. The gait has already
been described.

SYMPTOMS OF NERVOUS DISEASES REVEALED BY THE
EMPLOYMENT OF VARIOUS TESTS.

The third section of my article is now reached. Before
the various tests which are commonly employed by the
specialist in neurology to determine the existence of dis-
eased states of the nerves and muscles are separately
discussed, it will be necessary to hastily summarize some of
the more important facts in nervous symptomatology.
Not only are some of these tests complex in themselves,
and therefore difficult of comprehension, but they would
be absolutely useless in practice if the clinical bearing of
each were not clearly comprehended. For example, a phy-
sonian who has acquired a smattering of nervous symptom-
atology is called upon to examine a patient who gives
evidence of impairment of motor power in some part of his
body. This paralysis may be due to some trouble either
in the brain of his patient, his spinal cord, or in some
special nerve. If in the brain, the physician is called
upon to decide (for himself at least) whether it is situated
in (1) the coverings of the brain, (2) the external gray
matter that invests it like a cap (the cerebral cortex), or
(3) in parts more or less distant from its exterior. It is
important, from a standpoint of prognosis and treatment,
that he comes to some definite conclusion also regard-
ing the character of the trouble. If the disease be con-

![Fig. 16.—Progressive Muscular Atro-
phy of entire Upper Extremity.]

![Fig. 17, 18.—Deformities of the Hand due to Paralysis.]

...ined to the spinal cord of the patient, it becomes neces-
sary to discriminate again between affections that fol-
low separate bundles of nerve-fibres (systematic lesions
of the cord) and those that spread transversely from
column to column (focal lesions of the cord); and to
decide also as to the height of the lesion, its pathological
characteristics, and the special regions that are affected by it.
Finally, if the paralysis be due to some spinal nerve, the
possibility either of brain or spinal disease must be ex-
cluded, and the cause must be sought for along the
course of the nerve whose function is impaired.

Before I discuss the clinical tests of nervous diseases
in detail, I direct attention, therefore, to some extracts
from the chapters on the diseases of the brain and spinal
cord that are embodied in the third edition of my work
on "Surgical Diagnosis."

Motor PARALYSIS.—Anything which tends to impair
the generating power of the nerve-centres or the conduc-
ting power of nerve-fibres may produce paralysis of motion
or sensation.

Motor paralysis can result, therefore, from any cause
which interferes with the motor convolutions of the brain,
or the nerve-fibres which start from them and are con-
tinued as the so-called "motor tract." The latter pass
through the following parts: (1) The white substance of
the cerebral hemispheres; (2) the corpora striata; (3)
the crura cerebri; (4) the pons Varoli; (5) the medulla
oblongata; and (6) down the motor columns of the spinal
cord.

The disturbing lesions may be therefore classified as:

---

1 This article comprises, in substance, the subject-matter of a course of lectures delivered by the author before a private class of post-graduate students.
(1) Those of the gray matter of the convolutions of the brain (cortical lesions); (2) those of the central mass of the cerebral hemispheres, including lesions of the “internal capsule;” (3) those of the corpora striata; (4) those of the crura cerebri; (5) those of the pons Varolii; (6) those of the medulla oblongata; (7) those of the spinal cord.

The various tests which are employed to determine the existence and extent of a loss of muscular power will be given later.

Cortical paralysis, or that form dependent upon some lesion of the gray matter of the cerebral convolutions (the cerebral cortex), may occur in connection with abscesses, blood-clots, spots of softening, tumors, depressed bone, meningeal thickenings, embolism, thrombosis, etc.

The researches of Ferrier have lately taught us the situation of special motor centres scattered over the convolutions of the so-called ‘motor area’ of the cerebrum.

Hemiplegia.—This condition is characterized by a paralysis of motion in one lateral half of the body. It is often associated with more or less anæsthesia, but it may exist independently of it.

Hemiplegia may be produced by any lesion which interferes with the free action of the ‘motor tract’ of fibres during their passage from the motor convolutions of the cerebrum to the columns of the spinal cord, and lesions of the spinal cord itself (if sufficiently high up and restricted to that lateral half of the cord on the side which corresponds to the paralysis) may also induce it.

If the lesion be within the cavity of the cranium the hemiplegia will be on the opposite side of the body; if it be spinal the hemiplegia will be upon the same side.

Hemiplegia from intracranial lesions may be the result of embolism, thrombosis, apoplexy, softening, abscess, tumors, compression of the brain from traumatic causes, destruction of limited portions by injury, general pressure from inflammatory exudations, etc.

Consciousness is generally lost when cerebral hemiplegia is developed. Convulsive attacks are not usually present at the onset of the paralysis. The paralysis is more profound, as a rule, than that of cortical lesions, and of longer duration. The special senses are not infrequently involved to a greater or less degree. Other cranial nerves, which are not associated with the special senses, may also give evidence of being implicated by the lesion.

By these guides the seat and extent of the lesion may often be determined with positiveness. The finding of a hemiplegia with or without paralysis is a valuable diagnostic sign that the exciting lesion is within the substance of the brain and not upon its surface. The exceptions to this rule are extremely rare.

The localization of non-cortical lesions is more difficult and less certain than those which are confined to the cortex. A careful study of all the symptoms presented (when combined with accurate anatomical knowledge) will often, however, lead to most positive deductions. It should be remembered that accuracy of diagnosis often leads to success in treatment of disease, and in no case is it better exemplified than in the nerve-centres.

Crossed paralysis.—A condition in which the face or some organ of special sense gives evidence of an impairment of a cranial nerve, while the body is simultaneously rendered hemiplegic on the opposite side, is termed “crossed paralysis”—the “paralysie alterne” of the French authors. We owe much of our knowledge of this subject to Professor Romberg, of Berlin, who has written extensively upon it.

The more common forms of crossed paralysis are named from the cranial nerve which exhibits an impairment of its functions. They are as follows: First cranial nerve (olfactory) and body type; third cranial nerve (motor ocular) and body type; fifth cranial nerve (trigeminal) and body type; seventh cranial nerve (facial) and body type.
It may be well to remark in this connection that "crossed paralysis" is of special clinical importance, because it often imparts the most positive information to the surgeon in regard to the seat of the lesion which has produced it.

**Complete paralysis.**—When a lesion is situated at the base of the brain, and is sufficiently large to involve the motor tract of both hemispheres, the body may be completely paralyzed below the head.

Various cranial nerves—chiefly the third, fifth, sixth, and seventh—are liable to then exhibit the effects of simultaneous pressure upon them; hence the general paralysis of the body is apt to be associated with paralytic symptoms confined to the face. Bilateral spinal lesions, when situated high up in the cervical region, may also cause a form of complete paralysis of the body—the so-called "cervical paraplegia."

**Sensory Paralysis.**—The sensation of special parts of the body may be so modified by lesions of the nerve-sensations, as is evidenced by a perceptible interval of time between the contact of a foreign body with the skin and its conscious appreciation by the patient when the eyes are closed. The pricking of the skin with a needle is a test commonly employed to determine this condition. It is clinically related to lesions of the spinal cord only.

Some of these conditions will be now considered in their more important aspects. Others will not be separately described, as they would require too much space, provided such a résumé was attempted.

**Hemianesthesia.**—This condition is characterized by a loss only of sensation (not of motion) in one lateral half of the body. It is often associated with more or less marked hemiplegia.

The tests employed to determine the existence of this state and its degrees of intensity are the same as those employed in any form of sensory paralysis. They will be described later.

Hemianesthesia indicates that the exciting lesion has impaired the conducting power of the fibres associated with the so-called "sensory area" of the cerebral convolutions. There is strong clinical evidence to sustain the opinion that these fibres run in the posterior third of the "internal capsule." Lesions of this latter region are not infrequently the cause also of more or less impairment of sight, smell, hearing, and taste, in addition to their effects upon general sensation. Charcot, Ferrier, Rendu, Raymond, and others who have studied the effects of lesions of the posterior third of the internal capsule of the cerebrum concur in this statement.

Hemianesthesia is frequently accompanied by the development of choreiform movements after the paralysis has developed. These may assume the type of athetosis, or true ataxia, or tremor. The same may also be said of that type of hemiplegia which occurs as the result of lesions of the internal capsule of the cerebrum.

Finally, a condition characterized by an abnormality of the eyes, termed "conjugate deviation," may be associated with lesions of the white centre of the cerebral hemispheres. I quote an extract, from my late paper upon the "Diagnosis of Lesions of the Internal Capsule," regarding this symptom:

"When, in connection with rapid softening or an extravasation of blood into the substance of the cerebrum above the level of the basal ganglia, this peculiar symptom is developed (either simultaneously with or following paralysis and coma), the patient's head and eyes will be observed to be turned constantly away from the paralyzed side and toward the side upon which the seat of the lesion is. Various attempts have been made by late authors to throw discredit upon the clinical significance of this symptom, as particularly indicative of a lesion of the cerebral hemisphere, but I am convinced that it is a valuable differential sign. Ferrier has demonstrated that a cortical centre, which he locates in the first and second frontal gyri, near to their bases, presides over conjugate movements of the head and eyes and causes dilatation of the pupils. He attributes this symptom, when occurring in connection with hemiplegia of cortical or ganglionic origin, to the unanitized action of the corresponding centre of the uninjured hemisphere, thus explaining the fact that the distortion is toward the side of the lesion. Clinical evidence of the correctness of this view has been brought forward by Hughilina Jackson, Priestly Janith, Choue, and others; and in some cases reported the situation of the lesion has been verified by pathological observation. The opportunity to record pathological observations upon cases where this symptom was well marked during life is, unfortunately for science, a comparatively rare
one. It is impossible, therefore, to speak positively concerning the diagnostic value of this symptom, although the weight of clinical evidence seems to be strongly in its favor."

Finally, it must be said that in cerebral hemianesthesia there is more or less insensibility to touch, pain, and temperature, and also abolition of muscular sensibility with complete retention of electro-motor contractility. The mucous membranes of the eye, nose, and mouth are also frequently rendered anesthetic.

(To be continued.)

NOTES ON DEFORMITIES AND THEIR TREATMENT.

By STEPHEN SMITH, M.D.,
NEW YORK.

Displacement of the upper extremity of the femur on the dorsum illii.—There is a class of deformities about which little is written in surgical treatises, and which receive but slight attention from surgeons. I refer to cases of displacement of the upper extremity of the femur on the dorsum of the ilium, either by separation of the neck from the head, or of the head from the neck. These cases differ materially from dislocations of the femur upon the dorsum which occur in the latter stages of hip-joint disease. They more nearly resemble unfractured parts of the neck of the femur in adults.

The difference between these two deformities is this, viz., in the dislocation the thigh is fixed in the position of adduction and flexion, while in the separation of the head or neck the limb has free motion, with slight, if any, flexion, and generally there is erosion of the foot, as in fracture of the neck. The following case illustrates the peculiarities of these deformities, and a method of treatment adopted.

In 1874 a girl, aged eight years, came under my treatment with the following history. When four years old, and while residing in Chicago, she fell upon the right hip. The injury was followed by a severe inflammation of the joint, an abscess formed, and when it was opened the surgeon removed a large globular mass of bone. A careful inquiry into all the facts of a long and tedious sickness, of her mother, who was a very intelligent lady, seemed to indicate that the abscess was the result of a previously dislocated or separated head of the femur. The case was subsequently a separation of the head of the bone from the neck, at the epiphysial junction, and that the head of the bone was finally removed from the cavity of the abscess. The symptoms were chiefly those of ordinary hip-joint disease, though it ran more rapidly through the several stages. She was believed to be in a very chronic condition, but under the tractive force the bone was removed she rapidly recovered. When she first came under my observation she was very stout and active, but was suffering from a painful limp, due to the shortening of the injured limb.

On examination, the right foot was found slightly everted, and the right leg was diminutized in size throughout, though the left was abnormally large, owing to the increased use to which it had long been subjected. On comparing the length of the limbs it was found that, measuring from the anterior superior spinous process of the ilium to the malleolus, the injured limb was found to be shorter by two and one-half inches; but measuring from the upper extremity of the trochanter major on each side there was no difference in the lengths of the limbs.

On manipulation of the affected limb the upper extremity of the trochanter was found on the dorsum of the ilium and near its upper edge. On rotation of the limb the trochanter turned upon its axis in the grasp of the fingers without a radius. The motions of flexion, adduction, and abduction were limited about one-fourth. On attempting extension it was found that the limb could be lengthened an inch.

The treatment proposed was extension until the greatest possible degree of lengthening of the limb was obtained, and then the application of a splint which should maintain this extension during the period of growth, or until a new point of articulation or support of the trochanter should be secured. The patient was accordingly placed in bed, and a common hip splint made but slight extension, and that only intermittently. In this case continuous extension was required. To meet the indications the following splint was devised and applied. The description is by Mr. Söhiman.

The apparatus has two upright steel bars, which are fastened by screws or rivets under the sole of the shoe. These bars have corresponding joints at the ankles. Instead of continuing upward in a direct line, they pass under the knee- joint and are united by a joint, A, with the two, thigh bars, which latter separate and pass medially upon both sides of the limb, the inner bar stopping below the perineum, the outer one extending above the head of the femur to pad G. The padded strap, D, passes under the gluteal muscle and acts as the superior counter-extension. B C are bands to confine the limb to the brace. A knee-cap, M, is fastened on both sides to bars K K. The brace has a strap over the instep and also over the heel of the foot (not shown on the wood-cut). These, with the lacing of the shoes, act as counter-extension, when the peroneal band, D, is drawn tight and the leg stretched.

The great advantages of this splint consist in its constant and uninterrupted extension of the limb when the patient bends the knee-joint, in consequence of the joint being under the knee; while, on the contrary, the usual brace, with joints on the sides of the knees, causes the limb to lose the extension with every bend.

This splint was worn continuously until the patient reached the age of eighteen, being extended from time to time to adapt it to the growth of the limb. During this period the limb remained of the same length as at the first application, a new joint formed, and the ability to walk without the appliance, and with but a moderate limp, is fully and, probably, permanently established.

SUCCESS OF VACCINATION IN INDIA.—It might have been supposed that of all the countries in the world India was the one in which the bitterest opposition would have been offered to compulsory vaccination. This, however, does not appear to be the case. According to the latest report of the sanitary condition of the country, the working of the acts, wherever they have been applied, has not been attended with any great difficulty. The people in most cases yield to simple persuasion, and in a few instances where they prove refractory the issue of a summons is almost always effectual. Opposition fostered by caste prejudices is in some places still offered, but as a rule the masses now accept vaccination with readiness, and in some parts it is even sought after and paid for. In Bengal, Madras, and Bombay, the Punjaub, the northwestern and central provinces, Burmah, Assam, and the island of Ceylon, 14,200,000 persons operated upon during the year was over 4,400,000. Generally speaking, the treatment appears to have been successful, the ratio ranging as high as 98.39 per cent.
ON THE ALTERATIONS IN THE SIZE OF THE PUPILS IN THE INSANE.

BY HENRY G. CORNWELL, M.D.

LAKE PROFESSOR OF OPHTHALMOLOGY AND OTOLOGY, STANFORD MEDICAL COLLEGE, COLUMBUS, O.

It is the purpose of this brief paper to add to the statistics already published concerning the frequency of pupillary changes in the insane, those obtained by myself as the result of an examination made in September, 1883, of a number of persons so affected in the Asylum for the Insane at Athens, O.

Alburt, who has studied the eye-symptoms of insanity with a great deal of care, says that sixty per cent. of the cases have contracted, unequal, or sluggish pupils. Nasse, who examined the eyes of 220 patients in the Asylum at Seiburg, found 73, or about thirty-two per cent., with dilated, contracted, unequal, or sluggish pupils. Castiglioni examined 146 cases, and found 110, or over seventy-six per cent., having the same condition. I examined the eyes of 250 insane patients, and found a pupillary affection in 90, or about thirty-six per cent. Of this number all, or about thirty-seven per cent., had contraction of the pupils, and 20, or about twenty-three per cent., had dilatation of the pupils. Among the cases having contraction of the pupils, the condition was observed to be monocular in 48. Among the cases of dilatation of the pupils, in only 2 was the condition observed to be monocular. One of the cases was a patient having dementia with epilepsy, in whom the right pupil was dilated. The second was one of chronic mania, having also dilatation of the right pupil.

Pierd'hoy found among 190 insane in the province of Mombello, a difference in the size of the pupils in sixty per cent. of the cases. He also found, among 81 epileptics, a pupilary difference in 42 cases, or about fifty per cent., among his cases seventy-five per cent. with unequal pupils. Nasse found sixty-four per cent. with unequal pupils in 250 cases I found only twenty per cent. with pupillary difference. Nasse observed pupillary difference in 90 out of 105 cases of general paralysis of the insane. Siebert found the same condition in 17 out of 23 cases. I found a pupillary difference in 16 out of 39 cases.

Vincent found reflex iridoplegia ("Argyle Robertson's pupils") in 8 of 21 cases of general paralysis of the insane. In 11 cases he noticed the reaction was less marked to light than the accommodation. Boy found absolute iridoplegia in 68 of 76 cases. I found, among 39 cases of general paralysis, 13 cases of reflex iridoplegia. Among 48 cases of acute mania, I found 24 with dilated pupils. In 13 of the 24 cases the affection was monocular. In 67 cases of chronic mania there was dilatation of the pupils in 5 cases; monocular in 1 case. Among 4 cases of acute melancholia the pupils were dilated in 3 cases on both sides, and contracted in 2, 1 monocular. Pierd'hoy observed, among 21 cases of dementia paralytica, the pupils to be elliptical in form and unequal in 12 cases. He found that unilateral myosis was present in most of the cases, but that unilateral mydriasis was oftener present in the more advanced cases. In 84 cases of dementia I found that the pupils were dilated in 3 cases on both sides, and contracted in 25, and in 18 of this number the contraction was either monocular, or was greater on one side than the other.

Pierd'hoy found among 30 cases of idiocy examined seventy-five per cent. having dilatation of the pupils. In 17 cases, I found thirty-six per cent. with dilatation of the pupils.

The fashionable antiseptic in all the hospitals of this city is the solution of bichloride of mercury, one part to fifteen hundred or two thousand of water.
which were found to be of malarial origin, and yielded readily to quinine.—Centralblatt für Klinische Medicin, January 5, 1884.

Hemostasis by Transfusion.—In the Revue des Sciences, No. 3, July, 1883, appeared an abstract of a paper by Professor Hayem on "The Formation of Intravascular Blood-concretions." He was led to make the experiments, the results of which are embodied in the above-mentioned paper, by certain questions as to the hemostatic effect of injections of blood into the circulation. The paper has slyly been noticed, contains facts of wide applicability to human pathology, and may be also considered as a contribution to the experimental study of hemostasis.

It occurred to Hayem, in 1882, that the blood itself, containing active hemostats, should have a marked influence on coagulation than other substances, when injected into the vessels. The experiments referred to, in which he studied the influence of distilled water, artificial serum (made with sodium chloride), blood-serum taken from an animal of the same age and sex as the different species, natural, not spontaneously coagulable normal serous liquids, solution of fibrin-ferment, normal blood, and defibrinated, confirmed this opinion. The active power of blood serum is important to remark, however, that the modifications produced in the coagulability of the blood by intra-vascular injections is only evinced, in the living body, in stagnant blood in the interior of vessels. Furthermore, one will observe the singular fact of almost immediate coagulation of stagnant blood in a vascular area, while, apparently, nothing occurs in the general circulation, and to obtain this it is sufficient to inject a few cubic centimetres of serum into the blood. From this it must be concluded that the hemostatic effect is only sensible in the vascular areas in which the blood is arrested or slowed in its course.

The following is quoted from Hayem's paper, also: "The possibility of rendering stagnant blood more coagulable by introducing into the vessels liquids not hurtful to the organism, is applicable in therapeutic to the treatment of severe hemorrhage, and perhaps also to the treatment of aneurism. In this lies, to some extent, the experimental demonstration of the existence of active hemostatic procedures, and of agents which, when injected into the general circulation, may favor the formation of clots in aneurismatic vessels. In all these cases, my experiments having been made with the various liquids utilized for transfusion, it appears certain that the principal practical result of these operations consists in the increased coagulability of the blood. This will be especially applicable in cases of severe hemorrhage, in which the blood has become less coagulable, and when there is a necessity for furnishing a renewed quantity of liquid to the circulatory apparatus."

To obtain the maximum useful effect it is necessary, as Hayem has already remarked, to use serum, that is to say, the normal liquid which, according to A. Schmidt, constitutes a larger proportion of the undetermined substance to which he has given the name fibrin-ferment. Normal blood is one of the less active agents for this purpose; defibrinated blood, artificial serum, or distilled water are the more active, but less so than blood-serum.

It has been suggested that blood-serum from some of the lower animals be used instead of that from man, but this may cause very serious consequences. The serum of beef-blood into the vessels of a dog, death has been caused in a very few minutes, the pathological appearances being those of purpura hemorrhagica. This pathological state is the consequence of a variety of coagulation to which Hayem has given the name coagulation by precipitation. The effect of the blood-serum of another kind of animal on the circulating blood is such that it immediately becomes filled with thousands of concretions which are arrested in the smallest vessels, thus producing numerous hemorrhagic infarctions.

It would seem that Hayem has sufficiently established his theory to warrant a practical trial in selected cases of aneurismal tumors, and in cases of hemorrhage in subjects of hemophilia. It is based upon facts which have been known for some time in a disconnected way, and we do not doubt that further experimentation will develop and strengthen it.

Indirectly apropos to this subject it has occurred to us that transfusion, so successfully used by Dr. Halsted in cases of carbonic oxide poisoning, may be of greater service in protecting blood vessels from the injury of the ligature of the large artery, until the collateral circulation is established.

Transfusion of Blood in Bright's Disease.—At a recent meeting of the Société des Hôpitaux (Progrès Médical, January 19, 1884), Dr. Dieulafay read a communication on transfusion in Bright's disease. He referred more particularly to a case of uremia in which threatening symptoms had rapidly disappeared after the transfusion of four ounces of blood; not only that, but a notable diminution of albumen was inaugurated by this measure. The patient was able to leave the hospital, but returned several weeks later, the albuminuria having again increased. Subsequently grave uraeamic symptoms were developed and a comatose condition supervened. Again transfusion was practised, and again rapid improvement followed. Later on, however, the patient died, and at the autopsy pronounced general hypertrophy of the heart, and extensive atheromas were found. In seeking for an explanation of the good effects of transfusion, in spite of such profound structural alterations, Dieulafay emphasizes the fact that the dyscrasia of nephritis may often be more important than its organic lesions. He concluded by pointing out the dangers of dashing in transfusion practised on patients suffering from chronic Bright's disease.

Bichloride of Mercury in Ringworm.—In the February number of the Journal of Cutaneous and Venereal Diseases, Dr. R. W. Taylor recommends a solution of corrosive sublimate in the treatment of the various forms of ringworm. He found that the efficacy of the mercury was much enhanced by dissolving it in tincture of myrrh. The strength of the solution was four grains in an ounce. The dermatitis, in general, was readily cured by thoroughly painting the affected parts with this parasitic solution. It was applied twice daily. He believes that the tinctures of the gum-resins make excellent vehicles for various agents in the treatment of skin diseases.

Revival of the Alum Treatment of Whooping-Cough.—Not so very many years ago alum was one of the favorite remedies for the relief of pertussis. But of late it has been almost entirely superseded by other less unpalatable drugs. Now it seems to be again entering upon a time of favor and appreciation. Dr. Warfvinge, of Stockholm, records in Hygia a series of cases of pertussis of varying degrees of severity in which he employed alum with encouraging results. He exhibited the remedies as a rule, the first dose being given when the paroxysms were declared, and the earlier the treatment was begun the better were the results obtained. In one case of a boy, eight years of age, who had had a cough for three weeks, and who had just begun to whoop, the symptoms disappeared entirely after the use of alum, in a two per cent. solution, for two weeks. In another case of a girl, six years of age, who had had moderately severe attacks in a day, the cough was cured in ten days by the same means. The remedy was given usually in a one or two per cent. solution in equal parts of water and orange syrup, in the dose of a teaspoonful four times a day. Even in the later stages of the disease the attacks seemed to be greatly reduced in frequency and severity when alum was exhibited to the exclusion of all other remedies.
THE MEDICAL RECORD:

GEORGE F. SHRADY, A.M., M.D., Editor.

Published by
WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, April 12, 1884.

THE ENFORCEMENT OF A PLEDGE AT THE NEXT MEETING OF THE AMERICAN MEDICAL ASSOCIATION.

As the meeting of the American Medical Association is near at hand, it is proper to call attention again to a certain feature in its management which has excited much criticism. We refer to the exacting of a peculiar pledge from all members-elect.

The Constitution of the Association says: "Every member-elect prior to the permanent organization of the annual meeting... must exhibit his credentials to the proper committee and sign these regulations." These "regulations" are specified in previous sections of the Constitution as being such as regulated the general organization of the society; they were reported in 1847 by a different committee to that which in the same year reported the Code of Ethics, and the gentlemen who wrote the words "these regulations" could, therefore, by no possibility have had in mind any ethical code. Up to the year 1883, members-elect were never required to sign the Code of Ethics. For some years previously, in fact, no signing had been done at all. For reasons which are very apparent, a revival of the practice was deemed expedient last year. The gentlemen, however, having the matter in charge did more than revive the provision of the Constitution in question. They did not simply ask members to "sign the regulations" of the Association, but they drew up the following pledge:

"CLEVELAND, O., June, 1883.

"In acknowledgment of having adopted the Constitution, By-laws, and Code of Ethics of this body, and of my willingness to abide by them, and use my endeavors to carry into effect the objects of this Association, I hereunto affix my name."—Extract, vol. xxxiii., p. 623.

Then follows name, address, etc. We think it will be very apparent to every candid reader that the above contains more than a simple "signing of the regulations." This latter would promise only conformity. The form actually presented requires the expression of "a willingness to abide by" and "an endeavor to carry into effect" these regulations, and the Code of Ethics besides. It practically cut off many gentlemen who, while willing to obey the regulations, including even the Code, wished at the same time to make efforts to change them.

It appears to be very plain that all which a judicial or other committee can constitutionally ask is a simple acknowledgment of adherence to the regulations as specified by the constitution of the Association.

It is indeed claimed that the Code of Ethics is part of the organic law of the Association, and, therefore, comes under the head "these regulations." We do not think it necessary positively to oppose this view, but simply claim that there is here a legitimate ground for difference of opinion; especially in view of the fact that the Association existed twenty-six years before it was discovered that every one must sign a paper acknowledging a willingness to abide by the Code of Ethics. Certainly there is no other scientific or social organization in the world which, at every meeting, exacts such a singular requirement.

There is, however, another phase of the matter to which we would particularly call the attention of the permanent members. The bone of contention appears to be in the clause regarding the consultation with homoeopaths. This clause has always been interpreted to mean an absolute prohibition from all professional intercourse with homoeopaths. The present president, however, interprets it differently, for the reason that many so-called homoeopaths are not believed to be of the class that "base their practice on an exclusive dogma to the rejection of the accumulated experience of the profession."

Many other physicians believe very conscientiously that the American Code of Ethics does not forbid consultation with all homoeopaths, contending, as does Dr. Flint, that they do not altogether reject the aids of experience and science. The query arises whether a permanent member, with such conviction fortified by the opinion of the venerable president of the Association, could not properly and conscientiously sign the regulations of the Association, even if he believes in personal liberty as regards consultations. This was, indeed, done in a few cases last year, some physicians signing under protest.

Certainly the fairest way, however, would be to require nothing but a simple signature to the regulations, asking no more than has been done in previous years.

No one can complain of such a plan; but the profession, without regard to Code sentiment, will resent a repetition of inquisitorial attempts to suppress a movement so widely felt as that for further ethical elevation and reform.

HEALTH MATTERS IN CONGRESS.

The temper of Congress on public health matters is illustrated by its action last week in the House upon the following resolution, which was reported back from the Committee on Public Health, April 1st, with an amendment:

"Whereas, It is popularly charged and generally believed that divers and various articles of food, drink, and medicine are adulterated by admixture with base and usually deleterious substances; and

"Whereas, Such adulterated compounds are injurious to public health and calculated to shorten human life; therefore be it

"Resolved, That the Committee on Public Health be authorized and directed to inquire into the truth of said alleged abuse, and to report to this House the result of their investigation at as early a day as practicable; and if it shall be shown that such practices exist, then to suggest or recommend in their report what further legis-
tion, if any, is necessary to correct the wrong. And that they may the more effectively do their work, be it further

"Resolved, That said committee be and they are hereby empowered to send for persons and papers, and to employ such chemical and medical experts as they may deem necessary to carry out the aim, end, and object in view."

The amendment of the committee was as follows:

"Strike out the words, 'and to employ such chemical and medical experts.'"

A prolonged discussion of the resolution followed, participated in by Mr. Brown, of Indiana, who objected to the resolution but not to its consideration, and by Mr. Beach and Mr. Parker, of New York, and Mr. Wait of Connecticut, favoring the resolution, and by Mr. Cox, of New York, and Mr. Reagan, of Texas, in opposition.

Mr. Kasson, of Iowa, moved to amend the resolution by providing that the expenditure in making the investigation shall not exceed $1,000.

Mr. Cox moved to lay the whole matter on the table. A vote by yeas and nays was then taken, resulting in 114 yeas and 124 nays, 83 not voting; so the motion to lay on the table was not agreed to.

The previous question was then ordered, Mr. Beach accepting the amendment of Mr. Kasson, which amendment was agreed to.

The amendment to strike out the words "and to employ such chemical and medical experts" was also agreed to. The question was then taken on adopting the resolution as amended. Upon a division there were, yeas 80, nays 70—no quorum voting. Much discussion followed; Mr. Cox moved to recommit the resolution, and Mr. Beach moved to lay the motion to recommit on the table. The vote resulted, yeas 66, nays 83, so (no further count being called for) the motion to lay on the table was not agreed to. The question recurred upon the motion to recommit the resolution to the Committee on Public Health. The yeas and nays were called for and resulted, yeas 117, nays 116, not voting 88. So the motion to recommit was agreed to.

Thus the oleomargarine and other interests of that character have had a temporary victory.

GOOD MEDICAL ADVICE FROM THE "CHRISTIAN ADVOCATE."

It is with a feeling of more than ordinary gratification that we notice the wise course of the distinguished editor of the Christian Advocate in advising his readers concerning the proper course to pursue in case of sickness. It is so seldom that gentlemen of the standing and influence of Dr. Buckley dare to be so outspoken against quackery, and consistently practise what they preach, that we take pleasure in quoting from one of his recent articles, "On the Care of the Health," thus allowing him to speak in his own way:

"Next to intemperance in the use of alcohol and tobacco, I place as the most injurious habit common among the American people the practice of self-medication by the use of patent-medicines."

"My counsel concerning medicine is this: If sick, and the symptoms are not so alarming as to demand immediate attention from a physician, take no medicine, eat nothing until appetite naturally returns, keep warm, and drink plenty of water, hot or cold. If appetite exists, reduce the food for a few days one-half or two-thirds, and make it of a simple and easily digested kind. If the symptoms do not diminish under this regimen, send for a sensible doctor. In case of a chronic disease, such as protracted indigestion, signs of lung disease, unaccountable pains in any part of the body, accompanied by any general derangement of the system, try no experiments upon yourself in the way of medicine. Take no remedies recommended by others. Pay no attention to patent-medicine advertisements, whether of drugs or gas. Believe no man who says, I was just as you are, I took so and so, and got well; but consult a wise, serious, successful, and conscientious physician, tell him all about yourself, and then do what he tells you."

Well said, Dr. Buckley! These are truths plainly and bravely spoken, the patent-medicine men to the contrary notwithstanding. How few religious papers dare follow such an example! The hand of Mammon has too firm a grip upon their advertising columns to allow them to do so. More the pity for them, and more the praise for the exception. Again we repeat, in all our strictures upon the alliance between the religious newspaper and the healers who play upon the credulity of the gullible, we gladly except the Christian Advocate.

AN UNWISE COMMISSION.

The Commission recently appointed by the Government to inquire into the prevalence of trichinae in American hogs has made its report, and a very disingenuous one it is. After giving one hundred and fifteen pages of irrelevant discussion and statistics, about twenty pages are devoted to the main question: how extensively is the American hog affected with trichinae? And the commission concludes that it is less affected than the swine of Germany or France, and that any inspection of American pork would be superfluous or ineffective.

This is, we believe, the wrong way to meet the question. American swine, as we have often stated, are more largely affected with trichinae, in many parts of the country, than are those abroad. This is clearly shown by the statistics which the present Commission collected, of examinations made from 1873 to 1883. The results were as follows:

Dr. Harding and Robbins found 16% per cent. of hogs were infected with trichinae (Indiana); Dr. Belfield and Mr. Atwood, 8 per cent., and on another occasion 2 per cent. (Chicago); Drs. Gath and Miller, 6.5 per cent. (Indiana); Dr. H. J. Detmers, 2.04 per cent. (Chicago); Dr. F. S. Billings, 4 per cent. (Boston). In the South—Dr. Deverson, 0.4 per cent. (New Orleans); Dr. C. A. Simpson, 0.6 per cent. (Atlanta); Dr. R. W. Stieger, free (Tennessee); Dr. W. Myers, 0.6 per cent. (Texas).

Thus, with but one exception, trichinae were found on all occasions, the exception being an instance of an examination of only 180 hogs in a part (the South) where the hogs are comparatively free from infection. These figures show that the Western hogs are more or less infected with the parasite, and that certain districts are a centre of infection—the State of Indiana being pre-
eminent, with its average of over 16 per cent. Other States enjoy an enviable reputation of 8 per cent.

The argument, therefore, for American swine, which we have always put forward, is not that they are free from trichinae, but that, so far as known, exported American pork has not yet caused any cases of trichinosis. Upon this practical ground, our country has been able to take a strong position.

But it would be a foolish and short-sighted policy to adopt and cling to the opinion that American hogs are less free from trichinae than those of Europe.

THE SIXTH CHOLERA REPORT OF DR. KOCH.

Following very closely after Dr. Koch's fifth report, dated January 8th, comes another, and probably the last one for the present, dated February 2d, at Calcutta.

This latest bulletin from the cholera commission is both interesting and disappointing; interesting because Dr. Koch now announces definitely and positively that he has discovered the cholera-bacillus, but disappointing because he does not give us the demonstrative evidence that his announcement is true.

The organisms which the commission believe to be the cause of cholera are described as follows:

"They are not quite straight, as other bacilli are, but slightly curved, comma-like. The curvature may be even so marked that the stave may almost present a semi-circular form. From these curved staves, S-shaped figures, and more or less elongated, slightly undulating, linear forms may be developed in 'pure cultivations,' of which the first two segments and the last correspond to the form of the bacillus as found in cholera, and which, continuously increasing in number, remain attached to one another." Furthermore, they manifest very lively voluntary movements, which are best seen when examined in a drop of nutritive fluid suspended from the under surface of a cover-glass. In such a preparation the bacilli may be seen to swim with the greatest celerity across the field. Their behavior in nutrient gelatine is particularly characteristic; they form colorless colonies in it, which are closed at first, and look like strongly refringent accumulations of glass-fragments. These colonies gradually liquefy the gelatine, and extend themselves over a limited area. Further, they may be distinguished with tolerable certainty when cultivated in hollowed slides, as they are always found at the margin of the drop of nutritive fluid, and their peculiar movements may be observed as well as their comma-shaped forms after the application of solutions of anilin-dyes.

These bacilli were found in all the intestinal discharges of cholera-cases, and in the contents of the intestinal canal at post-mortem examinations, but not in any other disease, nor were they to be found in specimens of dirty water from various sources. As it is known that cholera-like symptoms are induced by arsenic, an animal was poisoned with this substance, but cholera-bacilli could not be detected.

They were only twice observed in the vomit. In the early feculent dejections only a very few were present. As the dejections became odorless and watery they appeared in great numbers, while all the other bacterial forms coincidently disappeared. As the dejections re-

turned to a natural character again, the bacilli disappeared.

Inoculation of the cultivated bacilli in lower animals uniformly failed to produce the disease. Dr. Koch believes, furthermore, that such attempts will always fail, because although cholera has been endemic throughout Bengal for years, no instance of the disease occurring in animals is known.

The opinion that the peculiar bacillus described is the specific cause of cholera rests upon other evidence, therefore, than that of inoculation. This evidence consists mainly in the fact that the organism is limited to the seat of the disease, that it is not found in other tissues or in other diseases, and that its activity keeps parallel with that of the cholera process. To the very obvious objections that the growth of the peculiar bacillus is simply favored by the peculiar conditions of the disease, Dr. Koch gives answers which cannot possibly satisfy scientific criticism. The great confidence felt in the carefulness and skill of the distinguished investigator, however, will lead many to accept his judgment, but such acceptance must as yet be based more on faith than sight. In fine Dr. Koch has found a bacillus, but he has not found, for science, the cholera-bacillus.

News of the Week.

SPONTANEOUS GENERATION.—An international competition is invited by the Second Teyler Society of Haarlem, for a gold medal worth four hundred florins, for a critical study of all that has been said for and against spontaneous generation, especially during the last twenty-five years. Details may be had by application to "La Maison de la Fondation de feu M. P. Teyler van der Hulst, Haarlem."

THE SENTIMENT FOR HIGHER INDIVIDUAL MORALITY.

—We venture to say that if every member of the American Medical Association had the courage to speak and vote just as he feels and thinks, more men would be found in sympathy, proportionately, with the New Code movement than have ever dared express themselves in favor of the New York Code in New York State.—Denver Medical Times.

CHARITY ORGANIZATION WORK.—We have received the report of the District Committee of the Tenth District, showing what has been done in relieving pauperism during the past year. The report states that a corps of forty Friendly Visitors has been organized, a directory of the district prepared, visits made, and cases investigated. We trust that similar organizations will soon be made for the whole city. By their aid the abuses of medical charity could be lessened.

THE LONDON HEALTH EXHIBITION.—The New York City Board of Health has appointed Dr. Woolsey Johnson and Professor C. F. Chandler delegates to the London Health Exhibition, which opens in May.

THE HOMEOPATHIC PHYSICIANS OF ST. LOUIS have been circulating a petition for presentation to the city fathers, asking that a portion of the City Hospital be set aside for treatment of patients according to the methods of their school.
MEDICAL LEGISLATION IN CONGRESS.—Mr. Finnerty, of Illinois, introduced a bill for the purchase of grounds and the erection of a house for disabled and indigent sailors of the U. S. Merchant Marine and Navy at Chicago, which was read a first and second time and referred to the Committee on Naval Affairs and ordered printed. Mr. Barksdale, of Mississippi, reported back with an amendment the bill providing for the purchase of property on Staten Island, N. Y., for a marine hospital, which was referred to the Committee on Appropriations, and the accompanying report ordered printed. Mr. Hoar, of Massachusetts, presented a petition in behalf of the Moral Education Association of Massachusetts, asking for the insertion of certain limitations in any bill that may be passed by Congress to amend the act entitled "An Act to Prevent the Introduction of Infectious and Contagious Diseases into the United States and to Establish a National Board of Health," which was referred to the Committee on Epidemic Diseases. Mr. Frey, of Maine, presented the petition of the New York Committee for the Prevention of State Regulation of Vice, officially signed, praying that the jurisdiction and powers of the National Board of Health be specifically defined and limited. Same reference as above.

THE PROTECTION AND PRODUCTION OF MEDICINAL PLANTS.—Mr. Morse, of Massachusetts, presented a petition from the Massachusetts Pharmaceutical Association praying for an appropriation to provide for the introduction of foreign medicinal plants and the protection of domestic medicinal plants.

DR. HENRY J. BOWDITCH AND THE AMERICAN MEDICAL ASSOCIATION.—Dr. Bowditch, of Boston, ex-Presidential of the American Medical Association, was invited to participate in a debate at the meeting of the Association in June. In his reply to this invitation Dr. Bowditch regrets his inability to be present, and mentions as one of the chief causes of this regret the fact that he will thus be obliged to forego participation in the discussion on the Code, which he believes "will inevitably come up, with disastrous consequences." Speaking for Massachusetts, he says the terms of admission to its State Medical Society were established long before the American Medical Association was thought of. Its "Code," he intimates, is superior to that of the National Association, and its delegates will not consent to bind it to give the latter preference. He sees in the action of the Judicial Council, at Cleveland last year, requiring the signatures of delegates to a renewal of their fealty to the Old Code, an apparent trick, which, he intimates, will scarcely bear a repetition. He maintains that the fact that a physician does not wish to sign the whole Code, many parts of which he declares to be the height of absurdity, "is no proof that he is an unworthy person to act as a delegate from a State society of honorable physicians." He should object to signing the Code because of these absurdities. We would add, without comment, that Dr. John V. Shoemaker, of Philadelphia, thinks directly the opposite.

THE DRUG TRADE IN 1883.—Mr. D. C. Robbins, of this city, has prepared an elaborate review of the drug trade of New York for the twenty-sixth annual report of the Chamber of Commerce. He says that during 1883 manufacturers of special articles which are controlled by patents or by combinations of capital have made money, while ordinary business transactions have neither brought good profits nor heavy losses. Special attention is called to the growth of the opium traffic in this country. Mr. Robbins says: "It is noteworthy that while the importation of crude opium for medicinal purposes varies but little, as we imported 229,012 pounds in 1883 and 227,126 pounds in 1882, the increase in the importation of manufactured opium for smoking purposes has been enormous. We imported in 1883 of this vicious preparation 298,153 pounds, against 106,221 pounds in 1882, and the Government received, at $6 a pound, a customs revenue of nearly $200,000,000." The imports of cinchona bark for the year ending December 30, 1883, were 11,250 bales, against 29,200 bales in 1882 and 31,700 bales in 1881. The sales of bark in the New York market in 1883 were 14,150 bales. Mr. Robbins states that the average of bark from South America now in the markets of the world will not yield more than one and a half per cent. of quinine.

A DIPLOMA MILL IN ST. LOUIS.—The daily papers of St. Louis contain an account of "The American Anthropological University," an institution chartered in 1875 by the Legislature of Missouri, and having a central office in Logansport, Indiana. The object of the Association was the establishment of branches all over the world, and "the conferring upon graduates and such other persons as may be deemed worthy any academic or honor degrees as are usually conferred by similar institutions of learning." It seems to have been the object originally to institute examinations in various branches of learning, and after the examinations degrees were to be granted. The scale of prices was as follows: M.E.L., $5; Business College, $10; A.M., $15; M.D., $25; D.D., $25; L.L.D., $50; A.B., $10; Ph. Student, $10; B.L., $25; D.D.S., $25; Ph.D., $50. The "University" was gotten up by a visionary clergyman, who died last December. Attention was called to it through inquiries made in England and Scotland, where it was found that a number of clergymen had secured the degree of D.D. The Association appears to be now practically defunct, and it is not thought that it ever did a very active business.

THE SOUTHERN MEDICAL COLLEGE, of Atlanta, Ga., held its annual commencement on February 25th, graduating fourteen.

THE MEDICAL DEPARTMENT OF THE WESTERN RESERVE UNIVERSITY held its annual commencement in February, graduating a class of seventy-three.

DEATHS AT FOOT-BALL.—The "Rugby game" and the "toy-pistol" will soon have to be classed together as equally potent agents of destruction. The result in one day of four foot-ball matches played in England was that two young men lost their lives and two sustained fractures of the leg. One of the deaths was caused by fracture of the odontoid process due to an attempt to use the head as a battering-ram. One of the fractures was a severe compound one. The constituted authorities, says the British Medical Journal, ought to be able to make regulations which will diminish the present high rate of mortality and accident.
THE CODE IN DAKOTA.—Perhaps one could expect nothing better than the following from Dakota. It is written by Dr. Edward Watson, of Sioux Falls, to the Medical Age. "To see the true beauties of this instrument [the Code] in the organization of medical societies governed by it, one must live on the frontier prairies and see the class of men who organize these societies. Abortionists, drunkards, blackguards, and disreputable characters of every kind—these are the loudest in their talk about the glories of the Code. It matters not that none of them has ever read it nor has the faintest idea of what it means. It is sufficient for them that it is 'the correct thing' to laud and swear by it."

MEDICAL DIPLOMAS AT BUFFALO.—A despatch states that the Erie County Medical Society is taking steps to prevent the granting of medical diplomas by the Niagara University, otherwise known as the Seminary of Our Lady of Angels, situated at Suspension Bridge, Niagara County. Such diplomas granted by the institution are declared illegal, since the college has authority only to confer degrees in military courses. The attorneys for the society have made an examination into the matter, and furnished the Board of Censors with an elaborate opinion to that effect.

CANADA MEDICAL ASSOCIATION.—The meeting of this Association will take place in Montreal on August 25th, 26th, and 27th. The meeting of the British Association for the Advancement of Science begins on the 27th of the same month.

PITY THE PHYSICIANS.—Medical men may not be very rich, but they are a busy class and by no means unhappy. Therefore they would object to the title of an article in the New York Sun, "Pity the Physicians." The demand for pity is based on an interview held by a Sun reporter with a New York physician. The latter says: "To tell you the truth, the medical profession is poor—very poor. And doctors who talk of incomes of twenty or twenty-five thousand a year simply talk for effect. I earn from twelve to fifteen thousand and think myself well off if I actually collect one-third of it. The rest I may or may not get some day—probably not; and I know that my practice is larger and my clientele more lucrative than that of at least one pretender to $25,000 that I could name. I keep a carriage, to be sure, and a colored man with very bright buttons; but it is often that I haven't a dollar in my pocket to pay for a cab if my own equipage should happen to break down a couple of miles away from home." "But how would the substitution of a State Board of Examiners for the present system mend the matter?" asked the reporter, to whom this lugubrious view of the situation was novel. The reply was interspersed with copious citations from a budget of statistics gathered by the friends of the movement. There is now, it seems, in ratio to population, such an excess of doctors in the United States that the best equipped graduates start with scarcely a prospect of success. Taking the whole area of the United States into calculation, the ratio is 1 doctor to every 650 persons. In this State it is 1 to 600; in this city 1 to 550. In England the ratio is 1 to 1,800; in France, 1 to 2,500; in Germany and Austria, about 1 to every 2,000. In any community, city, town, or country district the number of persons constantly sick is found to be 18 to 22 in 1,000—depending upon salubrity of situation and other conditions. It is safe to say that in this city the number, in every 550, who are regularly on the sick list is not more than 10; and 80, on the average, New York has one physician to every ten sick persons. Count out two or three of the ten as disabled by age or incurable disease, and at least one as too poor to pay, and a physician has an average of six or seven paying patients. Of course, some have fifty to a hundred patients, and a great many have two, three, half a dozen, or more; but the average ratio is not altered by this inequality of distribution. The best that half a dozen patients could be depended upon to pay, on the average, would be $800 to $1,000 a year. "It is supposed," the physician added, "that with a common English education to start with, any young fellow with a tolerable memory, and $300 to spare, can enter the profession in two years, and be ready to commence practice. No preliminary, collegiate degree is necessary to matriculation. A clever ploughboy, by passing no more than an actual twelvemonth in the college, can obtain his diploma; and, in many cases, all that is required of students is to matriculate, and take out and pay for two sets of lecture tickets. They may attend or not, as they wish. It is believed, by the best friends of the movement for a higher standard of medical education, that one condition precedent to success is to take from the college diploma its prima facie right to practise, and to vest that right in a license granted by an independent board of examiners only after a rigid and stringent examination. The colleges have uniformly opposed this movement as detrimental to their interests; and so far, though supported by the ablest men in the profession, with few exceptions all legislation directed to that end has failed."

SUING A STEAMSHIP COMPANY FOR INSUFFICIENT MEDICAL CARE.—Mr. Anthony O'Donnell, of Pittsburgh, is about to sue a well-known, reputable ocean steamship company for damages for the loss of his wife. She died, it is said, from heart disease, but the company was negligent, it is charged, in that during her illness, which lasted for several days and was caused by sea-sickness, no one, from the captain to the stewardess, and not excepting the surgeon of the ship, paid her even one visit. "There is too much reason," says The New York Times, "to believe that the case does not stand alone. The medical transatlantic service, as a whole, is wretched. According to a recent return to Parliament, only 27 of the 147 surgeons who had charge of the ships bringing passengers to the United States were qualified men over thirty years of age; 46 were under twenty-five; 60 would have been ineligible for service in any British regiment, man-of-war, or prison. That is to say, the passengers were at the mercy of medical men incompetent to kill or cure convicts and paupers. As the rate of mortality is 1 to 509, it appears how shocking this is. The trouble is, the service is disorganized and uncontrolled. A surgeon has no rank among a ship's company, and his wages, at the best, are about $50 monthly. His employment is usually by the voyage, like a common sailor. He has no assistant, and not seldom undertakes the duties because he is an invalid and needs the voyage."
CARRYING OUT THE SUGGESTION.—The *Lancet* writes: "Every week we are flooded with hand-bills, pamphlets, and newspaper advertisements by practitioners whose names appear in the Medical Directory. These are evidently doctors who are carrying out such a plan as has been so unfortunately permitted by our venerable friend of the American Medical Association, viz., that of 'printing and publishing a doctor's card (with his limitation) as freely as he likes.'"

PROF. ALFRED STILLE, of the University of Pennsylvania, is to tender, early in May, his resignation of the chair of the Theory and Practice of Medicine, which he has held for nearly twenty years. The reason assigned is that he is nearly seventy-one years of age, and desires to lay aside the cares of teaching and enjoy a well-earned rest and recreation. It is thought likely that Dr. Pepper will succeed him as Professor of the Theory and Practice of Medicine.

THE SIMS MEMORIAL FUND.

To the Medical Profession and Others throughout the World:

The great achievements of Dr. J. Marion Sims call for some more lasting testimonial than obituaries and eulogies. The Sims memorial fund has earned for much brilliant and original work, especially in gynecological surgery. Those who have been benefited by his teachings and new operations, and such as have had the direct advantage of his personal skill are among the first to recognize and acknowledge this debt.

To him is due the honor of giving the first strong impulse to the study of gynecological surgery in America. It is believed that the medical profession everywhere, the vast number of women who owe their relief from suffering directly to him, and those who realize the benefits he first made possible, will gladly unite thus to honor the man through whose original and inventive genius such blessings have been conferred upon humanity.

At the suggestion of many friends, therefore, the subjoined committee has been organized, and it is proposed that a suitable monument be erected to his memory in the city of New York.

To this end the active co-operation of the medical profession and the many other friends of Dr. Sims throughout the world is respectfully solicited. Contributions of gold and upwards may be forwarded to the journal which has been constituted the treasury of this fund—The Medical Record, New York.

THE USE OF THE OLEATES IN SKIN DISEASES.—In a communication on the above subject in the *Medical and Surgical Reporter*, March 15, 1884, Dr. Stelwagon speaks as follows: Of all the oleates so far introduced for the treatment of diseases of the skin, the following may be considered as possessing therapeutie powers which experience has attested: olete of mercury, olete of zinc, olete of lead, and olete of bismuth. The other oleates have as yet failed in adequately supporting any attested claim to curative powers; further experience in their use may, however, prove them worthy of a permanent place in dermic therapeutics. In ordering the oleates several points are to be kept in mind. If the action of the proposed ointment is to be mainly protective, then the olete is best made up with one of the paraphenates; if there is to be a certain amount of penetrating power along with a protective influence, then a mixture of lard or oleic acid with a paraphenate is to be prescribed as the base of the olate ointment; again, if absorption is the main point sought at, then the olete compound should be made up of lard, oleic acid, or a combination of the two. In some cases (and they are by no means few) the oleates are found to disagree; instead of an improvement, a slight or marked aggravation occurs. In not a few instances this may be due to the bad quality of the olete used, but that it may occur with oleates which are of the best market manufacture is unquestionable. Oleates, if properly prepared, will keep almost indefinitely; but if prepared in the old way, with an excess of oleic acid present, they will frequently be found to deteriorate. In conclusion, it may be said that the oleates are to be considered merely as additional means of treating cutaneous diseases, and are in no sense to be looked upon as panaceas, for often enough they must be discarded to give place to the older and tried methods of dermic medication.
Reports of Societies.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Adjourned Stated Meeting, April 7, 1884.

ALFRED C. POST, M.D., LL.D., President pro tem.

DR. DAVID WEBSTER, Chairman (Dr. Joseph W. Howe, Associate Member), reported that the Committee had received the records, more or less complete, of 51 cases. In 47 there was total obstruction of the bowels, and in 4 the obstruction was incomplete.

In 24 cases there was no stercorous vomiting, and in 3 cases there was no obstinate constipation. In one case there was no vomiting at all, only nausea, and in two of the cases, in which the vomited matter was not stercorous, it had a gangrenous smell.

Twenty-one cases out of the 51, or over 41 per centum, revolving. It is interesting to note that out of 9 cases in which the abdomen was opened and peritoneal bands found and divided, there were two good recoveries. There would probably have been a third but for imprudence on the part of the patient and his friends.

The age of the patient is reported in 31 cases: From five to ten years, 1; ten to twenty years, 3; twenty to thirty years, 8; thirty to forty, 5; forty to fifty, 2; fifty to sixty, 6; over sixty, 1.

As to sex, that of only 30 patients is reported, of which 22 were males and 8 females.

In 16 cases the causes of the obstruction were ascertained by operation or by autopsy. They were peritoneal adhesions, 9 cases; stenosis of the gut, 2 cases; stricture of the gut in 1 case; invagination of the gut in 1 case, and impacted feces in 1 case.

The Chairman then reads the histories of the cases reported. First those sent by Dr. T. Herring Burchard, who concludes his report as follows: "Nine cases of intestinal obstruction have fallen under my observation. In seven cases only have I complete histories, or been able to verify the diagnosis by operation or autopsy. The other two cases recovered. The principal symptoms were local distress, increasing to intense paroxysms of pain, distention, vomiting, collapse (more or less prolonged), and in four out of seven cases stercorous vomiting. I have performed gastroscopy or abdominal section three times in these cases. The condition of the bowel occurred in eight hours; in the second case, recovery; in the third case, recovery from the operation, but death took place on the seventh day from acute peritonitis resulting from rash feeding. In all the cases obstinate constipation was a marked feature (of course fecal accumulations in the rectum or colon are excluded). Gaseous dilatation of the gut above the stricture I regard as a highly significant diagnostic symptom."

Dr. A. B. Atherton, of Fredericton, N. B., Canada, reported four cases of internal strangulation of the bowels; three of the patients were operated upon. The report closed with the following remarks: "There can be no question I think that it is of the utmost importance in all cases of internal strangulation, just as in external, that operation for its relief should be undertaken as early as possible after the symptoms have become clearly established, and after perhaps one or two attempts have been made to relieve it by large enema. In order, of course, that resort may be judiciously had to the operation, it is first to be decided pretty certainly that this condition exists. The points which he should rely in making a diagnosis in these cases of twists and bands are the following, viz.: The sudden onset of the symptoms; the persistence of the eructations and vomiting; the non-passage of wind per anum, except in cases where the occlusion is incomplete, as in the third reported above; the absence of the board-like feel of the abdominal walls which is got in ordinary peritonitis; the sometimes irregular form of the abdominal enlargement; in some cases where the strangulation is high up in the small intestine the entire absence of any distention of the abdomen; and finally the occurrence of either intestinal or stercorous vomiting after the first two or three days. The last-named symptom is of course an important one in fixing the diagnosis, but it is apt to occur rather late in the disease, and therefore is not so useful in leading to an early diagnosis as some others. It was present in a more or less degree in all the cases reported, but in only the first was it distinctly stercorous. I should mention that the previous history will assist, as Case 2, in making a diagnosis. I was not able to decide certainly that the water used in the enemata stopped at any one point in the bowels, but I imagined that, in one or two of these cases, there was a point corresponding to the seat of the obstruction where the wind as it rolled about seemed to bring up. This was most noticeable at the time when an eructation occurred. In all three cases operated upon I made my incision below the umbilicus near the median line, and used Listerian precautions throughout."

Near the close of the reading of the histories of the cases, Dr. Piffard moved that the further reading be suspended, requesting the engrossment and printing of the minutes, printed, and that discussion be postponed until after the members shall have received the printed copies. Carried.

Under the head of unfinished business, Dr. Piffard brought up the subject-matter of the bill now before the Assembly to incorporate.

A COLLEGE OF MIDWIFERY IN THE CITY OF NEW YORK, and commented at some length on the provisions of the bill. Dr. A. W. Warden offered the following preamble and resolution, which gave rise to a spirited discussion, participated in by Drs. T. H. Manley (who opposed it), Piffard, Corning, Garrigues, Garth, and Lewis, and was adopted with considerable amendment.

Whereas, An effort is being made to incorporate, by act of Legislature, a private institution under the name and title of the College of Midwifery of the City of New York, asking that such proposed institution have the right to confer the degree of graduate in midwifery, and that such diploma be a license to practise midwifery in the State of New York; and,

Whereas, The bill incorporating such institution is defective in many important respects, and the objects sought by such bill are considered injurious to the interests of the people of the State of New York, and to the medical profession of the State; and,

Whereas, No opportunity has been afforded to the medical profession of this State or to the Medical Society of the County of New York to be heard in regard to this measure; therefore,

Resolved, That the Medical Society of the County of New York hereby petition that the Assembly of the State of New York defer action until such time as this Society can be heard on this important matter.

Resolved, That a copy of this resolution, signed by the President and Secretary of the Medical Society of the County of New York, be transmitted without delay to the Assembly of the State of New York.

Dr. Piffard then moved that a committee be ap-
pointed to go to Albany, as soon as practicable, to oppose the bill now before the Assembly, and that the Comitia Minora be requested to appropriate a sum of money sufficient to defray the ordinary expenses of such committee. Carried.

Dr. Garrish moved that the committee consist of two members, to be appointed by the Chair. Carried.

The President appointed Drs. A. W. Warden and H. J. Garriges as the committee.

The Secretary announced the death of Drs. John Hurdsfield, P. W. McDonnell, and James Kennedy.

The question of delegateship to the next International Congress was referred to the Comitia Minora with power. The Society then adjourned.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, March 7, 1884.

Dr. Beverly Robinson, President, pro tem., in the Chair.

Dr. A. Brayton Ball read a paper entitled

SOME REMARKS ON THE ACOUSTIC PHENOMENA PRODUCED BY THE FLOW OF FLUIDS IN TUBES, AND ALSO UPON THE OPERATION AND MECHANISM OF CARDIAC FUNCTIONAL MURMURS (see p. 393).

Dr. W. J. Morton suggested that the murmur under consideration might be due to change in the position of the pulmonary artery itself; for instance, an increased curve upward.

Dr. Ball said the experiments of Balfour and Russell showed that there was a change in the pulmonary artery, not the curve spoken of by Dr. Morton, however, but simply that the artery was brought up farther and carried over to the left, and that such a change had no effect whatever in producing a murmur.

Dr. F. P. Kinnicutt had been greatly interested in Dr. Ball's paper, which presented the most satisfactory resume of the literature of the so-called anemic murmurs with which he was familiar.

He confined his remarks to the systolic murmurs heard at the apex and in the second interspace in many cases of chlorosis and anemia. In his own experience, in a large proportion of patients suffering from those conditions, in whom a systolic murmur was heard in the second left interspace, a corresponding murmur was also audible at the apex. The murmur at the apex was fainter than the former, as a rule was heard only over the mitral area; frequently there exists no more than a systolic impurity at the apex in these cases, especially in the early stage of the affection. He had been led to believe that the two murmurs were quite distinct from one another in their pathology. He thought that it would be generally admitted at the present time, that the conditions which obtain in anemia, viz., general muscular relaxation, in which the heart tissues share, and which theoretically and in reality, as is demonstrated by post-mortem examinations, result in dilatation of the heart cavities, might suffice to produce mitral insufficiency and a consequent mitral systolic murmur. That the systolic murmur heard in the second left interspace in such cases was simply conducted from the auricular ventricular orifice to this situation through the dilated appendix of the left auricle. He had been led to disbelieve, through a study of the careful anatomical investigations of Dr. Russell, of Edinburgh, and from some recent personal ones, Naunyn and Balfour's theory of the pathology of the murmur heard in the second interspace, which was quite as straight forward a fairly free regurgitation through the auricular ventricular orifice, and the near approach of the dilated left auricular appendix to the chest-wall, during the ventricular systole. And again, that the maximum point of intensity of the systolic murmur in the second space is not over the pulmonary artery at all, but is at a point one inch and a half to two inches to the left of the left sternal line in this space.

Dr. Russell has given a detailed report of six autopsies with particular reference to the first of the above-mentioned points. In all the cases the heart cavities were positively dilated without the existence of valvular affection. Careful examination demonstrated that in a moderate degree of dilatation the conus was occupied by the pulmonary artery, and that the same space was occupied by the pulmonary artery, and that the left limit of the vessel was from one and a half to two inches to the left of the sternum. In a greater degree of dilatation the conus arteriosus occupied the inner part of the second space for about two inches, and the pulmonary artery was under the second interspace. In both degrees of dilatation the auricular appendix was invisible from the front and was deeply buried beneath the pulmonary artery and the adjoining ventricle.

Dr. Kinnicutt was able to supplement these observations by some which he had recently made, only one of which he ventured to comment on as time by relating.

J. B.—aged fifteen years, died in hospital of parenchymatical nephritis of several months' duration, induced apparently by exposure. During the last weeks of his life he was markedly anemic. Physical examination of the heart during life revealed a soft systolic murmur over the mitral area, not transmitted to the left. A much louder, but soft systolic murmur was also heard in the second left interspace, with its intensity apparently one inch to the left of the left sternal line. The autopsy was made in my presence by Dr. Ferguson, the pathologist of the hospital. The intercostal muscles were first removed, by my request, without disturbing the sternum and the attached cartilages, the pericardium incised, and the heart and its great vessels viewed in situ. The conus arteriosus and the pulmonary artery occupied the inner and upper portion of the second space; the left limit of the pulmonary artery was one inch to the left of the left edge of the sternum. The extreme tip of the left auricular appendix was seen projecting beyond the pulmonary artery, the remainder of the appendix being deeply buried beneath the vessel. The distance from the internal surface of the lower border of the second costal cartilage to the tip of the appendix measured one inch and a quarter. The left ventricle was hypertrophied and dilated, and the muscular tissue contained some fat.

The left auricular appendix was not apparently dilated. The valves were normal. Weight of the heart, fourteen ounces. The above cases would seem to demonstrate, in the first place, that Balfour's theory of the mode of production of the systolic murmur in the second space, is correct. There were no heart cavities, and in my own case of a consequent insufficiency of the mitral valve without valvular disease; and secondly, the apparent impossibility of any close proximity of the left auricular appendix to the chest-wall in such cases; and upon the presence of the latter condition mainly rests Balfour's theory of the mode of production of the systolic murmur in the second space. Dr. Russell had also shown that the pulmonary artery in cases of dilatation frequently bears sufficiently to the left to correspond to the site claimed by Naunyn and Balfour as belonging exclusively to the auricular appendix. Dr. Kinnicutt's measurements of the breadth of the normal pulmonary artery corresponded with those given by Pirogoff; it varying from one inch to an inch and a quarter.

He personally had been unable to localize the maximum point of intensity of the systolic murmur in the second left space, heard in cases of anemia, as closely as Dr. Balfour. As a rule, it has seemed to him to obtain about one inch from the left edge of the sternum, which was quite as far away as the auricular appendix even in health. While he, therefore, was unable to accept Dr. Balfour's theory of the pathology of the systolic murmur heard in the second left space in chlorosis and anemia, he was wholly in accord with his belief that a mitral insufficiency exists in these cases.

Dr. Russell's theory was certainly one of intrinsic merit, and, it seemed to him, was not yet disproven.
The commonly accepted theory of the pulmonary origin of the murmur, with its dependence upon an altered composition of the blood, had yet to be clearly explained by its authors and supporters. In conclusion, he would ask the members if their experience coincided with his own, in regard to the very frequent existence of a mitral systolic aortic murmur in connection with a similar murmur heard in the second left space in cases of chlorosis and anemia, and also as to the maximum point of intensity of the latter murmur.

Dr. Sexton remarked that the question seemed to divide itself into two parts: (1) the source of the sound, and (2) its transmission to the ear. It seemed, as he thought, that if it originated in the connection orifice, its transmission to the walls of the chest must be in every direction from its source, and that it would be best heard, perhaps entirely, through the rapidly flowing current of blood by which it was propagated. Therefore, at the point wherever the vessel came nearest to the walls of the chest, the sound, would be heard best.

Dr. Beverley Robinson suggested that inco-ordination of the contractility of the muscular fibres of the cardiac valves might explain some murmurs heard during life, which received no explanation post mortem.

Dr. Ball said that was Walsh's idea, namely, that certain murmurs were due to spasm of the papillary muscles, but that the valves had been abandoned, because it was nearly impossible to stop a papillary muscle, the cardiac muscle generally acted regularly while in particular portions there was an irregular movement. Besides, it was difficult to believe in a continuously recurring spasm, such as would be necessary to account for the so-called dynamic murmur of chorea, for example.

With reference to the musculature of the valves, after death, he thought it amounted to little or nothing, because the cardiac muscle is not in the same condition as it is during life, McAllister had shown that the base muscles of the heart play an important part in closing the orifices in that portion; that is, squeezing them together so that the valves can completely close them; and that when the base muscles are weak, or unable to do that work under certain conditions, the orifices are not compressed so that the valves can close them, and a murmur is heard temporarily independent of anemia. Besides, it was well known how incomplete the tests for anemia were, and there might be very defective general nutrition, probably involving the cardiac muscle also, without giving rise to any of the murmurs of anemia.

Dr. Sexton thought it not impossible that the solar plexuses which supply the heart might act irrespective of each other, and thus give rise to irregularity in the action of the cardiac muscle in different parts of the heart.

Dr. Ball said that perhaps it was possible, but it seemed to him to be very unlikely that such was the fact. According to his observations, cases differed a good deal with reference to the point of maximum intensity; in quite a number the point of maximum intensity was nearer the sternal border than one and a half or two inches, and it also was extremely common to hear the murmur in the greatest intensity as far away as that distance. With regard to an apical murmurs heard in the second intercostal space he was sure that it was not at all infrequent, but usually not so loud.

Dr. Morton suggested that the microphone might aid in determining the exact point at which the murmur could be heard with the greatest intensity.

Dr. Sexton suggested that unless care was taken, a second murmur might be produced by the ordinary breathing.

Dr. Ball thought the sounds produced by the stethoscope should not be mistaken for murmurs by any one at all conversant with listening to cardiac murmurs.

Dr. Kinnicut thought it impossible that the noises produced by the stethoscope could have the rhythm and variation in pitch and quality accompanying cardiac murmurs. The Society then adjourned.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 3, 1884.

Horace T. Hanks, M.D., Vice-President, in the Chair.

Dr. H. J. Garrigues read a paper on the above subject, and began with the explanation that he made a distinction between placenta and afterbirth, the latter including the placenta and membranes. His remarks also referred only to cases of labor at or near full term, and not to abortion.

Thirty years ago Crede published his method of removing the placenta, which was by pressure from above, and not by traction from below. After the expulsion of the child the accoucheur lays the entire hand upon the abdomen over the region of the womb and makes slight friction; when the uterus is felt, contracting he seizes it with one or both hands, placing the thumbs in front, and when the contraction reaches its maximum he presses the entire organ, kneading it with his fingers and thumbs, in the direction of the cavity of the sacrum. When the uterus is manipulated in this way, the afterbirth may come away with the first contraction; but in most cases it does not until the third or fourth. The pressure must not be made when the uterus is not in a state of contraction.

German authorities claim that this method gives rise to several disadvantages, but, especially, difficulty in removing the secundines. The author of the paper had practised the method during the last eight years, satisfactorily to himself. He then gave the results with this method in 408 cases under his direction at the Mater Dei Hospital. There were six cases in which part of the membranes were removed separately after the placenta had been expelled. There were 400 cases in which Crede's method was employed, and in only six did it fail. All the method did was to increase the normal contraction of the uterus by which the afterbirth was expelled. Dr. Garrigues then gave a description of the physiological action of the muscular and ligamentous structure of the uterus, all of which were closely imitated by Crede's method.

In 408 cases post-partum hemorrhage had occurred in only two, and he regarded the method, when properly carried out, as the best means of preventing this complication. Discussion followed in which Dr. Down expressed himself in favor of the method, provided it be practised except when the uterus is contracted.

According to Crede the average duration of the third stage of labor had been 44 minutes, but, according to the experience at the Mater Dei, it had been somewhat longer. Dr. Garrigues then referred to the history of the method and the question of originality with Crede. The method has the following features:

1. It is used in all cases. 2. The uterus is grasped from all sides with both hands. 3. The placenta is squeezed out by decided pressure during uterine contraction. 4. The cord and placenta are never touched except in rare cases, when the placenta is adherent and has to be peeled off from the uterine walls. 5. The fingers are not introduced into the general canal, when the danger of infection is much greater than before the passage of the child.

Dr. Garrigues then spoke of the advantages of the method, discussed the merits and demerits of the method by drawing upon the cord, also the let-alone method, and concluded by saying that he thought Crede's method should be applied first. Pulling upon the placental treatmant could not be commended, and both had decided disadvantages.

Dr. A. S. Hunter believed that the uterus should always be allowed to expel the fetus, not only from itself but from the vagina, unless there were special contra-indications. Withhold manual aid and the uterus would almost invariably contract firmly upon the pla-
He made it a rule to examine the afterbirth in every case, and if it was incomplete he invariably introduced his hand into the uterine cavity at once and removed whatever was left. To leave such cases to nature he regarded as criminal. He did not accept the plan at all of allowing the placenta to remain and come away when it gets ready.

Dr. J. H. FRUITMIGHT regarded Crede's method as a good one to practise in most cases; but probably there were some in which it would prove of no avail. He did not favor the let-alone policy, but thought that, inasmuch as the placenta had completed its function, it should be removed.

Dr. ISAAC E. TAYLOR thought more harm than good was done by interfering with nature's method of delivering the placenta. During fifty years he had not introduced his hand into the uterus, for the purpose of removing the placenta, more than four or five times, nor had he made traction on the cord for that purpose. Indeed he knew of no authority for making traction upon the cord for the purpose of delivering the placenta. If the cord was not taken through the fingers close to the vulva, and slight traction made, it would be easy, if the uterus was contracted, to determine where the placenta was attached; if anteriorly, lift upward with the cord, and if posteriorly, separate the thighs of the woman and push downward, and the gentle traction with this manipulation would cause the prompt delivery of the placenta, and he would not have expressed. He also proved strongly of introducing the hand into the uterus at once after the delivery of the child, for the purpose of removing the placenta.

Although Crede's method might come in as an adjunct, he thought it better to allow nature to do her own work, which would not be attended by harm if delayed for hours or even two days. He thought the woman at least would be in no more danger.

Dr. E. D. RAMESDLE had been obliged to peel the placenta off in only two or three cases out of 743 cases of confinement which he had attended in private practice. He had had one death, which he believed to be due chiefly to the fact that the nurse, who regarded herself as extremely intelligent, gave, unknown to him, vaginal injections every hour for four days, and the woman died of peritonitis. He once had a case and waited forty-eight hours for the delivery of the afterbirth. He then proceeded to deliver it, found hourglass constriction to be the cause of the retention; septicaemia followed and the woman died. He then began to apply the method of making gentle traction on the cord and not too much pressure, moderating with moderate but firm pressure over the region of attachment of the placenta, and, had, on an average, removed the afterbirth within fifteen or twenty minutes after delivery of the child.

Dr. E. H. M. SELD did not treat all cases in exactly the same way, and while Crede's method might be excellent, modification of it, or other methods, might be best adapted to certain cases. During a practice of eighteen years he had introduced his hand into the uterus only once, and then in a case of monstrosity with adherent placenta.

Dr. GARRIGUES, in closing the discussion, said all would agree concerning the desirability of conforming as much as possible to the physiological processes of nature, and the diversity of opinion was only with reference to how nature's method could be nearest approached. There certainly was a difference between traction on the cord and manipulation of the uterus through the abdominal wall. He believed it best not to touch the cord at all, but try first to determine whether or not the afterbirth would come away at the slightest pressure. With reference to inversion of the uterus, he thought traction on the cord was one of the recognized causes of the accident.

With regard to Dr. Mundé's way of practising Crede's method, he thought it was rather a modification than the real method, because Crede contemplated expressing the
placenta from the fundus of a contracted uterus, not allowing it to stop until expelled from the vagina, and in Dr. Garrigues' cases it had nearly always been thrown completely into the bed. If the placenta was left until it entered the cervical cavity, surely Crede's method could not remove it. It was quite another thing to make pressure while the afterbirth was within the body of the uterus. Dr. Garrigues was unable to see how the location of the attachment of the placenta could be determined without introducing the hand into the cavity of the uterus. He agreed with Dr. Taylor entirely, that it was rash to introduce the hand into the uterus within half an hour after delivery of the child. While in his cases the average time was perhaps five minutes before the placenta was expelled, yet if it did not come away within that time, he would wait, if needs be, an hour or even more, but he would not allow it to remain and decompose.

The Academy then adjourned.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, March 12, 1884.

GEORGE F. SHAKES, M.D., PRESIDENT; IN THE CHAIR.

Dr. T. M. PRUDDEN, Chairman of the Committee on Microscopy, made the following report on the specimen received by Dr. Wyeth at the last stated meeting as one of

TUBERCULOSIS OF THE Testicle.

"The specimen shows much dense connective-tissue, diffusely and sparsely infiltrated in places with small spheroidal cells; in other parts, presenting larger and smaller circumscribed collections of similar cells. In a few places were circumscribed areas of cheesy degeneration. This is all the committee is able to report definitely, since on account of the imperfect preservation of the organ, the softer parts were almost entirely disintegrated. The microscopic examination, therefore, neither confirms nor speaks against the anatomical diagnosis of tuberculosis of the testicle, under which the specimen was presented."

Dr. Prudden also presented on behalf of a candidate a specimen of hydatid of the liver.

Dr. K. W. AMIDON presented on behalf of a candidate specimens of nasal polypi.

MALFORMATION OF THE HEART—PATENCY OF FORAMEN OVALE AND DUCTUS ARTERIOSUS—STENOSIS OF THE AORTA—HYPERTROPHY OF BOTH VENTRICLES.

Dr. L. EMMETT HOLT presented a heart showing the above lesions, taken from a child which died at the age of four months from capillary bronchitis, of four days' duration. The lungs showed the usual lesions of that disease. The heart weighed two and a half ounces, which was nearly three times the usual weight at that age. The walls of the left ventricle were considerably hypertrophied, and those of the right were about the same thickness. The opening of the ductus arteriosus was equal in size to the size of a straws. Just on the cardiac side of where this opened into the aorta, and beyond the origin of the great vessels, the aorta was constricted so as to diminish its caliber at least one-third. The valves were all normal. There was no marked hypertrophy of the auricles, and no history of cyanosis. The opening of the foramen ovale admitted an ordinary lead-pencil easily, but was valvular in character, and probably did not allow any considerable mingling of the blood-currents through it.

The hypertrophy of the left ventricle seemed plainly due to the contraction of the aorta. The cause of the hypertrophy of the right ventricle was not quite so clear, but appeared to depend upon the same lesion. As the observation with doubt, had persisted at the time of birth, the right ventricle had continued to do a part of the work of the systemic circulation, supplementing that of the left ventricle. Both together were able to compensate for the lesion and to keep the arteries filled.

These conditions—open foramen ovale and ductus arteriosus and hypertrophy of the right ventricle—are very common as associated lesions of pulmonary obstruction. Dr. Holt had never seen them recorded as depending upon aortic stenosis. Another point of interest in the case was the absence of cyanosis.

So far as it bore upon the subject at all, this case went to confirm the view that this symptom did not depend upon admixture of the arterial and venous blood. Considerable admixture certainly took place through the ductus arteriosus, and possibly some through the foramen ovale. He had seen a case recorded in which there was only a single ventricle, the aorta and pulmonary both opening out of it, and yet no cyanosis was present.

Dr. Holt thought it pretty clearly established that we were not to expect cyanosis in malformations of the heart unless marked pulmonary stenosis existed. But even this condition might be present, and yet be so compensated for that the symptom would be wanting.

OUR LONDON LETTER.

(From our Special Correspondent.)

COMPULSORY EDUCATION AND ITS DANGERS—LONDON CONSULTANTS AND THEIR MODUS OF PRACTICE—STUDENTS' NEW TEXT-BOOKS.

London, March 15, 1884.

Compulsory education may have its benefits, but from any hygienic point of view it has its drawbacks. Several children are alleged to have died within the last few months, from the pressure of overwork in board schools. It appears that children of tender years are not only kept at school for a good many hours daily, but are forced to do lessons at home also. Is it any wonder that the physical system should revolt? If we do not take care we shall have a nation of myopics, like the Germans. The lighting and ventilation of many schools are doubtless susceptible of improvement.

Home consulting practice in London is almost invariably conducted in the morning; the afternoon is devoted to hospital work and the visiting of private patients: societies occupy several evenings a week for those who choose to go. A busy physician begins his day's work at or even before 9 A.M. in his own consulting-room, and goes on till 1 P.M. or a little after. The stream of patients then flags, the doctor partakes of a scanty lunch, or perhaps none, and drives off in his carriage. Morning practice is thoroughly understood among the class patients, and scarcely any would dream of calling on any of our leading consultants in the afternoon, or at any rate later than 2 o'clock. Some little time ago a patient went to consult a well-known London physician and arrived at his house at 1 P.M. She met him just coming out to his carriage, and he actually asked her what she meant by coming so late in the hour. The patient, a new one, explained that she did not know, but the doctor strode off and rode off in his carriage to his hospital. The patient did not pay this physician a second visit, and I may remark that this is not a specimen of West End manners, as the busiest practitioners who knew his manners would scarcely treat a patient thus.

Patients usually wait in the physician's dining-room and are beckoned in in turn by the man-servant. Sometimes a judicious "tip" to the servant persuades that functionary to let a patient wait in the hall and thus slip into the consulting-room without having to wait his turn in the waiting-room. Those doctors who see a few patients gratis do not always let them have their fair turn, but keep them waiting while more profitable ones are
THE MEDICAL RECORD.

THE REASONS FOR ORGANIZING A NEW STATE ASSOCIATION NOT GOOD ONES.

TO THE EDITOR OF THE MEDICAL RECORD.

Sir : In the *Ephemera* for March, 1884, on pages 474 and 475, occurs the following passage:

"One of the chief reasons for organizing a new State society at this time is to be found in the fact that a large number of the county societies are in contempt of the Code of Ethics. The same duty should be imposed by law on such organizations as the State society. It is evidently that, notwithstanding each volume of *Quain's Anatomy* is likely to make a sail out of its sails. Pepper is similarly likely to supervene Bilroth and is quite up to date.

THE USE OF THE MENTHOL SPRAY IN NEURALGIA.

TO THE EDITOR OF THE MEDICAL RECORD.

Sir : Of late so much has been written concerning the external use of menthol, both in solution and as a pencil or cone, that it may seem superfluous to call attention to its efficacy when applied in the form of a spray.

Nevertheless I venture to suggest that as a spray the drug will most thoroughly and rapidly relieve the pains of intercostal neuralgia, spinal irritation, etc.

It has been my habit to use a saturated alcoholic solution of menthol crystals, to which a little sulphuric ether had been added, in an ordinary hand-spray. As a rule, the affected parts need not be sprayed more than once a day. Of twenty cases treated in this way all but two were promptly relieved, and in several cases the beneficial effects were permanent. Respectfully,

C. M. CAULDWELL, M.D.

THE INFLUENCE OF FRENCH MEDICAL JOURNALS THROUGH VOICE FROM THE "RED-SKIN" REGION.

TO THE EDITOR OF THE MEDICAL RECORD.

Dear Doctor: In The Record for March 3rd I notice a paragraph concerning *Le Moniteur de la Police-médicale*. I regret exceedingly that any article of mine which my esteemed friend, the editor of the *Philadelphia Medical Times*, thought fit to publish, should have given the irritable editor of *Le Moniteur* an occasion to attack medical journalism in the United States! The article on epilepsy referred to by this belligerent Frenchman was written at a lonely frontier post where, thank goodness, French medical journals are seldom, if ever, received.

Certainly, until to-day, I never heard of this French editor or of *Le Moniteur de la Police-médicale*, and I am sure I have never seen any translations, if such exist, of his valuable writings. I do not know what has been written against The Record by this same editor, but I fancy that, like a "luminous" American medical rival, it will not "push The Record very hard," should he continue his pusillanimous attacks. It is not necessary to congratulate the medical profession of this country that our medical journals compare favorably with those of any other country, and the ability of American medical prac-
titioner is, to say the least, 'quite equal to that of his con-
frère in France!' Hoping that you will pardon me for taking this much of your valuable space, and with best wishes for The Record and its worthy editor, I am,

Very sincerely yours,

W. THORNTON PARKER, M.D. (Munich).

Acting Assistant Surgeon, U. S. Army.

FORT UNION, NEW MEXICO,
March 30, 1884.

SOME POINTS IN THE TREATMENT OF DIPHTHERIA.

To the Editor of The Medical Record.

Sir: Much may be forgiven to the man to whom the flush of victory has brought perversion of judgment, but the local treatment with nitrate of silver, advocated by Dr. T. J. Hutton, in his astonishing article on diphtheria in your last issue, seems monstrous in the extreme. "Twenty grains of lunar caustic," says he, "in one drachm of water, is applied thoroughly every hour or two to the affected parts, and continued so long as there is formation of membrane, whether two days or seven." Should one application of so powerful a solution have arrested the development of the membrane he seeks to destroy, it would be worse than folly to repeat it. If it has not destroyed it, he is in no position to determine at the end of an hour or two, as the eschar left by the treatment obscures all the processes beneath it. Let us suppose he has used it for seven days, as he would lead us to conclude he sometimes did, here would be eighty-four applications at the least, of a painful, irritant character, the eschar sometimes slopping and leaving a raw surface, which in its turn is cauterized with additional torment. Could anything be more deplorable? What is gained? Ought not the lesson to have been long before inculcated in such a case that the caustic was hindering the object of its use? But at the same time he is having his patient gargle his throat "every fifteen minutes" with a solution of "one ounce and a half of chlorate of potassa dissolved in eight ounces of water!" Such scouring and rinsing may be refreshing to the crisp throats of Minnesota children, in their atmosphere at a "temperature of 60° below zero," but here we could not get so much chlorate of potassium to dissolve in so little water, let alone using it. It would seem impossible that, in the proportions of these two solutions, as given above, the saturated solution could have been made without heating the water, and keeping it so, as, ordinarily, a saturated solution is made with one part to twenty. Now a patient whose throat is being "cauterized thoroughly every hour or two," and who at the same time is gargling it every fifteen minutes, "whether for two days or seven," has no time for even "common liquid food," let alone sleep, and that he has the courage to survive the ordeal and enter upon the second stage of the disease and its treatment speaks well of the young citizen of the great Northwest. They whom we look upon as authorities have only voiced the private experience of thousands of physicians in every country, and almost uniformly disallow the use of nitrate of silver as a cauterizing agent in diphtheria. Where it is at all commended, as by Bouchut, its employment is limited to the tonsil at the début of the disease; a thing not used in his own practice, I infer, since he adds, "for the last ten years I have employed no other means than pharyngeal douches of coal-tar saponine, which prevent the production of septicaemia." Dr. Jenner recommends one single but efficient application of a strong solution of the nitrate of silver, which may stay the spread of the exudative inflammation, but on the whole prefers the application of the diluted hydrochloric acid. Squire, in "Reynolds' System of Medicine," advovates the local use of a strong solution of nitrate of sil-

3 Med. Times and Gazette, October 6, 1877.
stance, it could have been no uncommon thing in the bleak winter climate of Minnesota—that far frontier, where, as Touggin could say, the washerwomen hang their clothes on the rim of the sky—for many persons to crowd themselves for days in narrow rooms against the eager, nipping air. And how many winters must this have occurred, in how many hundreds of instances, without diphtheria, until these epidemics Dr. Hutton describes.

Hilbrand was infected by a cloak, which, after exposure to scarlatina, had been put aside for eighteen months. The poison of small-pox is so tenacious of vitality that, if protected from air, it remains active for an unknown number of years. Dr. S. B. Morrison relates that his own observation had taught him that the diphtheritic poison can remain quiescent for years and then break out suddenly. Squire gives an account of an infant which took the disease twenty-one days after exposure in a house that had been cleansed ten days before on the complete recovery of a servant affected there with diphtheria. But why multiply instances? Diphtheria is perhaps absent in no State of the Union at any season of the year. The average number of deaths from it in New Jersey, according to the Board of Health Reports, is not less than one thousand annually. In the large cities throughout the nation it is never entirely absent. With so many centres of infection the chances of its being borne through fomites, or in these days of rapid transit by some victim in whom the poison was late in developing after exposure to infection, to even the frontiers of Minnesota is not surprising. The question is the crowding of many persons in one small room furnished the conditions favorable to the development of the disease goes without questioning.

Geo. T. Welch, M.D.

THE REASONS WHY WOMEN CANNOT BE MEMBERS OF THE PHILADELPHIA COUNTY MEDICAL SOCIETY.

To the Editor of THE MEDICAL RECORD.

Sir: Your reference to the action of the Philadelphia County Medical Society on Wednesday last is incorrect. The amendment consisted in adding the word "male" to the resolution passed, it then reads:

"The Society shall consist of regular male physicians, residents of the County of Philadelphia, subject to the following provisions:

"Section 1. To entitle a person to membership in this Society, he must be a citizen of the County of Philadelphia, a graduate of at least one year's standing of a respectable medical school, and of good moral and professional reputation." A large majority, opposed to female members, declined to support the amendment before the vote was taken, being satisfied that the personal pronoun "he" was sufficiently explicit, and amendments generally are not favored by us. The decisive rejection of the female candidate voted for later, clearly indicated the views of our members then, as it has done at every election therefore.

The Society does not wish its usefulness curtailed or its life endangered by driving out the real workers through the introduction of women. Our proceedings are largely clinical, and although several of the supporters of female candidates have publicly stated that women would not enter their society, and partially, in common of the bill of fare provided, there are enough gentlemen left to decline mixed audiences, believing that what before men would be proper and legitimate, would before women be improper and indecent, and that one who would blush to expose his mother or sister, his wife or his daughter to clinical exhibitions, correct and dignified in themselves, cannot set aside his respect for women, be they professional or be they brazen.

There are other and special objections to the introduction of women as members, which pertain to this Society particularly, and which, not being of general interest, are not here noted. The real aim of the agitators in the question with this Society is well known, the pretensions of philanthropy and respect for females as practitioners, which they urge so persistently, are homeopathic in their potency.

WM. R. D. Blackwood, M.D.,
Chairman Committee of Publication.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from March 30, 1884, to April 5, 1884.

Woodhull, Alfred A., Major and Surgeon. Granted leave of absence for twenty-two days, to take effect about April 6, 1884. S. O. 72, par. 13, Adjutant General's Office, March 28, 1884.

White, Robert H., Captain and Assistant Surgeon. To be relieved from duty at United States Military Academy, West Point, N. Y., August 28, 1884. S. O. 74, par. 7, Adjutant General's Office, March 31, 1884.

Official List of Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service.

January 1, 1884, to March 31, 1884.

Fessenden, C. S. D., Surgeon. To proceed to Cairo, Ill., and Memphis, Tenn., as inspector. March 5, 1884.

Purviance, George, Surgeon. Granted leave of absence for thirty days. February 16, 1884.

Smith, Henry, Surgeon. To rejoins his station at Norfolk, Va. March 7, 1884.

Irwin, Fairfax, Passed Assistant Surgeon. Relieved from duty at Norfolk, Va.; to assume charge of Cape Charles Quarantine Station. March 7, 1884.

Carmichael, D. A., Assistant Surgeon. To report to Surgeon Purviance for examination for promotion. March 5, 1884.

Armstrong, S. T., Assistant Surgeon. To report to Surgeon Fessenden for examination for promotion. March 5, 1884.

Bennett, P. H., Assistant Surgeon. Leave of absence extended ten days. January 18, 1884.

Ams, R. P. M., Assistant Surgeon. Detailed for temporary duty on relief boat—Ohio River flood sufferers. February 16, and March 1, 1884.

Devan, S. C., Assistant Surgeon. Upon expiration of leave of absence, to proceed to St. Louis, Mo., for temporary duty. February 6, 1884.

Kalloch, F. C., Assistant Surgeon. To proceed to Charleston, S. C., for temporary duty. February 1, 1884.

Devan, A. D., Assistant Surgeon. Granted leave of absence for seven days. March 13, 1884.
WASDIN, EUGENE, Assistant Surgeon. Granted leave of absence for fifteen days. March 4, 1884.

BATTLE, K. P., Assistant Surgeon. To proceed to New York, N. Y., for temporary duty. February 4, 1884.

COOKE, H. P., Passed Assistant Surgeon. Resignation accepted by the Secretary of the Treasury, to take effect February 5, 1884, January 31, 1884.

WITTLER, KEMP, M.D., of North Carolina, having passed the examination required by the Regulations, was appointed Assistant Surgeon by the Secretary of the Treasury, February 2, 1884.

CARMICHAEL, D. A., Passed Assistant Surgeon. Promoted and appointed Passed Assistant Surgeon, by the Secretary of the Treasury, from March 1, 1884, March 18, 1884.

ARMSTRONG, S. T., Passed Assistant Surgeon. Promoted and appointed Passed Assistant Surgeon, by the Secretary of the Treasury, from April 1, 1884, March 28, 1884.

Official List of Changes in the Medical Corps of the Navy, during the week ending April 5, 1884.

WALCRO, P. S., Medical Director. Granted one year's leave of absence from March 25th, with permission to leave United States.

BATES, N. L., Medical Inspector. Ordered to Washington to attend sick officers.

BRADLEY, M., Medical Inspector. Ordered to continue duty at League Island Navy Yard.

GUNNELL, F. M., Surgeon-General. Appointed Chief of Bureau of Medicine and Surgery, and Surgeon-General of the Navy, with the relative rank of Commodore, from March 27th.

RUSH, C. W., Passed Assistant Surgeon. Ordered to Naval Academy.

MCMURTRY, D., Surgeon. Detached from Naval Rendezvous, Philadelphia, and to await orders for duty at Navy Yard, Washington, D. C.

NELSON, H. C., Medical Inspector. Ordered before Retiring Board.

GORGAS, A. C., Medical Inspector. To be Medical Director from the 4th March on the Active List.

Medical Items.

Cases.

Deaths.

This case of smallpox was sent from Brooklyn to Castle Garden.

How to Practice Medicine in Mexico.—A correspondent of the Therapeutic Gazette at La Paz, writes: "The medical faculty of this place consists of two Mexican physicians, graduates of the College of Guadalajara, and one American. They all have excellent pharmacies connected with their practices. To any who may desire to reside and practise in Mexico, it may be well to state that American physicians are not permitted to practise in any part of Mexico without a certificate of proficiency from the medical examining board of either the College of Guadalajara or that of the city of Mexico, a law which renders the country singularly free from quacks. A small, feeble weekly is published here by the 'Sociedad de Medicina de Guadalajara.'"

The Use of Damiana in Mexico.—Damiana is universally used on the western coast of Mexico, usually in the form of a hot infusion, a cordial, or as a domestic tincture. In its weaker forms it is esteemed as a general tonic and sexual power preservative, while the stronger preparations are held to be (and probably with some credit) powerfully stimulant to both the male and female sexual organs. It is undoubtedly an aphrodisiac of considerable power, somewhat tonic, slightly cathartic, and apparently having some hepatic action. The natives and midwives, and women of loose morals attribute enemagogic powers to it. Like at home, here abroad the druggists have patented what they call "Damiana" but the real thing is not prepared from the herb. It is extensively sold on this coast, and as it may interest some of the medical fraternity to know what merits are claimed for "damiana," I append a free translation of a wrapper, it so perfectly represents the popular idea of the efficacy of "Damiana Fort:"

"Taken before meals it gives an appetite, and prevents all indigestion in persons accustomed to eat and drink after meals. It exercises a wonderful influence upon the nervous system, and is an efficient aphrodisiac. The frequent cases of longevity observed in this territory, and the power possessed by sexagenarians of obtaining offspring, as though they were still young, are due to the use of damiana."—Correspondence of Therapeutic Gazette.

The Potassium-Mercuric Iodide Test for Albumen. Dr. George W. Dillon, of this city, writes: "The editorial in your issue of THE MEDICAL RECORD, February 23, 1884, on 'The New Urinary Tests,' contains the statement that Taurer's test—potassium-mercuric iodide—has no special advantage over the other tests for albumen. From an extensive experience with it, it has seemed to me the best known, especially by the general practitioner. My reasons are stated in detail in an article published elsewhere."

"May I also call your attention to a fact which I have never known noticed except by myself, that chronic acid is a delicate albumen reagent, ranking among the very best?"

Electricity for the Relief of Tinnitus. Dr. H. L. Morse, writing to the Boston Medical and Surgical Journal concerning the treatment of ear diseases in Vienna, says: "Another method employed to mitigate tinnitus, which is often so annoying, is the use of electricity. The constant current is at first tried, and if this fails to accomplish the desired end the induced current is used. The anode (copper pole) is placed upon the tragus, and the cathode (zinc pole) is brought in contact with some other part of the body, usually the side of the neck or the hand. A very weak current is at first applied, and its strength is gradually increased, until the patient feels a sharp stabbing pain in the ear, or has severe tinnitus; the strength of the current is then gradually diminished, until it is once more at zero, before removing the poles. The improvement due to electricity is sometimes permanent—often only temporary—and in some cases it has no effect upon the tinnitus. But even in these last cases it often relieves the dull, stupid feeling in the head, loss of memory, and complained of lassitude, in this way greatly improves their condition. Electricity is also very often used by Urbantschitsch for otalgia, and gives very good, and in many cases permanent, results."

THE RATIONAL METHOD OF TEACHING ANATOMY. ¹
By FRANK RAKER, M.D.,
Professor of Anatomy, University of Georgetown, D. C.

When the renowned traveller and surgeon, Lemuel Guliver, visited the Imperial Academy of Lagado, he found in vogue there a peculiar method of teaching science.

The proposition and the demonstration were fairly written on a thin wafer, with ink composed of a cephalic tincture. This the student was to swallow on a fasting stomach, and for three days following eat nothing but bread and water. As the water digested the tincture mounted to the brain, bearing the proposition along with it.

This has a grotesque resemblance to some methods used not so long ago at Lagado; yet methods which are, however, not always perfectly satisfactory, as was indeed the case with that of the Laputan Academy, for our amusing author continues:

"But the success hath not hitherto been answerable, partly by some error in the quantum or composition, and partly by the perverseness of the lads, to whom this bolus is so nauseous that they generally steal aside and discharge it upward before it can operate; neither have they been yet persuaded to use so long an abstinence as the prescription requires."

It is very often assumed by writers on natural science that here, at least, in the "sciences of observation" as it is the fashion to call these departments of human knowledge, we are not to hold entirely the Laputan method, and have succeeded in substituting a rational system of instruction founded on observed facts. But it is not always safe to assume that we are rid of Thoth, Dagon, and the other gods of the Philistines. They have a wonderful faculty for reappearance, with their staring, fish-like eyes and putty faces, right in the midst of the sanctuary where we thought we had forever chased them forever.

Let us see what is meant by our pet phrase, "founded on observed facts." Many a homly have I read to medical students exhorting them to rely only upon what they can see and demonstrate, to test all anatomical knowledge by strict comparison with the cadaver: many another do I hope to address them also, for all agree that that method and not the other is safe one. What do we mean by founding a science? Is it simply the gathering up of careful and laborious observations? Is it scientific knowledge to be aware that Herr Geislus has counted under the microscope the exact number of villi in the human intestine, and found that they amount to 10,125,603, or that M. Fousier has, after laborious patience, succeeded in finding almost the exact area of the mucous surface of the human lung? Facts are not only stubborn things—they are exceedingly dead things if not warmed to life by the action of human thought. It is time to come to a certain understanding on this subject.

The independent interest in the human body has been so great, and the necessities of the surgeon and physician have been such, that we have a vast accumulation of observed facts, vaster by far than in any equally limited biological field. How shall we deal with them?

¹ Read before the Biological Society of Washington, D. C., (November 19, 1879.)
tempt is made to vary the tedium by illustration or comparison. There is, for example, a little piece of the little palate bone, situated deep in the back of the orbit and of no surgical importance. It has perhaps the dimensions of a cubic quarter inch. Its situation and irregular shape give it, however, five surfaces, and this fact allows full scope for the peculiar function of art, which almost writes nearly half a page upon this insignificant little nodule, describing each surface, with its direction and articulations, with a proximity that is almost maddening. I have upon several occasions administered this bolus to students, and found the same results that Gallivier describes—"they generally steal aside and discharge it upward before it is so much as comprehended, it is so impossible to retain the matter in the memory as it is taught by Gray. It becomes simple when treated organically as part of the orbit. Then the whole mass of apparently disintegrated facts is supported and comprehended. We have not yet got much beyond the deep wisdom of Plato, who said: "A freeman ought to be a freeman in the acquisition of knowledge. Bodily exercise when compulsory does no harm, but knowledge that is acquired by compulsion has no hold on the mind."

Most students who commence the study of the human frame by means of descriptive anatomy alone, suffer a profound feeling of disappointment. They had expected to look exactly at the remains of the monkey, some corner of the shrouding veil of Isis uplifted, but they are put off with the husks of dimensions and relations of structures as shown in the cadaver, that is not deader than the method that describes it. It is notorious how quickly anatomical knowledge thus acquired is forgotten. Which one of the medical gentlemen present here to-day in fact could tell me, not immediately, but perhaps after a little reflection, exactly which corner of the internal maxillary artery? Which one can correctly bound the ventricles of the brain? Yet I venture to say that either of these series of facts learned by the natural method would never be forgotten. It is rather the art of anatomy you have learned, not the science. The geometry used by a practical mechanic in laying out his work is not science. He may be perfectly ignorant of the principles involved, and should a new case arise is helpless.

The great predominance given to surgery has hitherto overshadowed anatomical teaching and produced this result. But the increasing application of anatomy as an aid in diagnosis must necessarily work a change, even were it not for the popular and universal spread of biology. In such cases it is not sufficient to merely know the details of structures—it is required to understand their functional activities, the constant and incessant changes they undergo, the inherited characters and the possibilities of reversions, or of the persistence of fetal characteristics. Formerly the chair from which anatomy was taught was termed the "Institutes of Anatomy and Physiology." The vast extent of the subject occasioned by the advance of knowledge has made it impossible to teach the whole from a single chair. But by teaching it in this way there is to some extent a suppressio veri. The living body is in many respects like the dead one, and it is impossible to separate structure and function except in a wholly imaginary way. Anatomy reduced to the absurdity of suppressing all mention of function and change becomes a species of stereography.

Undue authority given to a text-book destroys healthy independence of thought. Let us give to our science a higher character, instead of remaining satisfied with the phenomena of correlation, give us the ultimate results of a vast series of sequences. The human body is not \( x \) but \( \frac{1}{x} \), there being inseparably connected with it the wonderfully complex interacting forces which make it what it is, shaping it from moment to moment, slowly, but as surely as the tides alter the coast-lines of continents.

To apply this practically is not difficult. In the first place, the facts of anatomy should be constantly explained and illustrated by the functional activity of the structure. The variations in the shapes of bones, the varying characteristics of muscles, viscera, and all other parts, should be referred as far as possible to the immediately antecedent conditions. The twisted appearance of the humerus due to the pull of its muscles, the obliquely spiral curve of the ribs a necessity of their use as lateral flanges for rhythmically expanding the thorax. An artery is not a mere abstraction whose relations are to be "committed to memory," its situation depends upon its function and the necessity for its protection. Closely connected with this comes what is sometimes called "applied anatomy," the application of the sciences of anatomy and physiology to pathological conditions. The strongest parts of the bones, the direction in which muscular force acts, the external configurations which guide to important organs, the many weak points by which disease or injury may invade the body, are of the highest importance. While but little prominence is given to this subject in Gray—the only branch adequately treated being that which has immediate application to surgery—there are yet many works which more or less completely fulfil the necessary conditions. Among them are the excellent ones of Hold- den and of Humphry, various manuals of physical diagnosis, and the recent book of Prof. Harrison Allen, which is the one I now propose to mention.

The second method I would mention is wider-reaching and goes nearer to the real backbone of the subject. It is the orderly review of the successive modifications of structure which occur throughout the life of man. It is customary to call this embryology, but as this seems to limit the examination to pre-natal conditions, the term antenomy, which the Germans have made for this purpose, is preferable. It is simply the previous method extended in time, and has this supreme and important advantage, which cannot be too highly prized by the teacher, that it proceeds from simple to complex. It is most surprising to me that this, the natural method of teaching the subject, should have been neglected for so long. Other departments of biology long ago reshaped their whole course by this means. But physicians have always looked with suspicion upon any innovations in the important branch which investigates the structure of the body. The story is as old as Herophilus, who was decapitated as an impious wretch because he dissected criminals; as Vesalius, who was razed at by all the physicians of Europe because he revealed the secret of the human body; and as Cuvier, whose famous dictum, "omnia vivum ex uno," was considered as vile blasphemy by his associates.

You will perhaps say that embryology is already sufficiently taught in medical schools. It is taught, to be sure, but not as an organic and essential pre-requisite to the proper understanding of the structure of the body. It is usually turned over to the chair of Obstetrics and there treated very properly, but imperfectly, as relating to the phenomena of pregnancy and parturition. In our anatomical text-books a similar fault is found. The whole matter is detached, extracted as it were from the place where it properly belongs, and relegated to a distinct and separate section of the book, but slight reference being made to it elsewhere. It is usually hastily passed over by students as of no great importance. In the current edition of Gray, the development of the ovum and the description of the tissues of the body are placed in an introductory portion written by Dr. Holmes. The matter is not treated genetically, and students find very great difficulty in understanding it. This is not the case with the first edition of Gray, in which the student finds in Quain's well known work, which is the great rival of Gray in all English-speaking countries, and has well-nigh crowded out its opponent, except in the United States. Published under the auspices of the London University, and edited by a corps of gentlemen each of whom is a specialist in his own branch, it is far superior to Gray as a scientific treatise representing the latest results. Two
great faults obscure it. Its illustrations, though many and fine, do not equal the graphic seizure of details which characterizes the intelligent work of Dr. Carter, the artist who illustrated Gray. Again, the book being fashioned by so many different hands, has suffered in logical and orderly development. The department of embryology is relegated to the back of the book, and the account of the tissues precedes the second volume.

In other sciences the student is led along by easy steps from the simplest rudiments to the greatest complexity; it is only in anatomy that the strange system prevails of treating each part of a highly complex whole as if the student were already acquainted with every other part. As he usually commences at osteology, he receives no information as to the genesis of bone and its intimate structure and properties. What is still more astonishing, there is no comprehensive view of the subject, and the student is plunged into the description of the vertebrae without any idea of the general arrangement or characteristics of the skeleton. A short chapter, illustrated by full-length views of the entire skeleton taken from various points, would seem absolutely necessary; but you will look in vain for anything of that kind in our best-known manuals of anatomy.

I am aware that you will probably say that I overlook the fact that the subject must be treated systematically. But there is such a thing as carrying system too far. A dictionary is a model of system and admirable for use in its place; but he who would attempt to master a language by committing it consecutively to memory, we sympathize with the old lady who thought that the stories were mighty short and didn’t seem to hang together well. Now, the arrangement of Gray is essentially that of a dictionary or cyclopædia. The known facts about a structure are given under the head of that structure with tolerable completeness, but the description is not an organic part of a systematic unfolding work, but a compendium arranged without reference to the gradual development of the subject or the mental needs of the learner.

I would, therefore, weave in the elements of embryology and histology in such a manner as to make them available for use to the best advantage in explaining and describing. There should be a preliminary chapter on the development and growth of the body. Having carried the human egg as far as the laying down of the membranes, the genesis of the tissues should be considered, the characteristics of epithelium and the great connective tissue group. Reserving the more complex tissues until the organs which they form come up for consideration, cartilage and bone tissue would logically be taken up as the highest examples of the connective tissues. After describing osteogenesis the attention should be directed to the structure and characteristics of bone, then to the osseous system as a whole, finally to the separate bones.

The remainder of embryology and histology should be dispersed throughout the work. The subjects would be treated in an elementary manner, not intended to supersede elaborate treatises on the subject. Each description of an organ or class of organs should be prefaced by a short account of its development and intimate structure. This may be called the historical method as applied to anatomy, an advance from simple to complex. I will give you an instance of its application. The ordinary way of teaching the anatomy of the joints of the human body is artificial in the extreme. Galen classified and named them, and although with the insight of genius he really did seize upon some of the essential characters, the classification is, as far as the student can see, as arbitrary as that of the bones into long, short, and irregular. The name based upon Greek comes, the name for the learner. Unnecessary elaboration is also used. He is told that a schindylesis is a joint where a thin plate is received into a cleft or fissure, and that gomphosis is the insertion of a conical process into a socket, the only example being the teeth. Now schindylesis is only a variety of suture where three bones unite, and the teeth are not bones, so that their insertion is not an articulation at all. Let us look at the subject of joints from the side of development.

A limb- or body-segment is first composed of embryonic or indifferent tissue. In its axis this tissue differentiates into a cartilaginous rod which at certain points shows a solution of continuity. (See Fig. A.) Around the rod and between the ends of its segments connective tissue is formed. That around the rod is termed the perichondrium; that between, which is of precisely the same nature, forms ligaments or straps uniting the applied ends. The fibrous tissue may be so scanty and the apposition of the ends so close as to make the two bones almost immovable with respect to each other; the joint is then called synarthrodial, of which the sutures of the skull are examples. It may be of considerable amount, allowing a slight and limited motion; the joint is then called amphiarthrodial, examples of this being seen in the vertebrae. (See Fig. B.) In case a greater amount of movement is advantageous, the amphiarthrodial joints sooner or later undergo a change in their interior. Certain of the connective-tissue cells become vacuolated, and these vacuoles or small cavities join together, making a larger cavity or cleft (see Fig. C), which is moistened with fluid derived from the cells. The fluid is called synovia, the cavity the synovial cavity. Joints of this kind are called diarthrodial. The interstitial fibrous tissue may not entirely disappear. Sometimes a synovial cavity is formed along the end surface of each segment, leaving an intervening disk of fibrous tissue which may become in part cartilaginous. This is termed an interarticular fibro-cartilage; example, lower-jaw joint. (See Fig. D.) The disk may become thinned and disappear at the centre, leaving a ring. (See Fig. E.) This occurs in the knee-joint. The complete disappearance is shown in Fig. F. The outside capsule may be variously thickened by bands and cords of connective tissue, all arising from the same original investing membrane continuous with the perichondrium, which, as the cartilage ossifies, becomes periostium. These bands are the ligaments. If necessary, a further classification can now be made having for its principal basis the shapes of the articular surfaces.

I do not claim that any novel facts are presented here—it is merely that the old system teaches them in the wrong sequence. By this method the subject is simplified, the classification made intelligible, and all anomalies and peculiarities are explained. It gives a rational basis upon which to arrange the known facts relating to any
joint. The ligamentous system is shown in its proper relation as a dependence of the osseous. I have indeed found a very considerable advantage in treating the two together, following the description of each group of bones by a description of the ligaments which unite them.

I could multiply instances to show that in ontogeny we find a key which unfolds the most complex structures. The temporal bone of the fetus presents far more clearly the essential characteristics than does that of the adult, its duplex function as sense-capsule and stop-gap being much plainer. Being essentially the otocrane, or skull of the ear, its features are better understood by examining the fetal bone before the ear-cavities are concealed by ossification. These internal cavities can then be described as they appear in the adult stage in their relations with the auditory and facial nerves and the great vessels. The minor details all group themselves around these, and the outside of the bone, which merely presents forearm of exit and entrance with certain muscular attachments and surface shapings not very clearly indicating the internal structure, should be described last. The current treatises on anatomy obscure the subject in the most absurd manner by giving in all detail the outside of the bone and treating the inside alone. It is true there is a great deal of special sense, toward the latter end of the book, the internal configuration is mentioned, but if that is the rule why not defer the description of the lateral masses of the ethmoid until that section is reached? The beginner knows nothing of what is beyond, and is condemned to memorize the minute details of the exterior, told that here a structure enters and there another has its exit, structures of which he knows absolutely nothing, the whole being as unpalatable as a dish of sawdust, "owing to some error in the quantum or composition."

Again, take the vascular system. Only by following its development from the earliest vacuolation of connective tissue until the formation of the artery can the vexation for its peculiarities. And by no other means do we get so good an idea of its possibilities, the origin of vessels in growing tissue and in the healing of wounds, the relations of the vascular system to the connective-tissue system, the structure of the spleen and of the bone-marow.

The study of the alimentary canal of the adult, with its specialization of parts, should invariably be introduced by a short account of its original state as a simple mesial tube with glandular organs symmetrically arranged. The peritoneum, with its complicated folds and double sac, becomes perfectly intelligible when its various stages of development are shown.

The more complex the organs the more successful is this mode of treatment. The human brain is a striking instance. Students find it almost impossible to form a correct idea of its interior. The old anatomists exhausted their ingenuity in inventing fanciful names for every feature, and as treated by the usual method of descriptive anatomy the mass of details has no more organic connection than a pile of jack-straws has structure. But if we commence at the embryo and describe the originally simple tube which first forms the cerebro-spinal axis, and then its successive modifications until it reaches the adult stage, the whole mass becomes vertebrated as it were, and can be understood readily. The brain cavities are the hollow of the tube, the structures its wall. I do not know a more striking instance of the enlightening power of real knowledge born of orderly arrangement and intelligent comprehension of facts, than is afforded by the flood of light which this conception throws upon the structure of the nervous centres. The idea has been admirably worked out by many anatomists, among whom may be mentioned Huxley, Wyman, and Wilder, but the student would have more striking instance of the enlightening power of real knowledge born of orderly arrangement and intelligent comprehension of facts, than is afforded by the flood of light which this conception throws upon the structure of the nervous centres. The idea has been admirably worked out by many anatomists, among whom may be mentioned Huxley, Wyman, and Wilder, but the student would have more

deduced existing rocks, yet we accept the human body, one of the most changeable things in the universe, as an everlasting entity to be described once for all.

The third method to which I wish to call your attention is one which should be used with more reserve than those already described. It is that of phylegeny, or the illustration of the anatomy of man by instances drawn from structures found in the lower animals, particularly those nearest the supposed line of descent. It is merely carrying the observations farther back in time, and the application is therefore more difficult. Not only does it corroborate and explain the facts of the development of the body, but it also gives important evidence as to the real nature of structures and their proper relations to each other. Occasionally an allusion to lower forms affords important secondary aid. A student will always remember two facts better than one provided they be genetically related, so the features of human structure may be impressed on the mind by showing how they differ from the same in lower forms. The many modifications produced by the erect posture are much more easily remembered by this method of contrast. Although this method gives a breadth of view highly desirable and not otherwise to be obtained, it is subject to certain proper and practical limits, as the medical student has no time to spend on comparative anatomy except as it immediately assists him in the study of the human body. English authors have not neglected this method. Holden constantly uses it, thereby making his books very delightful to students; and Mivart has a little work which has succeeded in almost concealing the anatomy of the human body by discussions of how it differs from lower forms; an excellent example of carrying a good system too far.

In teaching by the method I have described one very decided disadvantage is met at the outset. The doctrine of strict analogy, the ascent and descent of the animal kingdom, on which it is based, has not yet become a part of elementary teaching. Consequently the value and significance of many facts are not understood. Every treatise on human anatomy should therefore be introduced by a chapter giving an outline of the accepted theory and the most important evidence on which it rests. This could be done, with the wanton desire to give the student some care should be taken to introduce only authentic evidence and to guard against strained deductions. The phenomena of variability and adaptation, differentiation of organs and division of labor should be concisely explained. At present the inquiring student usually asks his teacher, "Do you believe that man was made from a lower form?" and when informed that he does not is completely bewildered.

I know that my professional brethren who have learned anatomy in the old way are secretly doubtful whether anything can avail but a steady grind at the old mill. Via trita, via tuta. Undoubtedly a steady grind will always be necessary, but it is surely better to work with the steam-power of the higher intellect as freemen (to use Plato’s phrase) than to grind away with a hand-mill like slaves simply because the venerable machine was used by our forefathers. The question you will put is, Does this method teach the anatomy which we as physicians must have to enable us to deal with the body intelligently in actual practice? There can be no doubt that it does this far better than the old system. The student attains to a real conception of the different structures of the body, and possesses more than a rote knowledge of topographical details. He not only knows what he needs as a surgeon, but also the numerous variations, malformations, and pathological changes which may occur. Should an undescribed condition arise, he can at once deal with it according to his studies in phylegeny. We cannot say whether it does not overload the student. It does not, for the reason that it classifies, arranges, and groups knowledge according to the true natural method, thus eliminating many wearisome repetitions and unimportant trivialities.
which disfigure our text-books. The method is shorter than the old one.

It seems strange that English science, to which we owe the greatest theory of organic life ever formulated, should be so backward in applying that theory to practical results. The methods that I have sought to outline in this paper will, I hope, not only bring to light the true course, but also dispose of the old theory in this matter, and ultimately place us in a better position to apply modern science to practical results.

The most important works on human anatomy are undoubtedly those of Germany. The descriptive anatomy of Henle is probably the best ever published. His descriptions are models of fulness and clearness, and his illustrations unequalled. The whole body of anatomy, when treated as a system, has been systematically arranged, each part being illustrated by a detailed description, with figures, which are clear and accurate. The system is comprehensive, and the whole is admirably calculated to facilitate the study of anatomy.

The most significant work that has yet been published on the subject of human anatomy is that which has recently appeared in Germany from the pen of Carl Gegenbaur, who, is, perhaps, the most eminent of living anatomists. It comes nearer to the ideal method of presenting the subject than any other with which I am acquainted. Prefacing a few chapters on the laws of heredity and the division of labor, he first treats of the simple cell, then of the development of the ovum. Osborn’s work, which is in part a continuation of Gegenbaur’s, is also a valuable contribution to the subject.

The work is a model of compression, and the principal fault I have to find with it is that it is too short. Its value would be enhanced by a proper interleaving of topographical, surgical, and applied anatomy. The illustrations are admirable: Dr. Carter’s method of imprinting the names of the organs has been adopted (and properly credited), not, however, with the success which followed its use in the hands of its inventor.

The ideal treatise on anatomy would be one on the plan of Gegenbaur, with more numerous illustrations and diagrams, both after the manner of Gray and of Henle, with the constant reference to practical application which makes the works of Holdén and Humphry so charming, and a thorough treatment of surgical and topographical features. I will cite a few passages from Gegenbaur’s preliminary chapters, to show how closely his views accord with those that I have expressed in this paper :

"The human organism is not isolated in nature, but is a single link of an endless chain, of which a knowledge of the connecting links enlightens us as to each of the series. . . . The genesis of the organism shows us the complex in its simple beginnings, teaches us to understand obscure conditions of association and connection of parts, and gives to anatomy founded upon this basis a scientific form, because it is then erected upon causal relations. . . . Ontogeny and comparative anatomy are therefore the scientific foundations for the anatomy of man. And as human anatomy did not at first rest on these foundations, but was brought into connection with them little by little, and in proportion to their improvement, so we may consider that the science will turn out to have laid exactly this principle, and gradually attain a higher grade of perfection."

It is an old and well-worn saw that there is no royal road to knowledge. Like most old saws, it is only half true. I claim an exception as far as anatomy is concerned; there is a royal road, and it is time we betook ourselves to it instead of following the flinty footpath made by sixteenth-century anatomists.

PRACTICAL HINTS REGARDING THE METHODS OF EXAMINATION EMPLOYED AS AIDS IN THE DIAGNOSIS OF NERVOUS DISEASES.

By A. L. Ranney, M.D.,
Professor of Applied Anatomy in the New York Post-Graduate Medical School and Hospital.

(Continued from page 405.)

Numbness and formication.—In connection with sensory paralysis, a condition of numbness, which the patient describes as feeling as if some special part was "fast asleep," is often experienced. In others a sensation which has been compared to the "creeping of ants" over some special region is complained of. The latter has been termed "formication."

These abnormal sensations are confined exclusively to those parts in which the sensory nerves are more or less impaired. This impairment may result from some lesion of the nerves after their escape from the brain or spinal cord, or from lesions of the nerve-centres which involve their fibres of origin.

By a careful study of the symptoms, a skilled anatomist is often enabled to decide whether the lesion is cerebral, spinal, or confined to special nerve-trunks. This field is too extensive, however, to be considered in detail here.

Hyperaesthesia.—In connection with lesions of the brain and spinal cord, a condition of excessive sensibility is sometimes encountered. It is termed "hyperaesthesia."

It may exist independently of motor or sensory paralysis; or, again, it may coexist with them. Its clinical significance depends upon its seat and extent and the other evidences of disturbed nervous functions which co-exist.

Hemianopia.—A loss of vision in one lateral half of each retina is termed "hemianopia" and "hemianopia." It is called "hemianopia" by some authors; although incorrectly so, as that term means "half-sight," while the two others mean what they are intended to express.

I quote from a late article of mine in regard to this condition, as follows:

"The following steps are commonly employed to detect the existence of the symptoms. Request the patient to close one eye by pressing the lid down with the finger, and to direct the open eye as to concentrate its gaze upon some fixed object near to it. [I usually hold up the forefinger of my own hand within a foot of the patient's open eye, and tell him to look steadily at it.] Having done this, take some object which is easily seen.
(such as a sheet of white paper) in the unemployed hand, and move it to the right and left of the object upon which the patient is gazing, and also above and below the object, asking the patient, in each case, if the two objects are seen simultaneously and with distinctness, and notice upon which side of the fixed object the patient cannot perceive the moving object. It is self-evident that the retina is blind upon the side opposite to that upon which the moving object is lost to sight.

"The most common form of hemianopia is that in which the nasal half of one eye and the temporal half of the other is blind; this condition being the result of pressure upon, or actual destruction of, one of the optic tracts, the pulvinar of the thalamus, the cortex of the occipital lobe, or the fibres that connect it with the optic tract. (This seems to be proven by the late researches of Munk, Wernicke, Starr, and others.) Lesions at the base of the skull frequently produce this variety of hemianopia, if they lie posteriorly to the optic chiasm.

"When the chiasm is affected, we meet the binaural type.

"There is still one more form which is occasionally encountered, viz., the bitemporal type. This has been interpreted by an autopsy made upon a case entrusted to the care of Professor H. Knapp, of this city. It must be evident that the chances would be extremely small of ever having a bilateral lesion which would affect only those fibres of the optic chiasm or optic tract which supply the temporal half of each retina, and at the same time leave the decussating fibres intact. How, then, are we to account for the fact that this form is sometimes met with? In the preceding portion of this article I have called attention to a peculiar arrangement of the arteries in the region of the optic chiasm. Now, it has been shown that atheromatous degeneration of the 'circle of Willis' (a peculiar arrangement of blood-vessels at the base of the brain) so impairs the elasticity of the arteries as to create a type of injury to the chiasm, so limited in its extent as to impair only the fibres distributed to the temporal halves of the retinae, and thus to create bitemporal hemianopia.

"We may, therefore, summarize the clinical significance of this peculiar form of blindness as follows: (a) The homonymous or crossed variety indicates lesions affecting the optic tract or its continuation backward, in order to reach the cortex of the occipital lobe of the same side. (b) The binaural variety indicates a lesion primarily upon the central portions of the chiasmatum. The bilateral variety indicates atheromatous degeneration of the circle of Willis. Possibly (?) symmetrical lesions of the outer part of the chiasm might also cause it."

APHASIA.—An impairment of the idea of language or its expression (independent of paralysis of the tongue) constitutes this condition. It is commonly described as of two varieties—the "amnestic," in which the memory of words is more or less effaced, and the "astatic," in which the memory of words is perfect but the subject cannot properly pronounce them, from an inability to perfectly co-ordinate the sounds involved in articulation.

The symptoms of this malady in either of its forms are always of great clinical interest, because some peculiarity in each case causes it to differ from others which may have been previously encountered.

In the amnestic variety the most familiar objects are commonly misnamed; the subject being oftentimes aware that the error has been committed and yet is not able to correct it. The form which this loss of memory takes is liable to vary with each case. As an illustration of this, some forget only names; others only numbers. In certain reported cases, the names of things only in dead or foreign languages were retained; in others, the reverse had been observed, the patient losing all memory of acquired tongues. Again, the sound of words often will not be recognized when the letters which form them will; and the reverse of this condition is not infrequently met with in aphasic subjects.

We owe to Broca the credit of the discovery that the centre of articulate speech could be located in the posterior portion or base of the third frontal convolution; and many of the later pathological works have thrown what once was the popular view, viz., that this centre is not confined exclusively to the left cerebral hemisphere. Subsequent pathological observation seems to have added strength to the view that lesions of the "island of Reil," as well as the medullary substance which intervenes between it and the centre of Broca, must be included in the so-called "speech-area," and that the amnestic form may be dependent likewise upon lesions of the so-called "sensory area" of the brain seems probable, so that the limits of the speech-centre are not yet defined with accuracy.

The "centre of Broca" is supplied with blood by the middle cerebral artery. An embolus within that vessel will tend, therefore, to arrest the circulation of that important area, and, at the same time, it will interfere more or less with the nutrition of the corpus striatum—the ganglion which probably controls all motor impulses sent out from the brain to the muscles of the opposite side of the body. Now we know clinically that embolism is a frequent cause of aphasia, and that hemiplegia almost always follows a bilateral lesion, it is evident that a left cerebral artery of the left side is the most frequent seat of embolic obstruction. This fact helps us to interpret the development of right hemiplegia in connection with aphasia, as is found to exist in the large proportion of such cases. Seguin found two hundred and forty-three cases in which right hemiplegia existed out of a total of one hundred and sixty—one left hemiplegia being present in but seventeen cases.

In the ataxia variety of aphasia the patient can usually write what cannot be spoken, thus proving that the memory of words is not effaced, but rather the ability to so co-ordinate the muscles of speech as to properly pronounce them. This condition must not be confounded with aphonia (loss of voice). Several cases have been reported where the amnestic form has given place to the ataxic, and the lesion has been found over the centre of Broca. It would seem, therefore, that the third frontal convolution (although placed in close relationship with the oral and lingual centres of Ferrier) has some connection with the memory of words as well as the simple physiological function of the chiasm.

Cases of aphasia should be subjected to a variety of tests which will tend to bring out the special peculiarities of each.

If lesions of the cerebral cortex exist as the exciting cause of the aphasia, convulsions may be associated with its development. If numbness or anesthesia coexist with hemiplegia and aphasia, it indicates that the "motor and sensory tracts" are involved, as well as the centre of speech.

PARALYSIS FROM SPINAL LESIONS.—Certain general axioms must form the basis of our ability to diagnose the existence of spinal lesions and the regions of the cord which are affected by them. They may be expressed as follows:

1. Lesions which involve the "kinesodic system," or motor tracts, may induce paresis or paralysis, spasm, and atrophy of muscles. They never cause anesthesia, numbness, marked and permanent pain, or other sensory phenomena.

2. Lesions of the "esthesodic system," or sensory tracts, cannot induce paresis, paralysis, spasm, or muscular atrophy. They can only create sensory manifestations (such as pain, hyperesthesia, anesthesia, numbness, etc.) and an inability to co-ordinate muscular movements (ataxia).

3. Paralysis and atrophy, when due to spinal causes, occur upon the same side of the body as the spinal lesion, and the same may be said of ataxia.
4. Sensory phenomena are manifested upon the side of the body opposite to the spinal lesion.
5. The so-called "cincture feeling," which may be referred to various parts of the body, can be taken as a valuable guide in deciding as to the probable limits of a focal lesion.
6. Contracture of paralyzed muscles is strongly diagnostic of lesions of the corresponding lateral column of the cord (the so-called "crossed pyramidal column," Fig. 21).
7. Atrophic changes in muscles point toward a lesion of the cord of the corresponding anterior horn of the spinal gray matter.
8. Symptoms indicative of destruction of any of the special physiological centres of the spinal cord are of value in determining the extent of both systematic and focal lesions of the cord.
9. Destructive lesions of certain parts of the brain tend to induce a descending degeneration of the fibres which pass chiefly down the lateral column of the opposite side of the cord.
10. Scratching or stroking the skin over certain regions of the body causes a reflex contraction of special muscles when the cord is healthy. These are the so-called "superficial spinal reflexes." They are of value oftentimes in deciding as to the upper limits of a lesion.

The more important of these superficial reflexes may be enumerated thus: (1) The knee-jerk or patella-reflex; (2) the foot- or ankle-reflex; (3) the peroneal or lateral foot-reflex. These tests are employed, like the preceding ones, to determine the state of the spinal cord when the existence of a lesion is suspected. They may be increased, diminished, or abolished, according to the character of the lesion.

11. The so-called "deep spinal reflexes" are called into action by first putting a muscle in a state of moderate tension, and then exciting it to contraction by some artificial stimulus, as a slight tap or blow for example. Among the more important of these may be mentioned: (1) The knee-jerk or patella-reflex; (2) the foot- or ankle-reflex; (3) the peroneal or lateral foot-reflex. These tests are employed, like the preceding ones, to determine the state of the spinal cord when the existence of a lesion is suspected. They may be increased, diminished, or abolished, according to the character of the lesion.

12. Pain in the region of the spine is a rare symptom of disease of the spinal cord. It is more frequent in disease of the bones or meninges.

In addition to these pathological axioms, certain physiological deductions concerning the spinal cord may be made. Fig. 21 will assist the reader to a clear conception of the columns referred to.

(1) The direct pyramidal and crossed pyramidal columns of each side contain only motor fibres. Those in the former (Türc's columns) are connected with the corresponding cerebral hemisphere; while those of the latter are connected with the opposite cerebral hemisphere.

(2) The posterior column of each side (comprising two portions—that of Goll and Burdach) serves to convey sensory nerve-fibres and also commissural fibres (7) which connect different segments of the cord; hence they are physiologically associated both with sensation and the co-ordination of muscular movement.

(3) The lateral column of each side probably conveys vaso-motor fibres. It has been proven to convey fibres also directly to the cerebellum (the "direct cerebellar column").

(4) The multipolar nerve-cells in the anterior horn of the spinal gray matter possess a "trophic function." When they are destroyed, the nerve-fibres arising from them, and the muscles also which are supplied by those fibres, undergo atrophy.

(5) The fibres of Türc's and the crossed pyramidal column have their "trophic centre" in the motor area of the cerebral cortex. Any lesion which tends to sear these fibres from this centre creates a descending degeneration of all the nerve-fibres so disconnected as far as their ultimate distribution to other segments of the cord below the lesion.

(6) The spinal nerves may be regarded as guides to the various segments of the spinal cord, each segment consisting of a disk of the cord of sufficient thickness to include a separate pair of spinal nerves which are attached to it.

(7) Each spinal segment, with its attached nerves, may be figuratively regarded as a distinct spinal cord for that limited portion of the body to which its nerves are distributed, viz., the muscles to which the anterior roots of the spinal nerves proceed, and the parts supplied with sensation by means of the posterior roots of the same.

(8) The superimposed segments of the cord are bound together by tracts of nerve-fibres. Some of these are continued into the brain, while others are purely commissural in type. We can attribute to the former (the motor and sensory tracts) the conduction of motor impulses from the brain to the various spinal segments, and, again, of impressions of a sensory character from the periphery of the body to the brain itself. The latter (the commissural fibres) serve to assist the different spinal segments in the performance of all acts where a harmonization and simultaneous action of several segments of the spinal cord is demanded.

(9) The two lateral halves of each segment of the spinal cord are not distinct from each other, because a connecting band of the gray substance of the cord (the gray commissure) and also one of the white substance (the white commissure) bind them together. The white commissure lies at the bottom of the anterior median fissure; the gray commissure fills the remaining space between the anterior and posterior median fissures.

(10) The anterior horns of the spinal gray matter contain cells of large size which are connected (1) with motor nerve-fibres joining each spinal segment with the brain, and (2) with fibres of the anterior root of the spinal nerve associated with the muscles controlled by each segment. Thus these nerve-cells are interposed between the fibres of the cord and those of the muscles; an arrangement which permits of an automatic action of the cord, irrespective of cerebral influences.

The cells of the anterior horns appear to control the nutrition of the muscles connected with them by means of the nerve-fibres.

(11) The cells of the posterior horns of the spinal gray matter are probably connected more or less intimately with the fibres of the posterior or sensory roots of each spinal segment, and also with the paths of sensory conduction to the brain. They do not exert any influence upon the nutrition of the parts associated with them by means of the spinal nerve-fibres.
The spinal reflexes are probably performed by means of an anastomosis of the processes of the cells of the anterior and posterior horns of each lateral half of a spinal segment. This enables a sensory impression, which is conveyed to the spinal segment by means of the fibres of the posterior root of the spinal nerve, to become transformed into motor impulses by means of the cells of the anterior horn. These are then transmitted to the muscles by the fibres of the anterior root of the spinal nerve. These reflexes will be considered in detail later.

All focal lesions of the spinal cord are liable to present combinations of both motor and sensory phenomena, and it is this peculiarity which distinguishes them during life from the so-called "systematic lesions."

The height of focal lesions of the cord and their extent in a transverse direction may be ascertained with some accuracy during life by a knowledge of the distribution of the spinal nerves, the point where each is given off from the cord, and the functions of the different columns of the cord itself. Such cases are of special interest to the anatomist.

If the motor tracts of the cord are involved by the lesion, all the nerves which spring from the cord below the lesion will give evidence of paralysis; should the lesion be unilateral, only the motor nerves of the corresponding side below the lesion will be affected, but if bilateral, those of both sides will be paralyzed.

The symptoms of incoördination of muscular movements are developed on the same side as the lesion of the cord; hence, when the lesion is bilateral both sides of the body will be affected in exact proportion to the amount of damage done to the columns of Burdach.

Sensory phenomena are produced on the side opposite to the spinal lesion, because the sensory fibres decussate before passing upward to the brain. Should a lateral lesion of the cord involve all of the corresponding lateral and posterior columns, motor paralysis and incoördination would exist on the corresponding side of the body below the seat of the destructive process, and all sensory manifestations would be confined to the opposite side of the body. There are rare exceptions to this rule, which are clinically observed, where the motor and sensory phenomena are upon the same side of the body; these are probably to be explained in one of two ways—either that the spinal nerve-roots are involved by the lesion, or that the ascending fibres are impaired before the decussation occurs in the cord, because we know that the crossing is not always immediate.

In focal lesions, as well as the systematic, the signs of atrophy in the muscles of the limbs points to a destructive process in the ganglion-cells of the anterior horns of the spinal gray matter.

Rigidity and spasm of the muscles, if occurring after paralysis (post-paralytic contracture and spasm), indicate a descending degeneration of the lateral columns, as a rule.

Alterations in the bodily temperature and sweating of the limbs, when they occur as a result of spinal lesions, are to be attributed to a disturbance in the so-called "vaso-motor" centres of the organ.

The nutrition of the bones, joints, and skin is liable to be affected by focal lesions. These are occasionally developed in connection with sclerosis of the posterior columns of the cord.

The sexual functions, and also the physiological acts of defecation and micturition, depend upon the integrity of centres in the lumbar enlargement of the cord. They may be seriously impaired by focal lesions of that region.

(To be continued.)

DANDRUFF: WHAT IT IS, AND HOW TO CURE IT.

By GEORGE T. JACKSON, M.D.,
Clerical Assistant to the Chair of Dermatology, College Physicians and Surgeons, Physicians to the Daily Dispensary (New Dispensary, Etc.),

The term dandruff, or dandriff, has often been very loosely used to designate at least four distinct diseases of the scalp, namely: pityriasis simplex, seborrhoea sicca, eczema erythematous, or squamoum, and psoriasis, and it is probable that a fifth disease has been included under it, namely, a diffuse trichophytosis capitis. Properly speaking, its use should be limited to that scaly condition of the head which is due to seborrhoea sicca or pityriasis simplex.

Whether these latter two diseases are identical or not is still an unsettled question. By the majority of the German systematic writers they are regarded as one and the same disease, but they present enough points of difference to entitle them to separate consideration. I have here placed them together for convenience, as they give rise to a somewhat similar condition of the scalp and are amenable to the same treatment. To draw the line sharply between the two is sometimes exceedingly difficult.

Seborrhoea sicca is a functional disease of the sebaceous glands in which an abnormal amount of sebaceous matter of abnormal consistency is secreted by them. This dries upon the scalp and either appears in the form of thin, fatty plates about the outlines of the face and adheres to the hairs in flakes, or, if of more pronounced nature, heaps up into thick, fatty masses or cakes which cling with a good deal of tenacity to the scalp. This latter form is seen very frequently in children during the early months of infancy. If portions of these crusts or cakes are rubbed between the thumb and finger they will impart an uncouth odour to the skin. The disease is usually pale or leaden-hued, and when the crusts are removed shows no tendency to moisture, or else exhibits a fatty, glistening surface upon which the crust is soon renewed. In some cases more activity is shown and the scalp is hyperemic. The affection runs a chronic course, is generally quite uniformly distributed over the whole head, but in some cases it is confined for the most part to the edge of the hair over the forehead and to the vertex of the head. Some pruritus at times is present, and sometimes, in consequence of scratching, there will be excoriations. When we have the head covered with thick, fatty crusts which give an unctuous feeling when rubbed between the thumb and finger, and upon being removed leave the scalp pale, there will not be any difficulty about the diagnosis. But in those cases in which only a few dry scales are present and the scalp is slightly hyperemic, our decision as to the disease cannot be so readily given.

Pityriasis simplex, or capillitis, is essentially an interference with the cornification of the upper cell-layers of the skin, on account of which, instead of the normally compact stratum corneum we have a constant shaling off of the imperfectly formed epithelial scales. The whole scalp may be quite uniformly affected, or the disease may be limited to the vertex, or it may occur in circumscribed patches. The scales are thin, easily detached from the scalp, sometimes so easily as to be readily blown off, and they do not pile up into crusts. When rubbed between the thumb and finger these scales do not impart the unctuous feeling as do those of seborrhoea sicca, though
there is usually a certain amount of sebaceous matter present, as in seborrhoea sicca there is always an admixture of epithelial scales. More or less hyperemia is usually present, though in some cases the scalp is of normal color. There is never any moisture of the scalp. Pityriasis often annoys the patient, especially when he is overheated or is using his brain actively, and this inviting scratching, excoriations are often met with.

These two diseases, differing mainly in their essential lesion and constituting dandruff, cause annoyance by the constant falling of the scales upon the shoulders of the patient, ruining the clothing or giving it the appearance of being powdered, and by the pruritus which attends them. It is for these reasons, in most cases, that the patients apply to us for relief. But dandruff is in many cases the forerunner of baldness, and the fact that a long-continued seborrhoea sicca, or pityriasis, is the most frequent cause of premature alopecia should stimulate us to use our best efforts to cure the disease.

Causes.—Dandruff frequently occurs in strumous individuals who are anemic and have a sluggish circulation marked by cold hands and feet. Adolescence is its peculiar time of appearance, and chlorotic young girls are apt to be annoyed by it. It is an attendant upon chronic debilitating diseases, as rheumatism, syphilis, phthisis, and those of anemical constitution, such as fevers and parturition. Dysepsia and constipation are very common exciting causes or aggravants of the disease. Improper care of the scalp, such as the fine-toothed comb, and of pomades, hair "tonics," and hair dyes will give rise to the disorder. In some cases there is apparently no cause for the disease, but careful inspection in such cases will usually bring out some latent cause, such as worry, overwork, mental or nervous strain, and the like. Malassez, Thin, and some others claim to have found a parasite as the origin of the trouble, and recent experiments by Lassar and Bishop would seem to prove that the disease, at least pityriasis simplex, is contagious. These investigators (Lassar and Bishop) took the hair and scales from the head of a healthy German medical student, made a pomade by chopping them up and mixing them with vaseline, and rubbed it into the back of a guinea-pig and of a rabbit. In the course of three weeks these animals presented an appearance similar to that of the student. The experiment was twice repeated, using the hair and scales from the head of another pair of animals respectively, and with like result.

Diagnosis.—Before we can intelligently treat a case of scurifness of the scalp we must arrive at a correct diagnosis, and must differentiate between dandruff and eczema, psoriasis, and diffuse trichophytosis, capitis on the other.

Eczema is distinguished by the scales not being so abundant nor so greasy as in dandruff; by their being more parchment-like, as if formed rather of dry sand than inspissated fat; by the disease not being so diffuse but more limited to certain patches, or to one side of the head, and implicating contiguous non-hairy parts; by the absence of a scurf of the scalp; by the moisture which is either present or readily inducible; and by the disease being far more pruriginous, and by its history. If thick crusts are present they will usually be of a greenish-yellow color, and when removed will expose a reddened oozing surface.

Psoriasis rarely occurs upon the scalp without being found on other parts of the body. It occurs in the form of circumscribed round, or oval reddish, itching patches, which if of large size are seen to be composed of a number of smaller round patches which have joined together at their edges. These patches are covered with a thick mass of grayish or white glistening scales which are not greasy, and on being removed expose a number of new papules which are covered with scales and is as quickly as those of seborrhoea. The disease tends to form a fringe under the hair on the forehead, and some times to push its white, glistening, scalv surface down upon the forehead, and often presents a patch just in front of the ear.

Trichophytosis capitis (tinea tonsurans), when occurring as a "ring-worm," should offer no difficulty in diagnosis. The circular shape and the presence of broken and gnawed-off hairs being pathognomonic. The diffuse form is rare, and is to be diagnosed by its history of gradual spread from numerous reddish points or papules, by its scales not being greasy, by the hair being broken off and fragile, and by the microscopical examination of the hair and scales, which will reveal the trichophytosis fungus in abundance.

Besides these three diseases lupus erythematosus may sometimes call for differentiation. It is rarely met with upon the scalp, and then occurs in the form of a sharply defined patch with an infiltrated reddened base covered by a thin adherent scale, which being raised shows on its under side a number of prolongations, the sebnum plugs withdrawn from the follicles. The disease causes loss of hair and well-marked atrophic changes in the scalp.

Treatment.—A good deal in the way of preventive treatment of dandruff can be accomplished by the proper care of the scalp and of the general health. More care than usual should be bestowed upon the operations of brushing and combing, washing the scalp, and upon the selection of the brush and comb. The brush should be composed of bristles well set into the back. The bristles should be placed in little clumps at regular distances and rather far apart, and those in each clump should be of unequal length and arranged so that the longest ones are in the centre of the group. It is well to have two brushes, one stiff enough to comb the scalp when used with vigor, and one quite soft. The comb should be made with large teeth set wide apart. When held up to the light the teeth should show no roughness or inequality of surface. The fine-toothed comb should be banished from the toilet-table, as it is an active agent in producing inflammatory conditions of the scalp, as many a case of eczema capitis in children will testify. In the morning the hair should be thoroughly opened up in all directions with the comb, and it and the scalp brushed vigorously with the stiff brush. Then the stiff brush should be laid away for the day, and the soft one used in parting the hair, in polishing it, and in subsequent brushings during the day.

Water renders the hair dry, and the daily soaping only washes the head superficially. A good shampoo is every week or ten days for those persons exposed to a good deal of dust, and every two or three weeks for other people, is sufficient for cleanliness. For the shampoo, soap and water, borax and water, or one composed of the yolk of an egg beaten up in lime-water, are all simple and good, but it must not be forgotten to wash out these materials with plenty of clean water and to thoroughly dry the hair and scalp.

Patent hair "tonics," pomades, washes, and dyes are to be avoided. Those containing grease—the pomades—are, to use an Anglicism, "nasty," give the hair an unnatural lustre, smear the hat-band and whatever the hair touches, and becoming rancid act as local irritants. One of these disadvantages is remedied by the healthy scalp, and the proper care of the scalp as above indicated will preserve the hair in better condition than they will.

The nearer the body can be kept to the standard of perfect health by means of bathing, exercise, and good diet, the less likely is dandruff to develop. When, therefore, the disease has appeared, and we are forced to relieve some of our first inquiries should be concerning the general health, and our first efforts addressed to
remedying anything found to be wrong. For important as our local measures are in relieving the local disorder, in most cases we must depend upon internal treatment to render the cure permanent. The internal treatment must be along the lines marked out in works upon general medicine—tonics, as cod-liver oil and iron, for the debilitated; the acids and bitters for the neurotic and dyspeptic; mercurials, podophyllin, and the like for the bilious, etc. Duhring recommends sulphur and the sulphide of calcium as of especial efficacy, and arsenic sometimes acts well. We should insist upon our patient obeying the laws of general hygiene, and instruct him in the above or similar rules as to the proper care of the scalp.

Various substances, all of a more or less irritating nature, have been recommended for the local treatment of dandruff. Such are tincture of campharades, 3 j. — 5 j.; tincture of capsiicum, 3 j. — 5 j.; tincture of nucis vomicae, 3 j. — 5 j.; chloral, 3 j. — 5 j.; bichloride of mercury, gr. ij. to ii. — 3 j.; the olate and other mercurials in proportionate strength; sulphur, 3 j. — 5 j.; carbolic acid, gr. x. to xx. — 3 j.; quinia, strychnia, etc. These have been given either in solution in alcohol, water, or the oils of olive, castor, rosemary, sage, etc.; or as ointments. A good menstrum for their exhibition is composed of glycerine and absolute alcohol. This is the best medium for their exhibition as ointments. Excepting where the hair is decidedly thin, so stiff an ointment as the ung. zinclipoxid. should not be used, and lard itself is apt to become rancid.

Of all the above remedies, I have been led by experience to place my main reliance upon sulphur and the mercurials. I should advise the following plan of local treatment. If the case presents itself with a decided accumulation of scales, or if crusts are present, direct the patient to saturate his head with oil, preferably sweet almond oil, before going to bed, and to place over his head a flannel cloth soaked in the oil, and outside of all an oiled silk cap. The next morning he should shampoo his head thoroughly with soap and water, using by preference the tincture of green soap, and wash out the soap with plenty of water. The scalp is then to be dried by vigorous rubbing with a coarse towel, and the hair by pulling it through a soft towel. If the crusts by this method are not completely removed, the oil should be kept on during the day, the head again soaked at night and washed with the soap and water, and the scalp should appear very hyperemic after the crusts are removed, anoint the head with vaseline or some simple ointment, as rose ointment, until the hyperemia is lessened. When the crusts are removed and the hyperemia overcome, have an ointment composed of one drachm of sulphur loti to one ounce of vaseline applied every morning to the scalp. If the scales form rapidly, apply the oil every night and the sulphur ointment every morning, and wash the head every second or third day. As soon as scaling is lessened stop the use of the oil, but continue the ointment, at first using it every second morning, then gradually reducing its application to once a week. About this plan of treatment the head should be shampooed about once a week with the tincture of green soap, borax and water, or the yolks of three eggs beaten up in one pint of lime-water, to which a half ounce of alcohol is added. Another excellent ointment for these cases, for the formula of which I am indebted to Prof. Bronson, of the New York Polyclinic, is composed as follows:

| B. | Hydrarg. ammon. .............. gr. xx. |
| B. | Petrolatum. ............ 5 j. |

This applied once or twice a day has yielded most admirable results in a number of cases of simple dandruff. Its consistence being that of a Mayonaise dressing renders it an elegant pomade for private practice.

Its use should be combined with the occasional shampoo as directed above.

The persistent and systematic use of either of these two plans of treatment, together with a proper oversight over the general health, should cure every case of dandruff. But we should be prepared for occasional relapses, and not give our patients promise of too speedy a cure.

AN OBSTINATE CASE OF OVARIAN DYSMENORRHOEA.

Oophorectomy, with Remarks on the Utility of the Operation.

By E. M. Hermance, M.D.,

Poughkeepsie, N. Y.

Miss Matilda B——, a virgin, twenty-three years of age, born in the United States, was ordinarily a healthy child. At the age of twelve began to menstruate, and did so normally to the best of her recollection for about a year, when she began to have dysmenorrhea. About this time her father was taken suddenly ill and she was sent for a physician, a distance of something over a mile. She ran rapidly back to the house and was going up the doctor's steps when she was seized with a severe pain in the left side and felt, as she describes it, something give way in her side. The pain was in her left liac region. This pain has continued ever since, i.e., for the past ten years. She was menstruating at that time and had been flowing for about a week, and continued so for about a week longer. This was her first attack of dysmenorrhea, and from that time forth every catamenial period was attended with intense pain.

Her suffering finally became so great that about two years after this time she applied to a physician for treatment; since then she has never ceased to be under a physician's care. On June 21, 1880, she applied to me for treatment, and I have continued to treat her ever since. At that time the case presented to me the following symptoms: Dysmenorrhea, leucorrhoea, dysuria, anorexia, anaemia, well-marked dyspepsia, reflex paroxysmal cough, facial and pelvic neuralgia, pain in the back, and the pain in the left side already referred to. These were the symptoms, and they naturally suggested to me the possibility of some ovarian disease, but the patient was a virgin, at that time twenty years of age, and very adverse to a uterine examination. I concluded to observe her carefully and try the effect of constitutional treatment. Accordingly I put her upon a course of chalybeate treatment with vaginal injections. This plan continued faithfully for three months. In the meantime, having observed her menstruate three times, and feeling thoroughly confirmed in my first impression that there was local difficulty, I insisted upon a uterine examination, and after stating to her parents my reasons for desiring such an examination, they finally consented, and in the month of September, 1880, Dr. F. E. Beckwith and myself made a successful examination of the patient. We discovered a stenosis of the internal os uteri. It was with the greatest difficulty that we could pass the smallest uterine probe; furthermore a slight retroflexion and a chronic cervical endometritis existed. This with the symptoms before enumerated completed the history of the case up to that time.

The doctor advised local treatment; and from that time I twice a week made local applications of iodine, nitrate of silver, etc., to the cervical canal, at the same time continuing my constitutional treatment. This I continued for some months and then had the patient wear a pessary for the retroflexion. In spite of this she did not improve any, and the dysmenorrhea was increasing in severity, so that the patient passed a most miserable existence. This state of affairs continued for about a year, when thinking that the dysmenorrhoea might be obstructive in character and depend upon the stenosis of...
the internal os, I asked Dr. Benedict to see the case with me. This he did in October, 1881, and we decided to perform hysterotomy. We accordingly did so (the operation was followed by more than not foreign body in the cervix) by means of a false ring and then placed a glass plug in the cervix. I did not, however, feel satisfied with this operation, and on December 9, 1881, Dr. W. M. Chamberlain saw the patient with me and agreed that it was certainly indicated that the stenosis should, if possible, be overcome. At my request he performed hysterotomy, and afterward thoroughly dilated the cervical canal and placed a glass plug in the cervix. This I kept in situ fourteen days, during which time the patient suffered intense pain, and required very large doses of morphone to all relieve her. This operation, like the first, was very unsatisfactory, as a subsequent examination revealed a considerable and marked contraction, so on April 27, 1882, Dr. Chamberlain again saw the patient with me and made a wholesale section of the cervix. We again placed a glass plug in the opening, and to make assurance doubly sure, kept it there for over a month. The operation was a perfect success, and as a result we had a patulous cervical canal, and were now able to positively state that if the dysmenorrhea continued it was not due to the stenosis of the internal os, but to other causes. It did continue and grew steadily worse. I then stopped all local treatment and operative procedures, and gave up the treatment of the uterus and proceeded to try the effect of anti-spasmodics. I administered tr. pulsatilla, cannabis indica, hyoscyamus,aconitia, nux vomica, belladonna, croton chloric cinnifuga, and the whole list of medicines that had been used for neuralgia. I also employed rectal suppositories of belladonna, opium, iodoform, etc., but all to no purpose. The patient continued to grow worse, and at this time was in a pittiable condition, pale, emaciated, anemic, in bed two or three weeks out of four; a victim to the morphone habit, and made so by myself; her condition cannot be described. Her sufferings were at times so intense that she would, as she often told me, rather die than live.

I had exhausted all the resources of art. I told her positively that I believed there was but one hope for her, and that was offered in the derrier researt of ophorectomy. I had thought the matter over and made up my mind that she could not long live as she was, and she was better off without her ovaries and free from pain than with her ovaries, suffering as she did.

November 7, 1883, she went to the Women's Hospital and was assigned to Dr. Thomas for treatment. He examined her on November 21st, and at his request I was present at the examination. After examining her a second time, I was then convinced that the operation of ophorectomy must be performed. She was transferred to a cottage, and on December 1, 1883, assisted by Dr. Wood, Dr. Thomas performed the operation. The patient had a pretty severe time. Large doses of morphone had to be administered, and at one time the temperature ran so high that it became necessary to use the cool pack. She, however, did well, and one week from the day of operation—

December 7th.—Temperature, evening, 101°.
December 8th.—Temperature, morning, 100°; evening, 100°.
December 9th.—Temperature, morning, 99°; evening, 100°.
December 10th.—Temperature, morning, 99°; evening, 99°.
December 11th.—Temperature, morning, 99°.

So you see she made a good recovery, and returned to Yonkers December 30, 1883, at which time I again resumed charge of the case. Three days after her operation she flowed considerably, so that they were obliged to administer remedies to check it. On the 9th, her regular time for menstruating, she had a show for about an hour; it then ceased. Again about February 9th she had a similar show, but since then she has not seen anything. Three months and a half after the operation she is moderately comfortable. It is true she has some pain, but she does not have those paroxysms of internal suffering. She has, as formerly, prolapus uteri, due to weakness and anemia, but I believe the result of the operation will prove satisfactory.

Now, it may be asked, was this operation justifiable? I have claimed that it was, and if you deny my conclusion you assert what seems to me to be an absurd proposition, namely, that her trouble and agonizing suffering, which must certainly have ended in a miserable death, was preferable to health and a continued existence, which without her ovaries might prove enjoyable.

It may not now be amiss to make a few remarks upon the operation. The object of the operation, as stated by Dr. Battey, who first performed it, is the production of the menopause by art. Dr. Battey, in a paper read before the International Medical Congress in 1883, says that the operation appears first to have been contemplated as early as 1823 by James Blundell, of London, and he himself, in October, 1865, first conceived the idea of artificially producing the menopause. On July 27, 1872, Hagar did the operation, and on August 1st Lawson Tait performed it at Birmingham.

The indication for performing it is summed up in the following: Osphorectomy to determine the change of life, and the change of life for any gross disease which is incurable without it, and which is curable with it," or, in other words, when a case presents itself ask these three questions: "Is this a gross case? Is it incurable by any of the resources of art short of the change of life? Is it incurable by the change of life?"

Dr. Battey goes on to say that the operation in its very essence opens a door for widespread abuse. Much as we must deprecate the still-existing prejudice which would offer a lifetime of untold misery, and even life itself as a holocaust upon the altar of some supposed sanctity in female sexual organs, we cannot forget that the medical profession is a degree the guardian of public morals, and is bound to maintain decency and self-respect; this operation, therefore, cannot in any case be received as an alternative for other means of cure, but must be held, as it was originally offered, as a 'dernier ressort.'"

"Proximate result of the operation: First, mortality. In the cases collected the death rate has been twenty-two per cent. for the complete operation, and nine and one-half per cent. for the incomplete.

Second, menopause. It is a well-known fact in exceptional cases the menses have reappeared. In Battey's cases, when even small fragments of the ovaries were left, the menses invariably continued, and in one instance a child even was born to the patient after the operation. "Female graces unimpaired, with often a positive gain. It is unfair and premature to set down any case as a failure until ample time has been allowed for the cyclical change to have become complete in its entirety."

The difference between Battey's and Tait's operations is that Battey removes the brains and Tait the brains and Fallopian tubes.

In speaking of this Lawson Tait says, "The most important point of all in the performance of this operation is the complete removal of the Fallopian tubes as well as of the ovaries."

Another Surgical Folly. — The local use of nitrate of silver for the intended destruction of a virus, or for the disintegration and removal of fungous or malignant tissue, is founded on error. Nitrate of silver, though popularly called "caustic," is not a caustic; it is a mere irritant, scarcely more active than the tincture of iodine. The caustics to be used by surgeons for the purposes mentioned are chromic, nitric, carbolic and acetic acids, potassa and similar active drugs, and the hot iron. Under many circumstances the best caustic is a sharp scalpel. — The Polyclinic.
Progress of Medical Science.

OCULO-CEREBRAL VERTIGO.—The following peculiar case is related by Dr. Cuignet, in the *Receuil d'Ophtalmologie*, vol. iv., No. 9, as occurring in the person of a lady of otherwise good health, thirty-four years of age. A dark veil seems to rise from the lower portion of the visual field of the right eye, and covers it completely in from thirty to sixty seconds. Then it appears in the upper part of the right eye and slowly descends, never, however, covering entirely the field of vision on this side. At the end of one or two minutes the sight slowly returns in the order in which it was obscured, the lower part of the field of vision of the left eye receiving the first impressions of light, and then, when this eye is clear, the veil falls slowly from the right eye. From the commencement of this obscuration the patient experiences a sensation as if she would fall unless supported. At the same time consciousness is almost lost. There are no sequelae to these attacks, but once they have passed the patient feels perfectly well and suffers no pain or disturbance of any kind. Dr. Cuignet was unable, after the most thorough examination of the patient herself and of her antecedents, to discover any cause to which these attacks could be attributed, and he was therefore driven to regard them as an idiopathic nervous affection. They recurred at irregular intervals from several times a day to as infrequently as two months apart. The patient had been subject to them for about six months.

WASHING OUT THE STOMACH IN INFANTS.—In the *Prager Medizinische Wochenschrift*, Dr. Epstein claims to have seen good results from washing out the stomach of nursing infants for various intestinal disorders. He uses for this purpose flexible catheters (Nélaton) of various sizes. By means of a small piece of glass tubing, the catheter is connected with a piece of rubber tubing of suitable length. Its introduction into the stomach of children, even if only a few days old, is said to be easy of accomplishment as into that of adults. Only ordinary precautions are necessary in performing this act, the tube being propelled by involuntary efforts of deglutition. Contractions of the stomach result from the irritation caused by the presence of the tube, and evacuation of its contents and irritation follow. Epstein uses thirty to fifty grammes of lukewarm distilled water to accomplish the washing, and to the water may be added a little bichloride of magnesium, or hydrochloric acid. The liquid is slowly poured down the tube through a funnel, which is raised (with the end of the tube) to a sufficient height, care being taken to prevent the introduction of air. If the infant should cry during the process, the latter must be suspended for the time. It may be necessary to repeat the washing—perhaps three times—before the liquid is returned without discoloration. With ordinary care, perforation of the walls of the stomach is not possible; there may, however, be slight capillary hemorrhages excited by the efforts at vomiting. There is also no danger that a tube of the given length will pass the pylorus and empty its contents into the intestine. In the case of an infant with diseased lungs or heart, the washing is contra-indicated. The indications for the procedure are cataract of the stomach, added to a similar condition of the mouth and intestines, fermentation and indigestion, with the peculiar products attending these conditions. At the commencement of infantile cholera it has also proved useful, and it should be continued as long as the child shows a disposition to vomit.

VARIATION AND DISAPPEARANCE OF CARDIAC MURMURS.—Grügg (Liverpool Medical Chirurgical Journal) writes concerning the variation and changes so often observed in certain cardiac murmurs, dependent on definite organic lesions. He relates the histories of several cases, from a study of which he draws the following conclusions: (1) Although murmurs are among the most constant of the physical signs of heart disease, still their presence does not necessarily indicate the existence of a curable disease, nor their absence that such lesions are not present. In forming a correct diagnosis and prognosis of any case, therefore, too much reliance must not be placed upon the presence or absence of murmurs, but other symptoms must receive careful consideration, for often on them alone is it possible to form a correct diagnosis. (2) The presystolic murmur of mitral stenosis, the most frequent of all murmurs, almost invariably disappears, the lesion still remaining. Mitral regurgitant murmurs, when due to simple relaxation of the heart's muscle and dilatation of its cavities and orifices, as in chlorosis and general febrile conditions, in most cases completely disappear under appropriate treatment. (3) Tricuspid regurgitation is occasionally a temporary condition, due to bronchitis, etc., and when the cause is removed this condition is recovered from, as is indicated by the disappearance of the murmurs. (4) Aortic systolic murmurs, due to a permanent lesion at the aortic orifice, may undergo changes in their intensity, but never completely disappear. (5) Aortic diastolic murmurs in certain extremely rare cases have been known to disappear; these cases a systolic aortic bruit is always present and remains persistent, thus indicating the existence of a lesion. (6) Pulmonary systolic murmurs are persistent when due to an organic lesion, but if non-organic, may disappear temporarily or permanently.

RECENT REMEDIES FOR GONORRHEA.—From a number of trials with remedies recently suggested in the treatment of gonorrhea Dr. Keyses (Journal Cut. and Vener. Diseases, March, 1884) concludes as follows: 1. A mild bichloride of mercury taken internally irritates the mucous membrane of the urethra more than it seems to irritate an open wound. 2. It appears that an abortive treatment of true gonorrhea is yet to be discovered. 3. The hot-water treatment of gonorrhea is unreliable.

POISONING FROM MURIATIC ACID.—A fatal case of poisoning from hydrochloric acid is reported by Dr. White in The Lancet, January 12, 1884. The patient, aged fifty-four years, recently discharged from a lunatic asylum, when brought to the hospital stated that he had swallowed two tablespoonfuls of strong acid three hours previously. On admission he was considerably collapsed; the skin was cold and clammy; the countenance anxious; the pulse small, weak, and frequent. He had vomited several times; the vomited matter was dark in color, viscous, contained blood, gave a strongly acid reaction with litmus, and a very copious white precipitate with a solution of nitrate of silver. On examining the mouth the mucous membrane was of a whitish color, with here and there a red patch, showing where the epithelium had been removed. He complained of a burning sensation in the mouth, throat, and stomach; and pressure over the latter viscous caused pain. He did not complain of thirst, even when interrogated. There was no diarrhea or tenesmus. Solution of potash, freely diluted, was administered, and afterward lime-water and milk. Hot fomentations, sprinkled with laudanum, were applied over the stomach, and hot-water bottles to the feet. He passed a restless night, vomiting almost incessantly; got weaker next morning, and died collapsed seventeen hours after swallowing the acid. An examination of the body was made thirty-two hours after death. The mucous membrane of the oesophagus was highly congested in its upper half; the lower half was black in color, thickened and contracted; the veins stood out prominently, being filled with black blood. Just before its passage through the diaphragm there was a perforation in the left lung, which wall was formed of fibrous and muscle tissues around the opening being black and pulpy, and infiltrated with granular material. The mucous membrane of the stomach and the first five inches of the
duodenum presented an appearance similar to that found in the lower half of the oesophagus. There was a perforation of the size of a florin in the stomach near its pyloric end, and a smaller one in the first inch of the duodenum. The contents of the stomach were found in the abdominal cavity, and the anterior edge of the liver was corroded by the acid. The peritoneal surface of the intestines was injected, and in some places covered with a thin layer of recent lymph. The action of the acid on the mucous membrane ceased about the middle of the duodenum; lower down the lining of the bowel was natural. The larynx and trachea were congested, the upper surface indicating that it is so improved by this treatment as to approximate the lower degrees observed in health. The main reason for this difference in the febrile organism with and without exposure to controlling influences, lies no doubt in the actual reduction of the temperature of the blood—pyrexia implying increased tissue-metabolism, while degeneration increases.

The phenomena of fever are linked together in an inscrutable way, some of them as causes, others as consequences, of the essential fact—the heightened temperature. Seek what explanation we may, it cannot be denied that the reduction of the excessive body heat is of good effect; and, as Sassetzky's research clearly points out, this reduction shown in the elimination of nitrogen and carbonic acid, and, as the demand for oxygen is lessened, the respiratory action falls, the action of the heart is improved, and the liability to circulatory disturbance in consequence of cardiac failure is mitigated, whilst the abeyance of the effects of the febrile process on the secreting organs permit of a more natural performance of their functions and a more ready assimilation of nutrition.

Excessive Production of Saliva due to Irritation of the Throat.—Dr. J. M. W. Kitchen, of New York, writes: "The following case is unique in my own experience, and I have not seen a similar one described in my reading. Miss M——, aged thirty, making a short visit to New York, consulted me in regard to trouble with her throat, which had existed for some four years. She particularly complained of the presence of excessive secretion collecting in her throat, especially at night. The annoyance was sufficient to frequently awaken her from sleep. She had the peculiar cough that is used to clear the lower pharynx of secretion. Whenever she came to New York her trouble increased, and also whenever she was 'caught cold.' It is impossible to show the number of cases from Stenon's duct, as the number of cases of malarial fever has notably diminished. This is, at least, the common impression, though it rests on no more satisfactory basis than the statement of physicians in practice in Rome, and on the smaller returns of quinine, given gratuitously by the municipality, or sold at the pharmacies. Malarial fever was not included in the list of diseases whose compulsory notification at the Capitol is supposed to be enforced on the medical men of the city. The real number of cases, therefore, occurring annually, cannot be known. The mortality returns contain the prevailing idea to a certain extent, as in 1882, all forms of malarial fever—pernicious, subacute, and remittent—caused 298 deaths; and this year, up to the end of October, 320; both figures being less than the average for a long series of years, if we bear the increase of population in mind. Still there would seem to be plenty of material to work on; but the pathologists hint that the causes of death, thus entered in the municipal returns, are not to be relied on. The malaria is the result of the physicians as well as the physicans and visitors to Rome; and hence it is believed that many deaths are attributed to it as an easy way out of a difficulty in diagnosis. This is the explanation very commonly advanced, at least, for the occurrence of such difficulties in the winter months, when deaths from acute malarial infection within the city are held to be almost unknown. Probably this is true of the well-to-do classes; and experience of practice among visitors confirms such a view, as no death from pernicious ague among these, during the season, has been registered for many years.

The Value of Hydrotherapy as an Antipyretic. —The study of fever has always occupied a large share of professional attention, and yet it will hardly be claimed that our knowledge of the febrile process is in any sense a complete and satisfactory one. Dr. Sassetzky (London Lancer, 1884) is one of the most prominent of the object. His attention was directed mainly to the intimate tissue-changes which occur in pyrexia. He also tested the effect of anti-febrile treatment on the assimilative processes. He found that invariably the cold bath diminished the elimination of nitrogen, and that a similar but far less marked diminution occurred in the cases treated by quinine and salicylate. The quantity of urine was increased by each method, but to the largest extent by the bath. The assimilation of the solids and nitrogenous constituents of milk was improved under the bath treatment, as shown by the very marked diminution in the fecal elimination of nitrogen; and the same fact was also noticed, to a less degree, by the other methods.

The main point is that it is so improved by this treatment as to approximate the lower degrees observed in health. The main reason for this difference in the febrile organism with and without exposure to controlling influences, lies no doubt in the actual reduction of the temperature of the blood—pyrexia implying increased tissue-metabolism, while degeneration increases.

The phenomena of fever are linked together in an inscrutable way, some of them as causes, others as consequences, of the essential fact—the heightened temperature. Seek what explanation we may, it cannot be denied that the reduction of the excessive body heat is of good effect; and, as Sassetzky's research clearly points out, this reduction shown in the elimination of nitrogen and carbonic acid, and, as the demand for oxygen is lessened, the respiratory action falls, the action of the heart is improved, and the liability to circulatory disturbance in consequence of cardiac failure is mitigated, whilst the abeyance of the effects of the febrile process on the secreting organs permit of a more natural performance of their functions and a more ready assimilation of nutrition.
NATIONAL HEALTH LEGISLATION.

The Committee on Public Health of the House of Representatives have been very much occupied recently with discussions of subjects relating to the National Public Health Service. Judging by the number of printed pamphlets now before us, containing the remarks of those who appeared before the committee, the discussion took a wide range and developed a degree of interest in public health legislation by Congress quite surprising, and yet very gratifying. By these publications we are placed in a position to estimate very accurately the present condition of the national sanitary service, and the value and importance of the proposed changes in the laws relating thereto.

We will first notice a bill entitled, "A Bill to Protect the Public Health," now before the Public Health Committee. The purpose of this bill is to abolish the present National Board of Health, and establish a new board, to be styled "The United States Board of Health." This new board is to be composed of the Surgeon-General of the United States Army, the Surgeon-General of the United States Navy, and the supervising Surgeon-General of the Marine Hospital Service. The bill provides that "such board shall have full power to make such regulations as may be necessary for the government of the quarantine service of the United States and the protection of the public health; and all the power and authority now provided by law for the control, management, and regulation of the public health of the United States shall be, and the same are hereby, vested in said United States Board of Health." Sections 3 and 4 define special duties as follows:

"Sec. 3. That such sanitary investigations as may from time to time be necessary shall be conducted, under the direction of the said Surgeon-General of the Navy, at the Museum of Hygiene of the Navy Department, and full report thereof made to the said United States Board of Health.

"Sec. 4. That the United States quarantine service shall hereafter be conducted and managed by the said Supervising Surgeon-General of the Marine Hospital Service, acting under the direction of the Secretary of the Treasury."

Let us first consider what kind of an organization this new board is to supplant. The present Board of Health was organized under the following provision of an Act of Congress, approved March 3, 1879, viz.: "That there shall be established a National Board of Health to consist of seven members, to be appointed by the President, by and with the advice and consent of the Senate, not more than one of whom shall be appointed from any one State, . . . and of one medical officer of the Army, one medical officer of the Navy, one medical officer of the Marine Hospital Service, and one officer from the Department of Justice."

The composition of the present Board is therefore eleven members, seven of whom are representatives of as many different sections of the country, and four represent the allied departments of the Government at Washington. The wisdom of this plan of organizing a National Board, for which the country is indebted to one of its ablest sanitary legislators, is apparent. In harmony with our form of government the National Board of Health was made a representative body.

Seven members represent the varied sanitary conditions and interests of seven grand divisions of the United States, and four are to bring to its councils the knowledge and experience of the Army, Navy, Marine Hospital Service, and the Department of Justice. Practically the plan was and is fully realized. The seven original members were so distributed that the New England, the Middle, the Northwestern, the Western, and the Southern States are respectively represented by men of large experience in the administration of health laws. The four members from the Departments at Washington rank among the best officers of their respective services. Though the membership of the Board has changed since the first appointments were made, yet it is assuring to notice that the representative character of the members is maintained. The present Board numbers among its members one President of a State Board of Health; three veterans in municipal sanitation; an eminent sanitary engineer; two life-long workers in yellow fever epidemics; an expert chemist; the chief officer of the Bureau of Hygiene, and the Assistant Attorney-General. It will be seen that the plan of organizing the Board is well adapted to create a deliberative body having a wide and varied knowledge and experience in public health affairs.

Nor is its organization less effective for the prompt performance of executive duties. It has an Executive Committee, composed of four resident members and two non-resident. The resident members, a majority of the committee, are so near the Board rooms that a meeting can be obtained at a few minutes' notice, at which all ordinary business may be promptly transacted. So that, as a deliberative body, the Board combines representation of local sanitary interests by experts, with the special knowledge furnished by the departments, and as an executive body it acts with the intelligence of at least four trained officials, and the promptness of a single head.

In contrasting the plan of organization of the present National Board of Health with the proposed United States Board of Health, we do not hesitate to decide that the former is, in every respect, immeasurably superior to the latter. The fundamental idea of the former, as is seen, is the representation of the great sanitary districts of the country in the National Sanitary Council, while the latter is a revival of the bureaucratic autocracy so dominant in official circles at the national capital.
is a matter of history that during the session of Congress at which the present Board of Health was organized the struggle of one bureau to absorb the service was so great and persistent as to threaten the defeat of all legislation. But, sustained by the almost unanimous sentiment of the sanitaryists of the country, Congress then emphatically rejected all such ambitious and partisan schemes, and laid the present broad foundations on which a national public health service can, by patient labor, be constructed. The issues which this bill raises, are of vital importance, and should receive the most serious consideration, not only of the Committee on Public Health, but of all who are practically interested in building up and maintaining a sound and rational system of public health service in this country. We have advanced to the present degree of organization and completeness of that service by painful and laborious efforts in the field of sanitary legislation, and we should be very careful that no retrograde step is now taken by any ill-conceived and ill-advised measures. We believe that all such narrow, centralizing measures, of which this bill is the outcome, are fraught with great peril to the health organizations of the whole country; for our public health service—municipal, State, and national—is now practically one system, and, therefore, whatever injury is inflicted upon any one part injuriously affects the whole.

HEALTH MATTERS IN CONGRESS.

Referring to an article in these columns (see Medical Record, page 406) on the temper of Congress with reference to a resolution reported back by the Public Health Committee of the House, providing for an investigation into adulterated food, drink, and medicine, and which was recommitted to the committee after an animated debate, it would seem that Congress is better disposed in preventing the import and export of adulterated compounds, than it is to their local control in the States.

The Senate Committee on Foreign Relations reported through Mr. Sherman, with amendments, Senate Bill 1,876, "providing for an inspection of meats for exportation, prohibiting the importation of adulterated food or drink, and authorizing the President to make proclamation in certain cases, and for other purposes."

Section 1 provides "that the Secretary of the Treasury may cause to be made a careful inspection of all salted pork and bacon intended for exportation, with a view to ascertain and determine whether the same is wholesome and sound for human food, and may authorize the proper officer of the customs to give an official certificate, clearly stating the condition in which such pork and bacon is found, and no clearance shall be given to any vessel having on board salted pork or bacon found, on such inspection, to be unsound for human food; but any pork or bacon may be exported to any foreign country without such inspection when it is proven to the satisfaction of the Collector of Customs that the same has been properly salted and packed more than sixty days prior to the date of the application for inspection, or manifest for exportation; and such Collector shall, in that case, certify to the fact that such meat was properly salted and packed more than sixty days before the date of such entry." This section requires three copies of any certificate issued by the Collector or Inspector, one to be filed in the Custom House, one attached to the service of each shipment, and the third to be delivered to the consignor or shipper.

Section 2 provides "that it shall be unlawful to import into the United States any adulterated or unwholesome food, or vinous, spirituous, or malt liquors adulterated or mixed with any poisonous or noxious chemical, drug, or other ingredient injurious to health. Any owner, agent of the owner, consignor, or consignee of the owner, or in privity with them, assisting in such unlawful act, shall be deemed guilty of a misdemeanor, and liable to prosecution therefor in the District Court of the United States for the district into which such property is imported; and on conviction, such person shall be fined in a sum not exceeding one thousand dollars, for each separate shipment, and may be imprisoned by the Court for a term not exceeding one year, or both, at the discretion of the Court."

Section 3 provides that any such imported adulterated articles shall be forfeited to the United States and destroyed, or returned to the importer for exportation from the United States, after the payment of all costs and expenses, and authorizes the Secretary of the Treasury to inspect such imported articles in order to ascertain whether the same have been unlawfully imported.

Section 4 authorizes the President to issue his proclamation, suspending the importation of such adulterated articles from any foreign country where there is good reason to believe such importation is about to be made, for such period of time as he may think necessary to prevent such importation; and during such period it shall be unlawful to import into the United States, from the countries designated in the proclamation of the President, any articles the importation of which is so suspended.

Section 5 authorizes the President, whenever unjust discriminations are made by any foreign State against the importation or sale in such foreign State of any product of the United States, he may direct that such products of any such discriminating foreign State, as he may deem proper, shall be excluded from importation to the United States, and make proclamation to that effect. He may at any time revoke, modify, terminate, or renew any such direction as in his opinion the public interest may require.

The provisions of this section shall expire on the 4th day of March, 1887, and shall no longer be in force.

The amendments reported back by the Committee are comprised in four sections:

Section 6 prohibits the importation of all cattle, sheep, and other ruminants, and swine, which are diseased or infected with any disease, or which shall have been exposed to such infection within sixty days next before their exportation. Anyone knowingly violating this provision shall, on conviction, be punished by a fine not exceeding $5,000, or by imprisonment not exceeding three years; and any vessel or vehicle used in such unlawful importation shall be forfeited to the United States.

Section 7 authorizes the President, at the expense of the owner, to place and retain in quarantine all cattle, sheep, and other ruminants, and all swine, imported into the United States, at such ports as he may designate and under such regulations as he may prescribe, respectively, for the several classes of animals; and for this
purpose he may have and maintain possession of all lands, buildings, animals, tools, fixtures, and appurtenances now in use for quarantine of neat cattle, and hereafter purchase, construct, or rent such as may be necessary, and he may appoint veterinary surgeons, inspectors, officers, and employees to maintain such quarantine and provide for the execution of the other provisions of this act.

Section 8 prohibits all animals described in this act from being imported into any port where there is no quarantine station, and requires the owners to convey them by vessel to such port if brought into any port where no quarantine is established. The Collector of the Port is authorized to cause to be slaughtered all infected animals, or those exposed to infection so as to be dangerous to other animals. It provides for reimbursement to the owner where cattle, exposed to infection but not infected, are slaughtered.

Section 9 provides for careful inspection of all imported animals; provides for disposition of all food, litter, manure, clothing, utensils, and other appliances that have been related to infected animals on board ship, so as to be judged liable to convey infection. Also provides for the disinfection of all vessels engaged in the exportation of animals, and of all barges or other vessels used in the conveying of such animals intended for exportation to ocean steamer or other vessel, and of all attendants and their clothing, etc.; the expense of all inspection to be borne by the owner of the vessel on which such animals are exported.

THE ANTI-VIVISECTION DISCUSSIONS.

The medical profession of Philadelphia has been much agitated over the subject of vivisection. The American Anti-Vivisection Society has been at work there and, strange to say, has received support in its object from a few medical men, and also, we regret still more to say, from two of the medical journals. Original work in experimental science is just beginning in America; and it is very unfortunate that any medical men should assist in a movement designed to impede its progress.

We shall be told, of course, that the present agitation is not so designed, but that the aim is simply to restrict it within proper limits. But we do not know that a single fact has ever been presented to show that it is not now within "proper limits," so far as absence of cruelty is concerned. The actual limits, indeed, within which vivisection is now confined in America are so small that it takes the keen scent of a trained sentimentalist to detect them. And an "American Association" for the abolition of American vivisection is very much like the assault of a phrenetic Jumbo upon a living skeleton. We perfectly appreciate the position of certain gentlemen favoring the movement, who say that popular sentiment will certainly in time demand the total abolition of vivisection, if "proper restrictions" are not put upon it in time. But there is certainly nothing in the present tendencies of public opinion to justify this alarm. Every year the triumphs of experimental physiology, pathology, and pharmacology are becoming greater, and every year the arguments in favor of the utility of vivisection are becoming correspondingly more unanswerable. To go no further for an illustration, the work of Pasteur and of Koch and their followers would have been impossible under a prohibitory vivisection law. As for a restrictive law, it killed physiological work in England, and it has yet to be shown that the advocates of anti-vivisection in this country will really stop short of practically total abolition here.

As a contemporary writer has said: "A stock company may immolate hundreds during the construction of a Panama railroad, a sovereign sacrifice thousands in the contest for a Crimean peninsula; the hue and cry only begins when the savant modestly begs permission to utilize a single life for the advancement of science."

In England, the establishment of a chair of Physiology at Oxford has given occasion for a renewal of the vivisection discussion there. Mr. Freeman, the historian, who kindly lectured to us Americans, a few years ago, for pecuniary considerations, has announced magisterially, that physiology is the only science that needs on moral grounds, to be restrained. If he had known more about the subject, he would perhaps have, arguing from his standpoint, included pathology and pharmacology. However, his opinions pleased many. But the great argument which has been lately adduced by the English agitators is, that if it is wrong to torture a man for the benefit of science or humanity, it is also wrong to torture an animal. This reasoning is pronounced sound by many unbiased persons. But if it is, then society is very inconsistent. For no one hesitates to incur a war where thousands of persons are tortured mentally and physically. Yet, what is the excuse for war, but the good of society or a part of society?

THE MOBILITY OF THE BRAIN.

It has long been known that the brain in normal conditions undergoes certain rhythmical movements. The powerful vessels at its base cause the cerebral mass to rise and fall with each systole and diastole of the heart. The brain also rises slightly with each expiration and sinks with inspiration. These phenomena are dependent, it is presumed, upon the presence of the cerebrospinal fluid, since when that is withdrawn the movements cease.

M. Luys, in a paper recently read before the Académie de Médecine, states that the brain is subject to still other changes in position, dependent upon the attitude of the body. If a man is in the dorsal decubitus, or lies upon his side, or stands upon his head the brain undergoes certain corresponding changes in position in obedience to the laws of gravity. The movements take place slowly, and the brain is five or six minutes in returning to its first position.

From these anatomical data M. Luys deduces some striking conclusions of practical interest. He explains, upon the theory of these gravitating movements, the symptoms of vertigo and faintness which feeble persons experience when suddenly rising from a horizontal position. He asks if the pains of meningitis are not due to an interference with these normal movements. In cases of insanity he calls attention to the excitability and agitation which often come on when the patient lies down at night. As a practical point in mental hygiene M.
THE ROOSEVELT COMMITTEE AND THE BOARD OF POLICE SURGEONS.

The Roosevelt Committee, which has been investigating the Police Department of this city, has made one of its most serious charges, we regret to say, against the Examining Board of Police Surgeons. Every applicant for position on the police service is obliged to submit to a physical examination before the Board of Surgeons. Unless he comes up to a certain standard, he is, theoretically, rejected. According to the Roosevelt report, however, practically if a candidate has sufficient influence, he can get by the board upon a re-examination. The Committee say:

"Men rejected at one examination for insufficient height, weight, or girth of chest, would at the next show an increase in the necessary particulars that would seem hardly explicable on other grounds. The cases of applicants suffering from organic troubles were even more remarkable. An applicant twice rejected for syphilis was decided to be cured on his third trial; another with varicos veins as speedily recovered. A man was rejected for hernia, but was reported perfectly sound when his case came up again. Another had varicose on his first trial, but not on his second, according to the report of the board, although the head surgeon actually inquired on the back of his last report that the man still had varicose, and was not cured. Mitral insufficiency in another case was quite as temporary a defect, and near-sightedness, obesity, and defective physical formation, all proved equally ephemeral disabilities. In other words, the examinations, in many instances, were merely farcical."

The Board of Police Surgeons is composed of Dr. M. H. Henry, President, and Drs. F. L. Satterlee, S. G. Cook, Charles Phelps, Wm. A. Varian, John H. Dorn, Geo. Steinert, P. W. McDonnell, S. B. W. McLeod, Wm. H. Ensign, S. Waterman, F. M. Purroy, S. K. Lyon, B. F. Dexter, W. F. Fluhrer, A. W. Maclay, David Matthews, R. H. Voorhees, and B. Wood. These have all been known as reputable gentlemen, and several are surgeons of deserved eminence. It is unfortunate that the asserted dereliction of a few should have thus thrown something of a cloud over the examining board.

News of the Week.

ITALIAN PROFESSORSHIPS.—M. Vincenzo Cervello has been appointed Professor Extraordinary of Materia Medica and Therapeutics at Palermo. M. Ugo Oodaro has been made Professor Extraordinary of Clinical Medicine at Parma. Dr. A. Paci, one of the editors of Lo Sperimentale, has been made Professor Extraordinary of Surgical Pathology at Pisa.

The Bill Legalizing Diplomas heretofore granted by the United States Medical College has passed the Senate.

SUICIDE OF A PHYSICIAN.—It is announced that Dr. John Tobin, a promising young physician of Cleveland, O., committed suicide on April 14th by taking morphia. Dr. Tobin was educated for the Catholic priesthood, and was one of the most cultured men in the city. Instead of entering the priesthood he began the study of medicine, and graduated from Wooster Medical College with the honors of his class.

KENTUCKY STATE BOARD OF HEALTH.—The Governor of Kentucky has appointed two homoeopaths members of the State Board of Health.

The American Medical Association meets at Washington, D. C., on Tuesday, Wednesday, Thursday, and Friday, May 6, 7, 8, and 9, 1884.

The Medical Department of the University of Louisiana held its fiftieth annual commencement on March 22d, and graduated a class of sixty-two.

The Louisiana State Medical Society will hold its annual session at Baton Rouge on May 21st.

The Kentucky State Medical Society has changed the date of its annual meeting to June 3d.
Medical Vienna.—At the meeting of the Royal Society of Physicians, March 14th, Professor Weinlechner showed a child with "congenital dislocation of the femur" forward—a rare form of luxation which he had seen only three times. Professor Billroth showed a young man from whom, eight years before, he had removed the entire humerus. Although the periosteum was retained yet there was no regeneration of bone whatever. Despite this, by means of an apparatus, the patient could use his arm very well indeed, and was very glad it had not been removed.

Billroth alluded to the fact that in some cases the trophic nerves seemed to be involved and there was no bone regeneration. In the same way two classes of bone and joint affections are met with, one in which the trophic nerves (of muscle and joint) are involved, the other in which they are not.

Dr. Wick showed specimens taken from a man who had died from glanders.

Professor Toldt has been called to the chair of Anatomy in the University of Vienna.

Hofrath Dr. Ritter v. Schmerling recently celebrated the fiftieth anniversary of his professional life.

On March 21st the Royal Society of Physicians celebrated its thirty-seventh anniversary. Professor Ludwig gave a review of the work of the Society during the past years. The librarian read a report showing the need of more room for the growing library.

The Society voted to entreat Dr. Koch, who expected to stop a few days in Vienna on his return from India.

Professor Billroth was elected President.

The Louisiana Board of Health.—The Louisiana National Board of Health was reorganized on April 12th, Dr. Joseph Jones voluntarily retiring from the presidency thereof after four years of arduous service. Dr. Joseph Holt was chosen his successor. Resolutions were adopted offering and inviting courtesies and reciprocal communication with the health bodies of all the States, and declaring that it is its fixed purpose to apply quarantine restrictions against all ports where contagious or infectious diseases exist, to the limit of the law, and if necessary it will advise the total suspension of all communication with such ports while so infected. Also that while guarding with sleepless vigilance the outlets of the Mississippi River, the board is not unmindful of the dangers that threaten from the rear.

Medical Berlin.—At three successive sessions of the Berlin Medical Society, the last being on March 12th, the subject of tuberculosis was animatedly discussed.

Dr. Benda opened the debate with a paper upon the "Relation of Tuberculosis to the Organs of the Body." As the result of a series of experimental investigations carried on at the Gottingen Pathological Institute, he claimed that tuberculosis was an embolic disease, due to the blocking up of blood-vessels with bacilli. And he proposed to substitute the term "bacillemia" for that of acute general tuberculosis. Dr. Baginsky disagreed with Benda, believing the tubercle to be a thing sui generis, not a harmless embolus. Professor Hirschberg also believed that the tubercle was the product of a specific disease-germ. At the next session, on March 5th, Dr. Fränkel read a paper upon the "Diagnostic and Prognostic Significance of the Tubercle Bacillus." He believed that the discovery of the tubercle bacillus in the spuata always signified that a bacillary destruction-process was going on in the lungs. If not found, there might still be bacilli in the lungs, but there was no destructive process present. Dr. Fränkel did not find that the number or size of the bacilli furnished any safe guide in prognosis.

At the meeting of the Society March 12th the discussion upon tuberculosis was continued.

P. Guttman discussed the various coloring methods and Virchow argued against Benda's theory of bacillary emboli referred to above. A number of pathological specimens were shown. One was that of a stone removed from the bladder by Dr. Landau. In the centre was a thread which, it is stated, was left in the abdomen after an ovariotomy performed several years before.

Medical Paris.—At the meeting of the Académie de Médecine, March 18th, the discussion upon lunacy legislation was finally brought to an end. At the Société des Hôpitaux, M. Férél showed a patient who had suffered from "pulsatile pleurisy." He had been subjected to the operation of Estlander, and was completely cured. M. Du Castel read a paper upon the "Clinical signs of Sclerosis of the Lungs." The Society has decided to set apart a day for the discussion of the subject of the "Prevention of Tuberculosis." At the meeting of the Académie de Médecine, March 25th, M. Le Roy de Mericourt reported a second case of "chromiodrosis," or colored sweating, in a child of twelve years. In the layers of the epidermis he had detected small red granules. He believed that it was a veritable case of transudation of coloring matters. M. Hayem read an article upon "Peritoneal Transfusion." He had injected the blood of a kid into the peritoneum of a dog, and very soon found the kid's red-blood corpuscles in the blood of the injected animal. He believed that peritoneal transfusion was equivalent to venous transfusion. M. Bechamp read an article upon the "Molecular Granulations of the Brain, and Hydrophobic Virus." M. Luys read an article upon the "Movements of the Brain in Different Attitudes of the Body." His views are referred to elsewhere. M. Delthil read a note upon the "Treatment of Diphtheria by Inhalations of the Vapor of Coal-tar and Turpentine."

Making out a Black List.—We learn from the daily press that the Richmond County Medical Society called a special meeting last week to act upon a resolution to the effect that any member of the society shall be prohibited from attending any person who is indebted to any other member of the society when such member shall have received notice of such person's indebtedness to a fellow-member, unless the case be accompanied by a receipted bill or permit for attendance from the protesting physician, the cash in hand, or an order from the Superintendent of the Poor or a Justice of the Peace or other authority competent to make the order collectible. Penalties are prescribed for those who attend the people thus put on the doctors' black list. The physicians of Staten Island have signed a remonstrance against the action of the telephone company that recently bought out the telephone system on Staten Island, because the company has issued orders that hereafter no person can use the
telephone of a subscriber to call a doctor, however urgent the case may be, without first paying a toll of fifteen cents. As most of the doctors have telephones to facilitate quick communication with patients, they express indignation at the new plan.

DR. D. HAYES AGNEW has resigned from the staff of the Pennsylvania Hospital.

BRITISH MEDICAL ASSOCIATION.—The fifty-second annual meeting of the British Medical Association is fixed to take place at Belfast on July 29th next, and three succeeding days, under Dr. James Cuming, of Belfast, the President-elect. Sir Andrew Clark has consented to deliver the address on medicine, and that on physiology will be undertaken by Professor Redfern, while Dr. G. H. Kidd will give the address in obstetrics.

PROFESSOR ALLEN THOMSON, formerly Professor of Anatomy at Glasgow, died on March 21st. He was a fellow of the Royal Society and joint editor of "Quain's Anatomy."

THE MEDICO-CHIRURGICAL COLLEGE, of Philadelphia, held its annual commencement on April 3d, and graduated four students. It is expected that the college will be reorganized during the coming summer.

PROFESSOR CHANDLER.—The Secretary of State has notified the Secretary of the Treasury that Professor C. F. Chandler, of Columbia College, New York City, has been designated as an Honorary Commissioner of the United States at the International Sanitary Congress, to be held at the Hague, August 21 to 27, 1884.

YELLOW FEVER.—The monthly report from Havana for March shows an increase in the prevalence of yellow fever, and a corresponding increase in the cases of "pernicious fever," which Medical Inspector Burgess states is carelessly and loosely diagnosed by the physicians, and which he is nevertheless confident includes not an insignificant proportion of true yellow fever cases.

INTERNATIONAL HEALTH EXHIBITION.—A somewhat novel feature in connection with the exhibition this year will be the establishment of a library and reading-room, for which the Executive Council have assigned space in a large double room in the Albert Hall, overlooking the Conservatory. Steps have been taken to secure a representative collection of works on vital statistics; of reports and regulations relating to public health; of regulations with reference to injurious trades and of works thereon; of reports, statistics, and other works on the science of education. Foreign powers have been invited to lend their co-operation in this effort to create an international library of works of reference bearing on the two divisions of the exhibition, and several responses have already been received. India and the colonies have also been asked to contribute toward the same end. Publishers and authors have likewise been invited to forward copies of their works. In addition to the library of reference, there will be a reading-room, to which the current numbers of periodical publications of a sanitary or educational character will be admitted. All books and periodicals sent to the library and reading-room will, under certain regulations, be arranged for the use of visitors, and not merely for exhibition. The books will be submitted to the jurors, and a full catalogue will be issued. All parcels for the library and reading-room should be addressed, carriage paid, to the Secretary of the Library Sub-Committee, Royal Albert Hall, London, S. W.

THE ASSOCIATION OF AMERICAN MEDICAL EDITORS.—The annual meeting of the Association of American Medical Editors will be held in Washington, May 5th, at 8 P.M., in Medical Hall, southeast corner Sixth and F Streets. The Annual Address will be delivered by President Leaturs Connor, M.D., on "The American Medical Journal of the Future, as Indicated by the History of the American Medical Journals in the Past." Dr. N. S. Davis will open the discussion on, "How far can Legislation Aid in Elevating the Standard of Medical Education in this Country?" in which Dr. A. B. Palmer, Dr. Henry O. Marcy, Dr. L. S. McMurtry, Dr. C. H. Hughes, Dr. Frank Woodbury, Dr. William Brodie, Dr. A. N. Bell, Dr. William B. Atkinson, Dr. W. C. Wile, Dr. W. R. D. Blackwood, Dr. Henry Leffmann, and Dr. Deering J. Roberts will take part. All members of the profession, especially journalists and authors, are invited to be present and take part in the meeting.

AMERICAN SURGICAL ASSOCIATION.—The next meeting of the American Surgical Association will be held on April 30, and May 1, 2, and 3, in the Lecture Room of the National Museum, Washington.

THE MANUFACTURE AND SALE OF OLEOMARGARINE.—The recent developments before the Legislative Committees in this city relative to the manufacture and sale of oleomargarine and the attempts which are being made to prohibit its manufacture, render of considerable interest a decision in the United States Circuit Court for the Western District of Missouri. The Court said "the statute of Missouri providing for the punishment by fine and imprisonment of any person who shall manufacture "out of any oleaginous substance, or any compounds of the same, other than that produced from unadulterated milk or cream from the same, any article designed to take the place of butter or cheese produced from pure unadulterated milk or cream of the same," or who shall sell or offer for sale the same as an article of food, is not in violation of any provision of the Constitution of the United States; and this, although the article is manufactured under a patented process. The sole object and purpose of the patent laws is to give to the inventor a monopoly of what he has discovered. What is granted to him is the exclusive right, not the abstract right, but the right in him to the exclusion of everybody else. He is not authorized by the patent laws to manufacture and sell the patented article in violation of the laws of the State. His enjoyment of the right may be modified by the exigencies of the community to which he belongs, and regulated by laws which render it subservient to the general welfare, if held subject to State control."

OUR FRENCH ADMIRER AGAIN.—At last the Moniteur de la Policlinique has touched us to the quick. The learned and lovable editor has called us red-skins and cocoa-nuts and has said that we were without wit, intelligence, or any of those illuminating qualities which characterize our French colleagues. This we do not mind, however, knowing the gentle ways of the third-rate Paris-
in editor. The last issue of the *Policlinique* attacks us again, however, and ends by saying: "After all, as physicians of the Faculty of Philadelphia, you are not perhaps any stronger in Greek than in clinic. We excuse you. *Non ticest omnibus.*" This is really too much. We can admit everything as regards the cocoa-nuts and similar trifles; but we protest against being placed and published in Philadelphia. We trust that our contemporary will correct an error calculated to do us some injury. We would state here for his edification that Philadelphia and New York are different localities. Philadelphia being a great inland city, New York a quiet suburban town. *Veritatem dies aperit!*

**AMERICAN MEDICAL ASSOCIATION.**—Delegates and permanent members desiring to attend the next meeting of the American Medical Association, at Washington, D. C., May 6th, are requested to address Dr. D. W. Prentis, Washington, D. C., for particulars regarding reduced railroad fares to and from that city.

**DEATH OF DR. PLINY A. JEWETT.**—Dr. Pliny Adams Jewett, one of the leading physicians in New Haven, died in Providence, R. I., April 10th, of pneumonia. Dr. Jewett was born in Hampton, Washington County, this State, in 1816. He received his education in Trinity College, Hartford, Conn., and afterward took a medical course at Yale. He was graduated from the latter institution in 1839, and went to Paris to further perfect his studies. He afterward settled in New Haven, and with the exception of two years' residence in Aiken, S. C., he has since lived there. For forty years Dr. Jewett had been attending surgeon at the New Haven Hospital, and he was for twelve years Professor of Obstetrics in the medical department of Yale. During the war he was surgeon of volunteers, and was afterward prosected to a colonelcy for meritorious services. Dr. Jewett organized Knight's United States Army General Hospital at New Haven, and he had charge of it from 1862 to 1865. He was a member of the Connecticut Medical Society for thirty-seven years, serving as its President in 1876. He was also an honorary member of the New York Medical Society.

**NOTICE TO THE OPHTHALMOLOGISTS, OTOLPGISTS, AND LARYNGOLOGISTS OF THE AMERICAN MEDICAL ASSOCIATION.**—Dr. J. L. Thompson, of Indianapolis, Ind., Secretary of the Section on Ophthalmology, Otology, and Laryngology, writes that, owing to a misunderstanding, no invitations have been sent out for papers to be read at the coming meeting of the Association. He now earnestly urges gentlemen to prepare papers for the section.

**THE QUESTION OF MIDWIVES.**—At the meeting of the Society of Medical Jurisprudence, April 10th, a paper was read by Dr. J. Henry Fruitnight on "The Status of the Midwife, Legal and Professional." Dr. Fruitnight said that his observations had satisfied him that there were a great many irresponsible and unfit women engaged in the practice of midwifery. The tenor of the paper was against midwives, but in the discussion that followed, some arguments were advanced in their favor. The conclusions drawn by Dr. Fruitnight were that the practice of midwifery by midwives should either be suppressed or that they should be better qualified and held responsible. The paper was discussed by Drs. H. J. Garrigues, A. W. Warden, J. C. Peters, A. Jacobi, R. Newman, and Dr. Harwood. A resolution was adopted at the close of the discussion condemning the proposed legislation in behalf of a college of midwifery, which is now seeking incorporation.

**THE ALABAMA STATE MEDICAL ASSOCIATION** held its annual meeting at Selma, beginning April 8th.

**THE MEDICAL SOCIETY OF THE STATE OF TENNESSEE** held its annual meeting at Chattanooga, beginning the session on April 8th.

**JEFFERSON MEDICAL COLLEGE.**—The fifty-ninth annual commencement was held on March 29, 1884. Degrees were conferred on 215 students.

**THE MISSISSIPPI STATE MEDICAL ASSOCIATION** held its annual meeting at West Point, on April 2d.

**THE MEMPHIS HOSPITAL MEDICAL COLLEGE** held its annual commencement on February 29th, and graduated a class numbering forty-three.

**THE KANSAS CITY MEDICAL COLLEGE** held its fifteenth annual commencement on March 5th.

**THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF KANSAS CITY** held its third annual commencement on March 13th, graduating a class of fourteen.

**THE Valedictory of Professor Alfred Stillé.**—Dr. Alfred Stillé delivered his valedictory to the students of the Medical Department of the University of Pennsylvania, on Thursday of last week. He said that, throughout the twenty years he had occupied his chair, the one principle that had governed his instruction had been to build up the walls of the students' education securely with the one hand, and with the other to defend them against the intrusion of hypotheses and unsubstantial theories, the most dangerous of all their enemies, because the most seductive to the young and ardent mind.

**DR. J. W. HOLLAND** has been elected Professor of Theory of Practice of Medicine in the University of Louisville, in place of the late Dr. Yandel. Dr. H. A. Cotell, editor of the *Louisville Medical News*, has been made Professor of Medical Chemistry and Microscopy.

**MORE "EPEMERAL" MISREPRESENTATIONS.**—Dr. Squibb is not content with hurling into print misstatements about the County Medical Society. He presents again unfairly the status of the profession with regard to the Code. The question put by the Old Code party was not a direct query: "Do you or do you not believe in the Old Code?" It was ingeniously put so as to involve another issue: "Do you favor a re-enactment of the Old Code until the National Association has taken some action?" The National Association having turned away the New York delegates, and refused to allow any discussion on the subject of change, a very large number of those whose names are on the Old Code list are really now in sympathy with the New Code and its advocacy of individual rather than corporate morality. Dr. Squibb will kindly state things more fairly.
Dr. T. Mitchell Prudden showed a series of microscopic preparations, histological and pathological, which illustrated the above method, and said: "Although this method was announced more than a year ago, it has not, I think, received the attention which its merits deserve. Its value for the demonstration of pathological as well as normal structures justifies its presentation before this Society. The staining agent is the so-called acid fuchsin, which is rosanilin, in which one atom of H is replaced by the radicle SO\textsubscript{4}H. That is, it is a sulphate of rosanilin. It thus belongs to the class of acid anilines, and it is not a nucleus nor a bacteria stain. It stains tissues diffusely, stains all the structural elements alike. The color is removed by solution of caustic potash, but as the nerve-fibres hold the color more tenaciously than other elements, we can obtain, by stopping the decolorizing action of the potash, a sharp differentiation of the nerve-fibres. The nerve-cells are not especially stained by it. Thus far only one particular preparation of acid fuchsin has been found to give good results. This is prepared at the Baden anilin factory and is known as acid fuchsin S.

Weigert was unable to get good results from the preparations himself, and my own experience is the same. This preparation may be obtained in small quantity from Dr. Grübeler, 17 Dufour Street, Leipzig. I will briefly summarize the details of this method of staining:

"The tissues must be carefully hardened in solutions of bichromate of potassium or in Müller's fluid. Alcohol should only be used, if at all, at the end, to complete the hardening. Thin sections are stained from one to twenty-four hours (it is not easy to overstain) in a saturated aqueous solution of the fuchsin. The decolorization and differentiation is accomplished by a saturated alcoholic solution of caustic potash diluted with alcohol in the proportion of one to ten. The exposure to the alkali is the deciding factor of the other experiments, for it will remove the color from the section altogether. In most cases it should remain not longer than five or six seconds, being moved to and fro in the fluid. The color will be discharged into the alkali. It should be now immediately transferred to pure water, which should be changed two or three times to insure complete removal of the potash. The section may now be dehydrated with alcohol, cleared up by oil of cloves, and mounted in balsam. Or a double staining may be obtained by the use of hematoxylin before dehydration. The outlines are sharpened and the color somewhat intensified by dipping the section after removal of the alkali for an instant into a solution of hydrochloric acid and water, 1 to 5. In such preparations the connections of the elements have a diffuse gray or violet color and their structural details are not distinct, but if hematoxylin be used the nuclei are stained purple. Although not especially stained, the nerve-cells may be seen with great distinctness. The nerve-fibres, on the other hand, stand sharply out in light or deep red. It seems to be a decided advantage to have portions of the myelin which are stained and a part of the non-myelinated fibres of the gray matter. It is difficult to speak in praise of this method in terms which will not seem extravagant to those who have not seen its results. It is not only the exquisite distinctness with which nerve-fibres and bundles, which we have been accustomed to see more or less clearly by the older methods, stand out against the diffusely stained background, but the marvellous wealth of finer and coarser fibres of whose existence the ordinary methods give but faint intimation, which seem to promise for this method the most useful results. The qualities which render it useful in normal structures recommend it for the morbid also. I have found it particularly useful in staining the cord in leucoencephalitis, in secondary degenerations, etc., and also for determining and demonstrating the presence of nerve-fibres in tumors and other structures in which they are not present in large numbers. In the peripheral nerves it furnishes a most admirable means of demonstrating the axis cylinder."

As verbal descriptions of the results of such a method are at best not very convincing or instructive, I have taken the liberty of sending in a somewhat imposing array of microscopes in which you may see a variety of preparations made in this way. Most of these specimens were prepared nearly a year ago, and have retained their colors with little change. It is to be regretted that you may not see them by sunlight, for the color and outline are much more distinct than by artificial illumination."

I have laid out transverse and longitudinal sections of the normal spinal cord with both single and double stain; sections of the cord in posterior spinal sclerosis and secondary ascending gray degeneration, longitudinal section of the sciotic nerve, and a section of a false neuroma showing scattered nerve-fibres running through it, and standing out clearly in it, and the surrounding connective tissue. I would especially commend, for the exquisite delicacy, distinctness, and intricacy of the picture, the transverse section through the human medulla oblongata at the level of the olivary bodies."

Weigert's original papers are in the Centralblatt der Medizinischen Wissenschaften, October 21 and November 15, 1882.

Dr. H. Heineman presented a specimen of COLLOID CANCER OF THE PERITONEUM, and also a specimen of SACULATED EMPYEMA.

Dr. Janeway had seen two cases of sacculated empyema this year. One was a case in which there were several sacs following pneumonia, and where his house-physician at Bellevue Hospital introduced the aspirator needle and drew off about four ounces of pus from one sac, then four ounces from a cavity below, and nearly four ounces from still another part of the pleural cavity. In the other case it was more difficult to explain the origin of the condition. There was hydro-thorax limited to the lower tube, which disappeared after a short time, and the patient recovered. The cavity evidently had quite a limited area, with free evacuation through the bronchi.

Last week, also, he made an autopsy in a case of suddenly developed hydro-thorax, which was found to be due to a communication from a bronchietatic cavity in the lower lobe through the interlobar fissure by a wound into the pleural cavity. In that case the pus was very offensive. The man died of sepsis from erysipelas following aspiration, and of the pus in his chest. It is very difficult to say exactly how such a condition originates with an extremely good history.

Dr. Heineman said that peptic pus was not infrequently met with in cases of empyema in which there was no communication with a bronchus, and in cases of general pyemia, and in which the febror gave rise to the suspicion that there was gangrene.

Dr. Janeway had seen such cases.

Dr. Frank Ferguson presented a HORSE-SHOE KIDNEY, removed from the body of a man who died in New York Hospital on January 18, 1884, the day of his admission. He had been suffering from extreme dyspepsia when admitted into the hospital, and said that for a few days past he had had slight difficulty with his breathing.
He had been using opium for the last five years, and at the time of his death used fifteen grains daily.

His dyspnoea was relieved for a short time by the administrations of digitaline and morphine. His breathing was superficial and labored; temperature 101° F.; and urine contained thirty per cent. to the column of albumen. Suddenly his respiration and heart action stopped, and ten minutes after the rigor mortis was well marked.

The real interest in the case, aside from the anomaly, was the fact that the entire organ showed well marked parenchymatous nephritis, which doubtless was the chief factor in causing the patient's death.

Dr. Ferguson also presented a specimen of CONGENITAL ABSENCE OF THE LEFT WING OF THE DIAPHRAGM.

A large portion of the intestines and stomach were in the left pleural cavity.

LARGE HEMORRHAGE INTO THE PONS.

Dr. Ferguson also presented a brain with the following history. It was removed from the body of a Russian sailor, sixty-seven years of age, who was brought to the hospital in an ambulance. His friends said that he had been sick, "paralyzed," for twenty-four hours, but that he worked out-doors the afternoon previous.

On admission it was found that the patient's surface was dry, his muscles were relaxed; his pupils were equal, contracted, and iridescent to light. Deep and superficial reflexes were preserved. Bladder was distended with urine, which when drawn was found to contain albumen ten per cent. Temperature was 101°, pulse 80, respirations slow and stertorous. Both legs and arms responded to stimulation made by pricking them with a pin. One-eighth grain of nitrate of pilocarpine, hypodermically, and hot air both failed to produce diaphoresis.

T.F.M.—Patient became partially conscious, and slowly raised his left hand to his mouth, and on being shown a glass of water and asked if he wanted it, feebly bowed his head and closed his eyes in affirmation. Water was given him, and he seemed easier after it. He died at 3:20 the following morning.

The brain showed a hemorrhage into the pons, which had escaped into the fourth ventricle also, and the pia mater was so raised as to perfectly fill the space between the medulla and the lobes of the cerebellum. There was almost complete destruction of the pons. The kidney was the seat of chronic diffuse nephritis far advanced.

Dr. Janeway remarked that the statement frequently seen in text-books that the presence of albumen in the urine would serve to distinguish between uremic coma and the coma from hemorrhage into the brain was altogether erroneous, as had been proved many times by post-mortem examination. He thought the presence of albumen under these circumstances served to puzzle rather than make clear the question of diagnosis.

Dr. Ferguson asked Dr. Janeway if he had seen frequently hemorrhage into the pons with chronic diffuse nephritis.

Dr. Janeway said he had seen several cases.

Dr. Van Gibson wished to reiterate what he had before stated to the Society with regard to diagnosis vibrating between coma from disease of the kidney and from hemorrhage into the brain. He thought that in most cases of coma from Bright's disease the premonitory temperature was elevated, whereas in hemorrhage into the brain the temperature was not nearly so likely to be elevated. That had been his experience, based upon quite a number of cases.

Dr. Janeway remarked that the primary temperature of cerebral hemorrhage had been said to be depressed, in severe hemorrhage into the pons, perhaps persistently so. Whether or not there were exceptions was difficult to say. Whether or not there was always primary depres-

sion of temperature with hemorrhage, or whether it might not occur with paralysis from some other cause, he had not been able to settle. The temperature in uraemia may be either depressed or elevated, and different statements have been made by different observers on this point. The premonitory temperature goes high in hemorrhage into the brain, and may not be especially elevated in kidney disease. One thing which would aid materially in studying the question was the primary temperature within the first few hours.

Dr. I. H. Sayre presented, in behalf of Dr. Lewis A. Sayre, sections of liver, lung, kidney, and of the aorta, together with a portion of new growth of fibrous tissue removed from the body of a man, with the following history:

CASE OF ASCITES FROM COMPRESSION OF THE LIVER AND PORTAL VEIN BY CHRONIC PROLIFERATIVE HEPATITIS; AND GENERAL ANasarCA FROM HYBERTROPHY OF THE HEART, AND GENERAL ATHEROMA OF THE ARTERIES, WITH CHRONIC NEPHRITIS—TAPPED DURING SIX YEARS AND FIVE MONTHS 187 TIMES, REMOVING 19,256 OUNCES OR 1,203 3/4 POUNDS, BEING MORE THAN SIX TIMES THE ENTIRE WEIGHT OF THE PATIENT.

H. H., aged sixty-six, a very large and robust man, six feet three inches high, and an average weight for many years of two hundred and thirty pounds. Was admitted to hospital in a poor health condition, in which he had a very severe attack of pleuro-pneumonia of both sides, which for some time threatened to be fatal. He finally recovered, but his respiration was never perfect from that time. In the winter of 1878 he slipped on the stone steps at his front door, which were covered with ice, and struck very heavily in the middle of his back, on the edge of the step, both feet having glided suddenly from under him. The concussion was very violent, and was followed in a few hours by almost complete paralysis of the lower extremities and the bladder. He recovered the control of his bladder in about three weeks, and almost perfect use of his legs a few weeks later. In the summer of 1879 (July), while sitting in a hammock between two trees, the rope broke near his head, and he dropped suddenly upon his shoulders, with his feet suspended in the hammock, causing a sharp curve in his back. This fall was followed by intense pain very near the seat of his former injury, and extending through to the pit of the stomach (as he described it), and it finally extended all over his abdomen, giving rise to intense pain of a spasmatic character, and also on the side of the thorax, similar to an intercostal neuralgia. These pains never entirely subsided, but required the use of hypodermic injections of morphine once or twice daily during the remaining six years of his life.

His nervous system became greatly impaired, being many times hypomanic.

Dr. Allen, of Ruland, Vt., who saw him in consultation with me, was of the opinion that some injury had been done to the solar-plexus or great sympathetic nerve.

In August after the last accident his limbs began to swell, and his abdomen showed evidence of peritoneal effusion. This gradually increased until his respiration was interfered with and I tapped him on September 25, 1878, for the first time, removing 240 ounces, or 15 pounds. I tapped him next on November 27, 1878, removing 416 ounces, or 26 pounds. From that time on he was tapped at varying intervals, as necessity required, until the time of his death, which occurred on February 17, 1884—in all 187 times. The average amount of fluid removed was by accurate measurement 19,256 ounces, or 1,203 3/4 pounds, being more than six times the entire weight of his body at any time during that period. His urine was examined repeatedly by Professor Austin Flint, Jr., and by Dr. Allen. Only once or twice was a slight trace of albumen found, and nothing else abnormal except deficiency in quantity. The average discharge of urine per twenty-four hours was,
in 1879, 35½ ounces; 1880, 33 ounces; 1881, 25 ounces; 1882, 23 ounces; 1883, 18 ounces; 1884, 20½ ounces in month of January and 10¾ ounces in month of February.

During the last forty-eight hours of his life he only passed 7 ounces, and died of uremia on February 17, 1884.

The post-mortem was made, twenty-four hours after death, by Dr. W. H. Welch, and is appended to this report.

**POST-MORTEM EXAMINATION.**

**Exterior.**—Moderate emaciation. No edema of lower extremities. Abdominal cavity distended with fluid. Scars of old punctures in median line below umbilicus.

**Brain and spinal cord.**—Not examined.

**Peritoneal cavity.**—Contains about 3,000 c.c. of clear, yellowish serum. The coils of intestine and other abdominal viscera are in great part united firmly to each other and to adjacent parts by old fibrous adhesions. These adhesions are most abundant in the upper part of the peritoneal cavity, so that the bulk of the fluid lies in the lower and lateral parts of this cavity.

The liver, measured in a depth, uniform, white capsule of fibrous tissue, averaging 6 to 8 mm. in thickness. The anterior surface of the stomach is firmly adherent to the inferior surface of the liver. The gastro-hepatic omentum is thickened, fibrous, and retracted, particularly around the vessels in its right border. The omentum is thrown up into a thick, fibrous striped transversely across the ventricle at about the level of the umbilicus. The spleen, like the liver, is surrounded with a thick layer of dense fibrous tissue, and is firmly bound down by old adhesions.

A similar fibrous thickening involves elsewhere a great part of the visceral and parietal layers of the peritoneum, and altogether the abdominal viscera so closely that these can be removed only in mass. (There are no tubercles in the peritoneum.)

**Plural cavities.**—There are old adhesions between the pleural surfaces upon both sides. A growth of dense, white, glistening fibrous tissue, analogous to that on the peritoneum, involves the diaphragmatic and adjacent costal pleura. This part of the pleura is in places nearly 1 cm. in thickness. It cuts like gristle. The fibrous growth extends on both sides 4 cm. upward from the diaphragmatic on the costal pleura. There is no fluid in the pleural cavity, this being, in fact, nearly obliterated by adhesions.

**Heart.**—The pericardial sac is obliterated by old adhesions. The pericardial sac is thick fibrous patches over the anterior surface of both ventricles. The heart is enormously enlarged. Freed from blood it weighs 38 oz. All of its cavities are dilated and hypertrophied, the left ventricle most extensively. The aortic valves are somewhat shrunk and thickened, especially about the noduli Arantii. The mitral valves are a little atheromatous. The change in the valves are comparatively unimportant and not sufficient to explain the hypertrophy of the heart. The dilatation is great as well as the hypertrophy. The musculi papillares of the left ventricle are somewhat flattened. The muscle beneath the endocardium of the left ventricle is yellowish in places. Examined microscopically it is found to be moderately fatty. The coronary arteries of the heart present some sclerotic patches, which, however, are not extensive.

**Lungs.**—The lower lobes are compressed. The upper lobes are somewhat emphysematous. There is considerable muco-pus in the larger bronchi, where the mucous membrane is reddened. The pulmonary tissue is firm, yellowish-brown in color, and rather dry. It presents the appearance of tissue already in the process of fibrosis.

**Spleen.**—The spleen is about three times its usual size. It is enveloped in a greatly thickened fibrous capsule adherent to surrounding parts. The splenic substance is dark red and firm. The trabecule are evident.

**Kidneys.**—The kidneys are about normal in size. Their consistence is very firm. The capsule strips off readily, leaving a surface with many depressed atrophic patches, some of considerable extent. Upon section the cortical substance corresponding to these depressions is thinned, elsewhere it is of about normal thickness. The color is dark red. The cortical markings are fairly distinct. A few yellowish lines, due to deposit of urates, can be seen in the pyramids. The branches of the renal artery present some sclerosed patches in the intima. There is considerable adipose tissue in the sinus of the kidney. Examined microscopically there are found in the kidney fibrous Malpighian tufts, thickened capsules of Bowman, increased inter-tubular tissue, atrophied tubes, and thickened vascular walls. These changes are in patches and are not very extensive. They resemble in distribution the lesions of chronic diffuse nephritis due to arteriosclerosis.

**Ureters.**—Normal.

**Bladder.**—Nearly empty. The walls of the bladder are somewhat thickened. The middle lobe of the prostate, in the situation of the uvea vesical, is considerably hypertrophied. This hypertrophy is in the form of a dense, irregular, grayish-white nodule, about the size of a bean, projecting from the floor of the vesical orifice of the urethra. Similar small fibrous nodules are present near the main one. Thick muscular bands (hypertrophied Bell's muscles) extend from the orifices of the ureters to the opening of the urethra. The lateral lobes of the prostate are moderately enlarged.

**Intestine.**—The coils of the small intestine are so firmly bound together that in many places the intestinal coats tear more readily than the adhesions. The mucous membrane is in places congested and coated with muco-pus, but in general it appears normal. The opening of the common bile-duct into the duodenum is normal, and upon pressure along the course of the duct readily gives exit to bile.

**Stomach.**—It is surrounded by thickened peritoneum and is adherent to the liver. It is of about normal size. The mucous membrane of the pyloric region is reddened and coated with muco-pus.

**Liver.**—The liver is rather small, and, as already mentioned, is completely enveloped in a thick, white, fibrous capsule, continuous at the transverse fissure with the thickened and contracted lesser omentum. The prevailing color of the liver-substance is yellowish. There are, however, places which are red and depressed. Examined microscopically the liver is found to be the seat of fatty infiltration, and of a moderate degree of red atrophy. The gall bladder is not greatly thickened. It is filled with clear, watery serum, containing transluent, gelatinous coagula of fibrin. The opening of the cystic duct into the gall-bladder is completely occluded. There is no bile-coloring of the fluid in the gall-bladder.

**Portal vein, etc.**—The hepatic and common bile-ducts are perversive, and although they are surrounded with much new-formed fibrous tissue, bile can be easily pressed through them into the duodenum. On the other hand, the portal vein is greatly compressed by the new fibrous tissue in the lesser omentum. The vein is compressed and flattened out, and can only be dissected with difficulty. It contains no thrombus, and its inner coat appears normal. The hepatic artery appears normal, although enveloped in fibrous tissue.

**Arteries.**—The aorta and other large arteries are very atheromatous, and present upon their inner surface many calcareous plates.

*William H. Welch.*

CORRESPONDENCE.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE GENERAL MEETING AT THE COLLEGE OF SURGEONS—
THE PATENT MEDICINES BILL. —THE DEATH OF PRINCE LEOPOLD.

London, March 19, 1844.

The general meeting of members and fellows at the College of Surgeons on Monday last was, contrary to expectation, neither large nor representative. Only one hundred and ten attended, and the discussion was practically carried on by only a few of those present. The resolution to allow voting by proxy in the election of members of council was, as expected, unanimously carried. This point has long been a grievance, as I wrote some time since. Several other resolutions of varying interest were brought forward, and a noticeable feature of the meeting was the decided stand made by the members to obtain more influence than heretofore in the management of the College. At present they have neither voice nor vote. The same, however, is the case at the College of Physicians.

A suggestion brought forward at the meeting on Monday, in Lincoln's Inn Fields, was that the two colleges should combine and obtain power to grant degrees in medicine and surgery, but it was negatived by twelve to six. Such a scheme, if carried out, would bring a degree within the reach of all students, and remove the anomaly at present existing viz., that nearly all students educated in London are obliged to content themselves with a simple diploma and the title of Mr. Of course I am not referring to those who are going to be pure physicians. They can, if they like, prolong their course of study and obtain a degree somewhere. But they even are compelled to go and reside for a term of years elsewhere than in London to obtain a degree, unless they can squeeze through the narrow portals of the London University. I made some remarks anent this institution in my last letter. I may add that of those who do succeed in obtaining a degree there, most of them spend about seven years in study after matriculation to obtain the M.D. degree. Of those who try to stress the matter, six out of every eight who matriculate and go on to the next examination, only two succeed in obtaining the M.B. degree, and only one the M.D. Add that every failure entails twelve months' delay, and that there are three examinations after the "matriculation" before the M.B. can be gained, and one more before M.D. can be won, and it will readily be seen that only a few of the rank and file of the profession can hope to graduate at the London University. No wonder students desert the London schools and flock to Edinburgh, where a degree can be obtained on easy terms, and almost in the same time in which a London student gets an ordinary diploma, which gives him no right to call himself Dr. The unrestricted sale of patent medicines—that is, unrestricted save for the imposition of the government stamp of three halfpence on every bottle or box sold—has long been a crying evil, and the profession have frequently drawn attention to the dangers resulting from the poisonous nature of many of the compounds sold. On Wednesday last a bill was introduced into the House of Commons which provided that, until these medicines had been analyzed by the Pharmaceutical Society and proved to contain no poisonous substances, they should come under the same conditions as the poisons scheduled in the Pharmacy Act, and sold as such. The bill was unfortunately negatived without a division, but the government admitted the necessity of the question, but proposed to treat it on broader grounds. It is rather ludicrous to note that the bill was introduced by Mr. Warton, the most indefatigable opponent in the lower House of legislation emanating from other people, so much so that he has been called "the most pestilent blockader" in the House.

London has been thrown into consternation by the sudden death, yesterday morning, of Prince Leopold, Duke of Albany, fourth son of the Queen. He was always delicate and for most of his life under medical care, as he was a sufferer from that strange and intractable malady, hemophilia. To this constitutional tendency I apprehend his death was due, as symptoms of cerebral hemorrhage are reported to have followed a slight fall. He was staying at Cannes to avoid our east winds, and a day or two before he died had written home that he was never in better health. His health, however, has never been robust. On his wedding day, nearly two years ago, he appeared to suffer greatly from the effects of a slight injury to his knee some time previously. His sudden death, however, is a great shock to all, and must be especially so to his wife, who is now in England, and in a delicate state of health. It has transpired that the trip to Cannes was undertaken in deference to medical advice, but he was not thought to be seriously ill—far less was his death expected. He was to have been in England on Monday next, and preparations were being made for his reception at Clannon, his residence, where his desolated widow now remains in a precarious condition. He was distinguished as the member of the royal family who especially devoted himself to literature, science, and the arts.

THE SECOND ARMY MEDICAL EXAMINATION, AS VIEWED BY A MEDICAL OFFICER OF THE NAVY.

[The comparatively late date of the following communication is to be explained by the remoteness of the writer, but his words are nevertheless in season, as bearing upon a topic that deserves a still further discussion.—Ed.]

TO THE EDITOR OF THE MEDICAL RECORD.

Sir: The letters discussing the second army medical examination that have appeared from time to time in The Record, have naturally interested us of the sister service in the facts that which were the nurtures of some of us, at least, to have a bearing as well.

If our case were no worse than that of our army confrères we would have no cause for complaint; but even Dr. Shufeldt's unusually hard experience with the Army Board is certainly no worse than that of the average naval candidate for the grade of Passed Assistant Surgeon.

I heartily concur in Dr. Brown's opinion, that some examination is necessary, to find out whether or not the former diligent student has become an inert sloth during the five (in the navy three) years of his new life, in which he has been deprived of the former stimulus of competition, example, and teaching, and if the requirements of the second examination are more exacting than those stated by him in The Record of February 3d, I think there is scarcely one among us who would emit a single groan on this subject.

My own experience of the years preceding the examination for promotion was very similar to Dr. Shufeldt's, though hardly so agonizing as he describes his, in spite of the severer trial awaiting me. Knowing the details of my mind prolonged, and searching character of our second examinations, and the frequency with which my confrères came out of them plucked and humiliated, I could not even read the medical journals with an easy conscience, for every line in them suggested some nerve whose ultimate minute distribution I had forgotten, or some tenebrist detail of which I did not know, and which I might be required to give when the examination overtook me. My expectations in this respect were fully realized, and a good
many small points that I had burdened my mind with, exclusively with the intention of getting rid of them permanently at the examination, did come up, besides others that I would have crowded in too if I had thought of them in time.

My examination extended over six days, the usual length of all naval medical examinations, all of them full of hard driving work, for from five to eleven hours, and I know of no more exhausting and stupefying labor than undergoing a prolonged examination. Indeed, more than one candidate that I can recall while writing this, who was found perfectly sound after thorough preliminary physical examination, has broken down under this ordeal.

I happened to pass successfully, with no great margin to spare, however, which, after some years of conscientious study, under considerable difficulties, on board ship, was discouraging enough, but worse than that, carried away with me such an intense and active hatred of the text-books, that for two years afterward I could hardly drive myself to use them, even for reference, and am only now recovering from the effects of years of slavery to them. In this regard my experience is not at all singular; indeed, I venture to assert that it is the rule.

Now, what practitioner, be he ever so studious, applies himself to anatomy, physiology, and the other text-books, for years after he begins active practice, as he did when a student, and what a man can develop on any originality, or can observe and investigate with any success, when he knows that the Board wants the books, and little else but the books, and that any time stolen from the tread-mill will jeopardize his chance of advancement, or even of remaining in the service?

One peculiar feature of our second examination, about the prudishness which I ought to say, however, that there are two diametrically opposite opinions, but which at least worked unfairly—I refer to their competitive character—has, I am glad to say, been recently abolished; but while it existed it was an added source of anxiety and distraction to the unfortunate assistant surgeon.

My grievance, in short, is not that we have to show cause why we should not be dropped from the service as useless cumberers, or unfitted for its varied requirements, not that the examinations are long and full—for the longer and fuller they are the more one unavoidable feature of all examinations, luck, tends to be eliminated—but that they are of such a character that we are kept in a condition of boyish torture in which we should be working and responsible surgeons; that this anomalous condition unavoidably gives many of us such a distaste for hard study that it is positively injurious, and that valuable period in a young practitioner's life, when, if ever, he begins to form habits of exact observation and investigation, is wasted to a great extent in dry, ungenial pegging at text-books that are not even new enough to excite his interest, as they did in his college days.

The examination of which Dr. Brown gives a sketch in his letter of February 2d, strikes me as a perfectly fair one, and after the entering examination, which can hardly be too thorough and searching, sufficiently complete to fulfill all the requirements of an examination, not of a student fresh from the lecture and dissecting rooms, but of a practitioner of recognized standing.

GEORGE ARTHUR.
Passed Assistant Surgeon, U.S.N.

SODE SALICYLATE AS A CAUSE OF METRORRHAUGA.—Dr. Walter J. Ransom, of Lockport, N.Y., writes: "I will add my testimony in regard to sode salicylate as a cause of metrorrhagia. I have a lady patient subject to occasional attacks of rheumatism. On two or three occasions I tried the salt, and on many times metrorrhagia occurred. On suspension of the remedy the flow ceased."

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from April 6, 1884, to April 12, 1884.

BAILY, ELISHA I., Colonel and Surgeon. Ordered to report to the Commanding General Division of the Pacific for duty as Medical Director of that Division, and of the Department of California. S. O. 78, par. 4, A. G. O., April 4, 1884.

SUTHERLAND, CHARLES, Colonel and Surgeon. To be relieved from duty in Division of the Pacific, and to report to the Commanding General Division of the Atlantic for duty as Medical Director of that Division, and of the Department of the East. S. O. 78, par. 4, A. G. O., April 4, 1884.

SMITH, JOSEPH R., Major and Surgeon. Directed to represent the Medical Department of the Army at the annual meeting of the American Medical Association, to be held in Washington, D. C., on May 6, 1884, and on the adjournment of the Association to return to his proper station (San Antonio, Tex.). S. O. 81, par. 7, A. G. O., April 8, 1884.

BAILY, JOSEPH C., Major and Surgeon. Leave of absence extended three months. S. O. 83, par. 8, A. G. O., April 10, 1884.

STERNBERG GEORGE M., Major and Surgeon. Ordered to be relieved from duty in Department of California, and to report to Commanding General Department of the East for assignment to duty.

MOSLEY, EDWARD E., Captain and Assistant Surgeon. Ordered to be relieved from duty in Department of the East, and to report to the Commanding General Department of the Columbia for assignment to duty. S. O. 78, par. 4, A. G. O., April 4, 1884.

WILCOX, TIMOTHY E., Captain and Assistant Surgeon. Ordered to be relieved from duty in Department of the Columbia, and to report to the Commanding General Department of the East for assignment to duty. S. O. 78, par. 4, A. G. O., April 4, 1884.

Official List of Changes in the Stations of Medical Officers U. S. Navy, for the week ending April 12, 1884.

BATTLE, S. W., Passed Assistant Surgeon. Ordered before Retiring Board.

WELLS, H. M., Surgeon. Detached from Naval Hospital, New York, to report at Bureau for Special Duty.

HIBBETT, C. T., Passed Assistant Surgeon. Placed on waiting orders.

STEWART, H., Surgeon. Placed on Retired List from April 10th.

SHOCK AS A THERAPEUTIC AGENT.—Dr. James P. Tuttle, of New York City, writes: "Your short notes on 'Shock as a Therapeutic Agent' recalls to me a practice among rude, country veterinary men, which I was able to see applied some years ago. It is the shock treatment for lock-jaw in horses, and is applied as follows: A board, one inch thick and about six inches wide, is laid across the forehead, and struck forcibly with an ax or hammer, staggering, or even felling the animal to the earth, when relaxation of the spasms is said to occur. Those who practise it aver it never fails. Certain the case I saw was good evidence of the truth of this assertion, for the spasms at once relaxed, and a tobacco poultice being applied, they did not return."

THE TIME FOR THE EXPULSION OF THE PLAGIATA.—Dr. H. J. Garrigues, of this city, writes: "Toward the end of your report of the discussion on my paper recently read at the Academy, it is stated that the plague, on an average, was expelled in five minutes. This is a mistake, and as the point is of practical importance, I hope you will correct it. I said that in the majority of the cases the plague had been expelled from five to twenty minutes after the birth of the child. I might have added that in a few the time was shorter, and in many longer."

THE WAY TO PRESCRIBE POTASSIUM CHLORATE IN SOLUTION.—Mr. Bernard Perel, hospital steward, U.S.A., sends us a note regarding the above subject. He states that potassium chlorate is only soluble in cold water (60° F.) in the proportion of 3 j. to ½ j., and that prescriptions are often written showing great ignorance of this fact. Large doses of the salt are best given by dissolving in boiling water and adding sufficient gum and sugar. As a sample of erroneous prescription, one given by Dr. Hutton in his article on Diphtheria is referred to.

TRAUMATIC RECTO-VESICAL FISTULA.—Dr. C. E. Foster, of Honesdale, Pa., sends us the history of a teamster, aged twenty years, who fell backward on a hickory stake which entered his body just behind the rectum for six inches. It was found that the rectum was penetrated and also the bladder. Gas, feces, and blood were passed by the urethra. A gum-elastic catheter was introduced into the bladder and kept there. The wound was dressed daily. The patient did well and was at work in six weeks. He still has a very slight recto-vesical fistula.

THE CONJOINT EXAMINING BOARD.—R. O'D. Parks, B.A.L.R.C.S.I., of Ashton, R. I., writes: "In your article discussing Professor Huxley's plan for a Conjoint Examining Board in Great Britain, this passage occurs: 'The Parliamentary bill creates three Boards of Examiners—one for England, Scotland, and Ireland, respectively. These boards will establish a minimum qualification and prevent the present practice of students who fear to fail in England, going to Scotland or Ireland.'

I am sure you would not willingly be a party to casting an unmerited aspersion on any nationality, but either you are misinformed, or the present practice has changed very materially from what it was some twenty years ago. At that time—and there are practitioners in New York City who can corroborate my assertion—it was the notorious and well-recognized practice for students who dreaded the ordeal of the Dublin examination, to go to London, where they generally succeeded in passing, or fearing to go there, or failing to pass, go to Scotland as a last resort. The Irish examinations had always the reputation of being remarkably stringent and searching, and if your statement is well founded they must have wofully degenerated, which I can find no reason to believe.

If you rely on English, and especially conservative sources of information for facts concerning Ireland, you will be very liable to fall into error.

Your sense of justice will, no doubt, induce you to give this insertion and prevent an erroneous impression from going forth.

ANOTHER CASE OF CHLOROFORM NARCOSIS DURING SLEEP.—Dr. John I. King, of Burgh Hill, O., writes: "In the issue of THE MEDICAL RECORD for March 8, 1884, I notice a report of chloroform narcosis during sleep. I was taught, and did believe this to be impossible, until December 15, 1883, when I was called to see Scott B.—a lad about nine years of age, of a highly nervous temperament, who had been kicked in the face by a horse. Perverseness and fear made it impossible to replace the different parts and tissues. Waiting until the boy fell asleep, I cautiously administered chloroform to complete anesthesia, and accomplished my object."

HEREDITARY PROGRESSIVE MYOPATHY.—At a meeting of the Académie des Sciences, M. Vulpin presented, in the names of M.M. Landouzy and Déjerine, a remarkable memoir on progressive muscular atrophy without neural symptoms. The first important memoir on progressive muscular atrophy were published in France. M. Luys had shown that in this affection there existed an alteration of the large cells of the spinal cord; but progressive muscular atrophy is sometimes hereditary, and may be observed in children. In these cases it begins in the muscles of the face, which is the exception in progressive muscular atrophy of adults. Duchenne (de Boulogne) had, by means of this characteristic, distinguished two varieties of the affection. M. Landouzy has had the opportunity of making an autopsy on a young man afflicted with the "hereditary" form of the disease; death had resulted from acute phthisis. This is apparently the first autopsy performed on a case of the kind. The main feature of the communication was the absence of any neural lesion. M.M. Landouzy and Déjerine have earned the reputation of competent observers in matters relating to the nervous system, and hence the importance of their results.—Lanecet.

MICROBOMANIA.—The symptoms and effects of this malady are described by M. Paul Somans in the feuilleton of a recent issue of the Gazette Médicale de Paris. He speaks of it in connection with the numerous maladies which have recently been discussed, such as agranophobias, claustrophobias, and morbidmania. Microbomania is an affection of adult or middle age, sometimes attacking those in advanced years. It is most frequently observed among educated physicians, those most given to biological research, and almost always ambitious. It is characterized at the début by a great desire for notoriety, accompanied by a slight degree of fever and a craving to find certain mobile corporules. The desire is soon followed by a desire for the most escape from the same craving. In the end hallucinations are developed as to the presence of corporules in impaludism, measles, scarlatina, even in mumps, and the minute organisms are charged with all the crimes imputable to each pathological individuality. The disease is irritable, and if several individuals under the influence of this form of mania should concentrate their attention on one and the same disease, they are very apt to find widely differing microbes.—Medical Press.

ORAL PATHOLOGY.—A red line on the gums, with fetor and metallic taste, indicates ptyalism. A blue line—lead poisoning. Great on the gums, and great fetor—scurvy. A red line about the teeth and along the gums—periodontitis. Purple gums and purulent discharge—necrosis. Gums hot, red, swollen, very tense

Sewerage and the Death-Rate.—It is quite suggestive to study the relations between the death-rate and the sewerage and water-supply. For instance, St. Petersburg has a death-rate of 35.2 per thousand, and has no sewerage, while the Neva is its water-supply. The Neva is contaminated by pollution from the privy-combed soil. Pekin has a death-rate of fifty per thousand and has no sanitary works worth mentioning. Cairo has a death-rate of thirty-seven per thousand; it has no sewers and the Nile water-supply is contaminated by excreta.

Mexico as a Residence for Invalids.—The constantly increasing intercourse between this country and Mexico makes a knowledge of its sanitary value of importance. The following notes from Dr. F. Semeleeder, of the city of Mexico, will therefore be read with interest. After speaking of the great variety of climate which Mexico offers, he says: "As a general rule, we may state that the coast of the Mexican Gulf offers no suitable place for invalids. During the warm season the coast proper is infested by the yellow fever up to a certain distance from the sea, and even higher up the heat is excessive. Immunity from yellow fever only begins at an altitude of 1,500 feet, and even here the nights are very cool, and with such violence, and the weather, sometimes for a whole week, is so unfair as to make anybody miserable and cause real danger to invalids. The tableland of Anahuac, the central plateau of Mexico, during the cold season is decidedly too cold, the more so as the style of lodging and living is not at all fit for the cold weather, and we have 1406 cases of flu. There are numerous places south and west of the capital, protected against the northers, where the climate is mild and delicious during the cold season, with hardly a cool breeze in the morning and evening, and where a suitable living may be had, and at reasonable prices. Yet your correspondent has produced a small printing office, and in these centres of population, the knowledge of the English language so far has spread very little, and the habits and style of living of the people are widely different from what Americans are accustomed to. As for the city of Mexico particularly (2,820 metres), I am of opinion that for most invalids the winter is too cold here, and for a short time only the air may be too cold and too dry. It is never very warm here during the warm season, while the evenings and nights, even in summertime, are cool and sometimes cold. The dryness of the air is sometimes extraordinary and unpleasant, and the swamps round the city, together with lack of cleanliness and bad drainage, give rise to malarial affections. No invalid should come here without providing himself with heavy winter wear and clothing. Board and lodging may be got here at from $3 to $5 a day. A good hotel on the American plan is greatly needed, and might prove a paying business. Mexico is a large city of more than 250,000 inhabitants, offering almost everything a cultivated mind and a spoiled body may require. As the Central Pacific and Mississippi railroads have now reached the States, there will be a quicker, and for many patients more pleasant opportunity for going to Mexico, as the trip by land, via Chicago and Kansas City to the City of Mexico, will take a little more than six days and nights, while it takes twelve days sea-voyage and one day railway travelling to come here from New York via Havana and Vera Cruz.

The weather, all the year round, is as follows (more or less): November, December, January, February, dry and cold, and sometimes windy and dusty; March, April, May, warm and dry, rains begin in May; June, July, August, September, rainy season, moderately warm, pleasant, rainy, thunderstorms, not windy; October, pleasant and dry. Medium temperature of the whole year (average of six years,) 15.6° centigrade; in winter (November, December, January, February,) 13.1° centigrade; in summer (March to November), 17.7°; lowest, in December, —2.5°; highest, in April, +30° in the shade, +35° in the sun; barometer at 0°, medium of six years, 586.80."n

Deaths from Anaesthetics in the Year 1883.—Dr. Ernest H. Jacob, of Leeds, furnished the British Medical Journal's table showing the deaths from anaesthetics that occurred in 1883. The list includes only England, however. The deaths from chloroform were eleven; from chloroform and ether, one; from nitrous oxide, one. The number of deaths is remarkably small compared with that of previous years, a fact due largely to the increased use of ether and greater care in giving chloroform.

A Rare Case of Suppurating Seraceous Cyst of the Umbilicus.—Dr. Walter J. Ransom, of Lockport, N. Y., writes that he was called to see a patient who had been suffering from pain about the umbilicus. The patient was a printer, unmarried, twenty-eight years of age, and had previously been healthy except for occasional umbilical pains. For about ten days he had had a bloody discharge from the umbilicus. "On examination," writes Dr. Ransom, "I found what appeared to be a polytoid growth bathed in a sanguino-purulent discharge. On gently passing a small probe around the growth I found it bleed very easily, and on palpation I found a cord-like swelling about one inch below the umbilicus, measuring about one inch below umbilicus, gradually receding from the surface; no sign of fluctuation was present, but it was very tender. Temperature and pulse were normal, tongue slightly furred. I applied pure carbolic acid to the apex of the growth, which consisted of proto-geranium tissue, and required him to come the next day or send for me if pain was worse. On the following morning I was called; found the patient up and dressed, but feeling quite sore; on examination I found a slight increase of tumefaction, and a decided increase of tenderness. I very carefully explored with the probe and immediately about half a drachm of pus appeared. I let it escape, and left a small dressing. Poultice applied hot, and renewed every hour; left the patient and called in P.M.; during the interval very little pus had escaped, and the pain (which I neglected to state immediately subsided after the pus was evacuated at my morning visit) had reappeared. I removed the tent and repeated the morning treatment, and again pus escaped. I then left tent out and ordered poultices continued, and left a preparation of morphia in solution, one-tenth of a grain to be given every half hour, if needed, to relieve any severe pain; also half drachm of opii tinct, to each poultice. I called on the following morning and found the pain quite severe. I also found that he had taken but two or three doses of the morphia, claiming that it made his head feel badly, and left directions to take 20 doses of opii tinct. every hour, if needed. I found considerable cheesy matter engaged in the opening, and cleared it away with my probe and explored the opening, which I found clear as far as I dared probe, which was about one inch downward and slightly inward. The opening being patulous and not very large, I concluded to introduce ten-drop size of morphia, and left directions to take 20 doses every hour. Notwithstanding their small size, on their removal there was quite profuse hemorrhage, which quickly subsided. I now looked upon it as a case of suppurating sebaceous cyst or tumor, which being deeply situated had escaped his notice. In view of the presence of pus
I thought proper to introduce a small drainage tube, and did so at my P.M. visit; it gave him considerable pain, and during the night the tube was removed. At my morning visit I found the pain severe, and more bad-smelling seaceous matter and pus. I directed more poultices and the adoneyx continued. This was about 7 A.M., at 11 A.M. I again visited him and found the swelling considerably increased and the patient anxious and alarmed. I separated the lips of the opening and gently pressed on the surface below the umbilicus, and out popped a large plug of foul-smelling seaceous matter, about one inch and a quarter long and one-third of an inch in diameter, partially inclosed in a sac. "The child was so frightened by the patient heaved a sigh of relief and so did the doctor, and now the case is progressing rapidly toward recovery."

A Woman with Four Mammary Glands.—Dr. W. E. Whitford, of Bossis, N. Y., writes that he was recently called to see a woman, aged thirty-eight, mother of five children, who was suffering from an abscess in one of her breasts. About three inches below the nipple, on each side, there were numerous mammary glands. After the examination these would become quite large and secrete milk for about two months.

Dental Hygiene at School.—According to M. Galipee, dental caries is frequent in boys and girls preparing for examination, and may be ascribed to the excessive efflux of blood to the head. Others suppose that the brain makes use of the phosphates which ought to be employed in the formation and growth of the teeth. M. Galipee states that dental caries is most frequent in young people who work hard, and are very successful in their examinations.

Medical Diplomas at Buffalo.—Dr. W. W. Potter, of Buffalo, N. Y., writes: "The well-deserved reputation of your journal for liberality and fairness in its treatment of all questions relating to the profession, whether involving individual, collective, or public interests, precedes the belief that you would willingly lend its columns to the cause of injustice, prejudice, or error. Nevertheless, in the weekly news column of your issue of April 12, 1884, appears an item with the above heading, which, if allowed to pass unchallenged, is calculated to do harm in all of the directions named. Let me briefly state the grounds for this assertion. At the annual meeting of the Erie County Medical Society, held January 8, 1884, a board of Censors was chosen, which consisted of the following named gentlemen: Drs. Edward Storck, F. F. Hoyes, H. R. Hopkins, P. W. Van Peyna, and A. H. Briggs. It is a well-known fact that the duties heretofore imposed by law upon the Boards of Censors of the several counties in the State, were swept away by the statute of 1880, known as the 'Medical Registry Law.' A Board of Censors elected since that time could, therefore, only exercise such powers as should be specifically delegated to it by special resolution of a county medical society. The Erie County Medical Society has not instructed its Board of Censors for 1884 to perform any duty whatever. A careful examination of the records made at a recent meeting of the Society, in the case of seventeen or more matters, disclosed this fact. The Board of Censors, acting for itself alone and without authority of the Society, has, however, seen fit to employ counsel in a so-called investigation as to the legality of the charter of Niagara University, which counsel has given an opinion apparently adverse to the legality of said charter. Moreover, this opinion was published in full in the columns of several of our leading daily papers, under date of April 5, 1884, and before the Society had obtained manual possession of the same, or even knew of its purport. It is proper to state in this connection, that the chairman of the Board, Dr. Storck, stated in a recent meeting of the Society, that he disclaimed for himself and for his associates any connivance in this premature publication of the report, and condemned the act in fitting terms. The same day the report was published (April 5th) a call was issued for a special meeting of the Society, to convene at Buffalo Medical College, April 8th, at 8 P.M., to hear the report of the Censors regarding 'pending legislation pertaining to the incorporation of medical colleges.' At this meeting above mentioned, the Censor found the Council hearing the report read, the writer moved to table such much of it as pertained to Niagara University, there being no authority for the same. This motion was lost by a vote of 35 ayes to 40 nays. The report itself received no further action at the hands of the meeting, which, after the transaction of some further business, adjourned sine die. Be it known that this is not the first time that the Council has been called to a new and different status of Niagara University: This institution was established last year under a charter granted by the Regents of the State, a special legislative act permitting the erection of its medical department in the city of Buffalo. The latter is organized in the interests of a higher standard of medical education. It has a three years' graded course, a preliminary examination for admission which includes Latin, and its graduates are required to pass the examination of a board independent of, and apart from the faculty. Its faculty consists of some fifteen or twenty well-known medical men, all members of the Erie County Medical Society, and other regular medical bodies, in good standing, and whose good faith and pure motives cannot be impeached. This much seems needed to be said, lest the Niagara University be confounded with a defunct medical college which fell to the ground last year, under a decision of the courts adverse to its legality."

Congenital Malformation of the Sterno-Mastoid.—Dr. S. Lillenthal, of New York, writes: "In The Medical Record of February 16th, Dr. Parks, of Ashton, R. I., publishes a case of congenital malformation of the stern-cleido-mastoid muscle. I had a like case a few years ago and followed Henoch's plan and nothing for it—and it disappeared entirely, although it took some time to do it. If the doctor will consult Henoch's Diseases of Children (Wood's edition, page 19), the doctor will find that this hematoma cannot be called exactly congenital, as it is a sequence of a tedious labor, and that they get well without much interference."

Why the Utah Medical Bill was Vetoed.—Dr. S. O. L. Potter, of Salt Lake City, sends us the following: "In your last issue you do a great injustice to the Governor of Utah by stating that he vetoed a bill to regulate the practice of medicine in this Territory at the solicitation of certain patent medicine men. Governor Murray vetoed the aforesaid bill in the interest of the regular medical profession, as the following facts will show. As first introduced, the bill gave the licensing power to the county judges (who are all Mormons), providing that any non-graduate desiring to practice should be examined by a board of examiners to be appointed by the said county judge, thus setting up a separate certificate factory for every county in the Territory. Before its passage (but after its publication) the bill was skillfully amended by inserting a proviso (I quote from the bill), that "the court may revoke the same (license) at any time for good and sufficient cause." Governor Murray believed that the indefinite term "good and sufficient cause" would (if law) place too much power over the Governor in the hands of arbitrary hands of the Mormon county courts. Hence the veto, and his action was supported by nine-tenths of the Gentile physicians and by some liberal-minded Mormon ones also, who did not believe that any hostile body should have the power by law to revoke a license, once duly issued, for any whimsical cause which, to the mind of a Mormon county judge, might appear to be good and sufficient."
Original Lectures.

ON THE METHODS OF STUDYING THE BRAIN.

ABSTRACT OF THE CARTWRIGHT LECTURES, DELIVERED BEFORE THE ALUMNI ASSOCIATION OF THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK, FEBRUARY 2, 4, AND 6, 1884.

BY BURT C. WILDER, M.D.,
PROFESSOR OF PHYSIOLOGY, COMPARATIVE ANATOMY, AND ZOOLOGY IN CORNWELL UNIVERSITY, AND OF PHYSIOLOGY IN THE MEDICAL SCHOOL OF MAINE.

(Continued from page 367.)

LECTURE III.

SOME POINTS IN ENCEPHALIC ANATOMY WHICH ARE NOT INFREQUENTLY OVERLOOKED OR MISUNDERSTOOD.

Continuing the discussion of colian circulation, the lecturer next considered the Endyma. By this term is herein designated the lining of the encephalic cavities. For present purposes it is not necessary to discuss its precise nature, or whether the above word is the right one to use. The coliae are certainly lined throughout by something which adheres closely to the parietes, whether nervous or only membranous, and which is reflected from the parietes upon the intruded pleoxuses so that these latter are in the cavities only in the sense in which the kidneys and other abdominal viscera are in the abdomen. In fact, the endyma is closely comparable with the pleura and peritoneum, and, like them, consists of a parietal portion and a visceral portion, the two being continuous at the points of entrance of the pleoxuses.

Whatever view may be adopted as to the microscopic constitution of the endyma, its continuity is absolute and unquestionable, excepting—apparently—at certain points in the roof of the metacele, now to be considered.

Foramen Magendi. It is commonly admitted that, in the adult human brain, the metata (roof of the metacele or "fourth ventricle") presents three orifices, one mesal and two lateral, by which the coliae are in direct communication with the subarachnoid space. As figured and described by Henle and by Schwabke, the mesal is rounded and near the tip of the colia; the lateral are longer and irregular, and near the flocculus at each side. The former is also figured in transsection by Kuechert and in longitudinal by Quain after Key and Retzius. Westbrook considers that the presence of an orifice is exemplified by the fact of material injected into the myelosubarachnoid space reaching the encephalic cavities. Allen and Gray do not mention the lateral orifices, and the latter states that the mesal orifice "usually" occurs.

In the days of Helkiah Crooke, or even Solly, no especial surprise might attend the supposed discovery of any number of direct communications between the encephalic cavities and the exterior of the organ. Now, however, the presumption is that the colian parietes are continuous, and the enus probandi rests with those who affirm the existence of the foramina of Magendie in either the cat or man.

Pseudocalyces. Since the "fifth ventricle" or "ventri-
ulus septi pellucidi" is, from the manner of its development, merely a portion of the interhemispherical interval which is intercepted between the callosum and the fons, the continuity of the caudal ends of those parts closes the space completely in that direction; in man, by the extension of the rostrum toward the terma, its cephalic boundary is also completed, and the cavity, according to Quain, contains liquid.

In man, and perhaps some other mammals, the corresponding portions of the mesal walls of the hemispheres become, or remain, thin and translucent, and the morphologically inappropriate name septum lucidum was given to them together. Each is thus a hemiseptum, and in the cat their thickness is such that the adjective has no application.

To the mesal or pseudocalyceal surface of each hemicsepum, Huxley gave the name septal area, the technical form of which is area septalis.

Whether or not this surface is devoid of epithelium (as stated by Quain), it seems proper to separate it from the true encephalic surfaces on the one hand and the ectocalyceal on the other, if only to emphasize the fact that the pseudocalyce, although simulating the true coliae, is in no time in communication with them.

The existence of an opening between the fornicolumen dorsal of the precommisur and leading from the third ventricle to the fifth, was formerly quite generally admitted, in the forbes at least (Tiedemann, Todd), and is credited in some recent manuals (Heath, Darling and Ranney, Harrison Allen, Gray), notwithstanding explicit denials by Mihalkovics, Henle, and perhaps others. In the last edition of Quain the facts are stated correctly.

Several years ago I satisfied myself that no such communication exists in the cat or in mammals generally, and so stated on several occasions. Although confident, from the nature of things, that any such orifice in man must be artificial, it is only recently that material has been at my disposal which, I believe, proves the existence of the fora calis in the brain of a young child. In the cat, when fresh, it has an almost gelatinous appearance, but becomes opaque in alcohol. It has not yet been examined histologically.

Crista. This is selected as an example of group a, because, while constantly present in the cat, it does not appear in the adult human brains examined by me, and has so far been observed only in the preparation of the brain of a young child. In the cat, when fresh, it is an almost gelatinous appearance, but becomes opaque in alcohol. It has not yet been examined histologically.

Terma ("lamina terminalis s. cinerea"). This is selected as an example of group a. Its existence and continuity are not generally recognized, but I have never seen it represented otherwise than in section, and usually it is shown as if quite thick, whereas it is very thin and quite transparent. As constituents of the encephalic parietes, and perhaps resembling closely the earlier condition of all of them, the terma and valvula merit more attention than they are apt to receive as components of an organ devoted chiefly to mental and nervous action.

Diataela, dorsal part of the diascollary parietes, or primitive roof of the third ventricle. In Quain it is correctly stated that "the third ventricle is roofed over by the epithelial lining of the cavities," the implication is, however, that, but for the fold of pia constituting the velum, the roof would consist merely of the epithelium.

1 From the peculiar relations and adhesions of the parts, it is very easy to make artificial openings through the roof of the "fourth ventricle," and I have not yet satisfied myself as to the existence of the Foramina of Magendie in either the cat or man.
There is no intimation of the primary existence of any proper diaceal roof, and the figure of a transection of the diacelae is not very distinct upon this point. In Gray the epithelium is not mentioned, while in "The Anatomy of the Head" it is described as constituting the "roof of the third ventricle." The transections by Reichert indicate, perhaps too distinctly, the separation of the fornix from the diacelian roof, for the presence and relations of the velum are not clearly shown. Certainly there is a general impression among medical men that the true roof of the third ventricle is the fornix, and that the velum and any possible epithelium are of no especial importance.

The origin and perpetuation of this impression are to be ascribed in part to the manner in which the hemispheres are commonly torn up from the thalamus, and partly to the non-recognition of the embryological facts that the mesial part of the fornix, like the callosum, is a later development; that the diacelae were already circumvated, and remains so when they are removed. It is true that in man and most of the higher mammals, in the adult state, the velum adheres closely to the primitive diacelae and sends intrusions through it in the form of plexuses; but in the frog these plexuses do not exist, in a young rabbit the fornix is seen to be uncomplicated, and in the adult cat, by being the velum may be pulled away, leaving the plexuses of course, but without tearing the diacelae from their attachments to the thalamus. Cephalad, the diacelae is attached to the fornix, and its epithelium is continuous with that which lines the aula and porte. The lateral attachment of the diacelae is along a line just dorsal of the habenae. In the rat there is the well known sulcus habenae, which I have not yet recognized in man. In general, however, in all mammals examined by me, the habenae indicates approximately the line of continuity of the atrophen diacelian roof constituting the diacelae with the hypertrophied lateral wall, thalamus. It thus also forms the boundary between the entocelal, endymal, mesial aspect of the thalamus and its ectocelal, pial, dorsal surface.

Is the thalamus a constituent of the procelain floor? A full discussion of this morphological question must be reserved for another occasion. The following is a summary of my understanding of the matter:

1. The fornix rests upon human anatomy a portion of the dorsal aspect of the thalamus is described as forming part of the floor of the lateral ventricle.
2. This idea is contrary to all the facts of embryology, and of the comparative anatomy of non-mammalian vertebrates.
3. In all the mammals examined by me, excepting Primates (man and monkeys), the margin of the fornix (limbus) is in close relation with the striatum, with only a small space between (rima) for the intrusion of the preplexus.
4. Hence the thalamus is wholly excluded from the procelain floor.
5. The brain of apes and monkeys have not been examined by me with reference to this point.
6. In man the fornix is relatively narrower than in most mammals. Its margin (limbus) is for some distance separated from the thalamus at the furrow (Sulcius limitans) between the striatum and the thalamus.
7. Consequently, a part of the dorsal surface of the latter appears to enter the procelain floor.
8. In all cases, however, the procelain endyma is continuous over the intruded preplexus, and thence to the thalamus and so upon the striatum. In some preparations this endyma is easily separable from the thalamus; when it adheres thereto, the line of rupture along the shallows groove (Sulcius choroidal of Schwalm) corresponding with the margin of the fornix, constitutes one of the ripsa.

The dorsal surface of the thalamus is thus in two divisions: pial or subfornical, and subendymal. The lateral margin of the former is the furrow just mentioned; its mesial boundary is the habenae or its sulcus already mentioned. The mesial surface of the thalamus is truly entocelal; the lateral portion of its dorsal surface is pseudo-entocelal; its mesial portion, like all the other surfaces, is pial or ectocelal.

In considering the dorsal surface of the thalamus, the distinction between the pial and the endymal portions should be indicated in some way, and with as much definiteness as is the distinction between the pial portion of the dorsal aspect and the endymal, mesial aspect.

5. Judging from the condition of the parts in embryos and in the lower mammals, this anomalous, apparent entrance of the thalamus into the procelain may be attributed to a disproportionate lateral growth of the dien; by which the thalamus and the endyma, at first separated only by the rina for the entrance of the preplexus, are moved apart, the endyma, however, extending itself pari passu so as to retain its continuity over the thalamus.

6. When the thalamus is described as entering into the composition of the procelain floor, some qualification should be added. Strictly speaking, such entrance might as well be ascribed to the cerebelum or a part of any other segment.

11. In order that the human anatomist may be satisfied respecting the circumscription of the procelain and the real exclusion of the thalamus, he would first recognize the segmental constitution of the entire brain; second, admit that the presumption is in favor of endymal continuity; third, study the brains of lower mammals; fourth, examine the human brain by other than the stereotyped methods.

SYPHILIS OF THE CENTRAL NERVOUS SYSTEM.†

BY L. PUTZEL, M.D.

NEW YORK.

My purpose in the present paper is to call your attention to the clinical history of various forms of syphilitic affections of the central nervous system, and to make a few remarks incidentally with regard to their diagnosis and treatment. To do this exhaustively would require a monograph, and I have limited myself to the presentation of certain of the more interesting and familiar types, taken from my history books.

The syphilitic virus, as you are well aware, may affect either the vessels of the brain and spinal cord, the nervous centres themselves, or their membranes. Syphilitic lesions of the brain itself, independently of an affection of the vessels or the membranes, are so very uncommon that their existence has been denied by many writers, but few authentic cases have been reported in the literature of the subject, and I have had the good fortune to observe such a lesion on the post-mortem table.

A striking peculiarity of the lesions of nervous syphilis is their irregular, disseminated character. Lesions of all the three structures mentioned above may be found present at the same time. It is not at all uncommon to find patches of syphilitic endarteritis in all or nearly all the vessels of the Circle of Willis associated with a gumma meningitis, a pachy-meningitis, or perhaps with a gumma tumor. This fact of pathological experience, which I have verified post mortem on a number of occasions, is of great importance from the standpoint of diagnosis, and consequently of treatment. It is a not uncommon affection of syphilis occur, in the majority of cases, during the tertiary stage of the disease, and perhaps many years after the development of the initial lesion.

It is also a peculiar feature of these affections that the secondary lesions of the original disease often are very

† Read before the New York Medical Society.
slightly marked, so that they have been entirely unnoticed by the patient, and he may be unaware of his infection with the specific virus. Reliance upon his statements, therefore, would be very apt to lead us astray. I would, accordingly, lay down as an important factor in diagnosis to be particularly well marked in every case of nervous disease in which the symptoms appear to be due to an organic affection and are grouped in an irregular and anomalous manner. Not that this is true of the majority, or perhaps even of a large proportion of cases, because many of them present a clinical history of monotonous uniformity. But the feature referred to has seemed to be particularly well marked in those cases in which the previous history of the patient has aroused no suspicion of the existence of syphilis. In fact I have often thought that those cases were most severe in which the secondary symptoms of syphilis had been remarkable chiefly by their absence—as if the syphilitic virus had reserved its energies for a final onslaught upon the nervous structures.

I also wish to make a few remarks concerning the great importance of headache in the diagnosis of cerebral syphilis. There are perhaps few cases of cerebral syphilis in which headache has not been a prominent feature at some time during the course of the disease, and it is very commonly observed at the very onset, before the development of any other symptom indicative of a serious implication of the nervous centres.

The headache of syphilis is usually characterized by a number of circumstances which of themselves should put us on our guard as to the true nature of the malady, apart from the previous occurrence of infection. This headache is usually localized in the temples, though it may be severe over the entire cranium; or, on the other hand, confined to a very small part of the skull, as in hysterical clavus. While the patients tell us that the pain appears to be seated in the bones, they also tell us that it extends inward, as if situated in the brain tissue itself; furthermore, the pain is usually of a dull, boring, pressing character, with marked nocturnal exacerbations as a rule, though like every other rule in medicine, there are a number of exceptions. It is also a peculiar feature of syphilitic headache that, unless subjected to proper treatment, it is apt to last without intermission for several months, and, under these circumstances, is usually complicated after a little while with impairment of memory or other evidences of enfeeblement of the mind. This complication, so far as I have observed, is a constant and a prorome of the most serious affections of the brain, that a patient suffering from it should be looked upon as already having an organic cerebral lesion, and should at once be placed upon antisyphilitic remedies. As a rule, the headache will soon yield to such measures, but we should not be satisfied even with its entire disappearance. The treatment should be continued uninterruptedly for at least a year after the disappearance of the last symptom. If this is not done the chances are strongly in favor of a relapse—and this time perhaps with graver and more permanent symptoms.

Perhaps it will be well to say a word here with regard to the etiological relations of syphilis and locomotor ataxia, a relation which has been brought prominently before the profession by Vulpian and Fournier, and has also been ably advocated by Erb. Despite the great weight of the opinion of these authorities, I am forced to declare that in the majority of cases in my experience either in capital or private practice, although careful search has always been made into the existence of previous syphilitic symptoms, they have been found in only a small portion of cases. A strong point against the syphilitic character of ataxia consists, to my mind, in the fact that the lesion of the latter disease is a systemic lesion, while all the other syphilitic lesions of the nervous system affect the tissues in an irregular manner. Another powerful argument consists in the uselessness of anti-syphilitic remedies in the treatment of ataxia. At all events, though I have employed these remedies for long periods and in large doses, I have yet to find a single case of ataxia benefited by them in any noteworthy extent. And the true view of the subject is in which the patient presented merely the lancinating pains and the absence of the patellar reflex, while true ataxia was still absent. But opinions on this question are so conflicting in their nature that it must still be regarded as an open one.

In the treatment of nervous syphilis our sheet-anchor is the use of iodide of potassium and mercury. In the beginning of my practice I relied almost exclusively upon the iodide, but I soon found that smaller doses of this drug, if combined with mercury, produced more rapid and better effects. My measure of the dose of the iodide which should be administered is the effect upon the nervous manifestations and the general condition of the patient. If the stomach is not irritated to such an extent as to interfere seriously with digestion, or if anemia and rapid loss of vitality do not result, the remedy may be given in rapidly increasing doses until our object is effected, viz.: the improvement of the symptoms. We should not falter at the enormous dose which is sometimes necessary to effect this object; in desperate cases I have frequently given an ounce a day. As soon as improvement is perceptible, the dose of the iodide should be gradually reduced. Another caution may not be out of place. The urine should be frequently examined during the administration of large doses of iodide of potassium, as cases have been reported in which acute nephritis has been produced. Without further preliminary remarks, I will now turn to the case histories of which I have abbreviated as much as possible, in order that their perusal might not prove too tiresome.

CASE I.—J. O——, aged twenty-nine years; family history unimportant, except that an aunt suffered from epilepsy. About three years ago he contracted gonorrhoea and soon afterward a chancre. No constitutional symptoms developed until two years later, when, his hair began to fall out and mucous patches appeared in the throat and mouth. Four or five months later he had intense headache at night and pains in the bones. At this time he would sometimes fall, on account of weakness of the lower limbs, and could get up with difficulty. At times his gait was unsteady, and his ideas of distance and proportion were imperfect, so that he was afraid to go on horseback, which he intended to pass. There was no trouble if the object was on his left side, but if on the right side his miscalculation would amount usually to about a foot. After while he learned how to make the proper allowance, and then met with fewer accidents. For four or five months previously he was unable to discharge his urine satisfactorily on account of lack of expulsive power, and if the bladder became distended, overflow resulted. There was also imperfect control over the bowels. At the end of two months he was slightly improved, with the exception of the bladder and bowels, and returned to work, still continuing under antisyphilitic treatment.

On October 8, 1851, while in a wagon on the right leg, and while at the table patient found that he could not raise the right hand to his mouth. He would drop articles of food, and would put them past his face on either side instead of into his mouth; but retained sufficient power to cut meat with this hand. Fluids dribbled out of the mouth on the right side, and the food had a tendency to collect in the right cheek. Sensibility was diminished in the right hand.
The inability to speak was due to a loss of words as well as to the difficulty in articulation. During the afternoon the power of speech improved somewhat. In the evening, when trying to pass to the left of an object, he would find it right before him. At this time the apathy was complete.

On the next day he was able to express himself to a physician, though in an indistinct manner; power of locomotion unimproved. Reading would be forgotten as soon as read. From time to time there was some tremor of the right leg.

On the following Friday he had improved so much, both as to mental condition and walk, that he began light work; then tried to do hard work, but found it too laborious.

Present condition: October 29, 1881.—The right arm is appreciably weaker than the left; dynamometer: right hand, 45; left hand, 53. The measurements of the limbs are equal on the two sides. Patellar reflex and ankle clonus increased on both sides. Tactile sensation is normal on both sides of body; sensation to pain is much diminished over the entire right side, with the exception of the shoulder, thorax, arm, and dorsum of the forearm. On the left lower limb there is diminished sensibility to pain and delayed conduction, so that when pricked with a pin the patient feels two sensations; the first is the pain, and the second after a considerable time, is the sensation after the first to be distinguished separately, is painful. Electrical reactions normal. Patient states that some aphasia still remains, though it is not evident; is not able to add a column of figures at sight as formerly; walks stiffly with a cane.

Notes taken February 27, 1884, show the following conditions: The right arm is now stronger than the left; the dynamometer readings are 74 for the right hand, 65 for the left hand. In fact, no loss of power can be detected in the upper limbs. The patient walks without the aid of a cane, but the right leg is weaker than the left, and is dragged somewhat. There is slight paresis of the power of flexion in the right knee when he walks fast, and the right foot grows cold. The patellar tendon reflexes are exaggerated, and ankle clonus is marked on both sides. Sensation is normal throughout the body, except in the right leg, where it is a little delayed. The bladder is very much improved. In other respects the patient feels quite well, and nothing abnormal can be discovered now.

It seems to me hazardous to venture upon the diagnosis of the exact localization of the lesion in this case. The coexistence of aphasia and right hemiplegia of motion and sensation would point to the left middle cerebral artery as one of the sites of disease. In the absence of a personal examination of the patient at the time when he was suffering from the peculiar affection of vision referred to above, I am unwilling to offer any explanation of the phenomenon, though I presume it was due to ocular paralysis. At the present time the lesions, wherever they may be located, have evidently resulted in a slight descending degeneration of the lateral columns of the spinal cord, and, to judge from my past experience of this condition, the chances of further improvement are very slight indeed.

Case II.—E. C., aged thirty years, entered the hospital November 9, 1880; has never indulged in strong drink. Four years ago he contracted a chancre; he then continued well until two years ago, when he contracted another chancre. This was cauterized a week after its appearance; the malady was over in three months, but the sore did not heal until three months after cauterization. Denies having had any eruption; about a year ago he had ulceration of the nose and hard palate.

Last June he suddenly fell unconscious, and remained in this condition for about an hour. In falling he struck the back of his head against the edge of a wash-tub, and has suffered since from a feeling of soreness at the point of contusion. This is worse at night and when he is excited. He has had three subsequent attacks of unconsciousness similar to the first. He felt as well as usual before and after the attacks, resuming work as soon as consciousness was regained; did not bite his tongue during the attacks. Does not think that he had convulsions.

Present condition.—Patient is apparently well nourished; appetite poor, bowels very constipated. No trouble with the bladder. Heart and lungs normal. The hair of the scalp is thin, and has been falling out for about two years. Tenderness of the shins and sternum; several cicatrizes upon the penis. Also has a cicatrix on the roof of the mouth. Suffers from frontal headache every night. The pupils are equal and respond well to light. Field of vision not diminished in either eye, but eyesight is slightly impaired in left eye. Has no trouble in walking, and thinks he is as strong as ever. Motion and sensation normal throughout the body. His face has a vacant and indifferent look. There is considerable mental obtuseness, and it takes several seconds for him to appreciate what is said to him. He is very slow and deliberate in his answers, and does not always finish a sentence. Memory is very poor. He has had attacks of mental aberration nearly every night during the past month. During these attacks he talks incoherently, and gets up without his clothes and goes out in any apparent object in view. When spoken to during the attacks he regains his usual senses and soon falls asleep.

The patient was placed under antisyphilitic remedies, and soon improved steadily in all respects, so that he was discharged cured, and at his own request, on February 24, 1881, after having been under treatment for three and a half months.

This is an illustration of what may be called the mental form of the disease, and the symptoms are probably the result of some diffuse lesions, perhaps involving the cortex of the convexity of the motor region. There is very little doubt in my mind that the patient is not permanently cured, and that unless treatment is steadily continued by him for a couple of years (which is highly improbable), a relapse will occur sooner or later, attended with more serious symptoms.

Case III.—September, 1878, Annie D., aged thirty years, had chancres and bubo at the age of fifteen years; secondary symptoms (eruption, pains in shins, alopecia) five years later; has always been a heavy drinker. Last November had an attack of right leg, and a burning pain in the calf. In December began to have convulsions. In the first two or three she did not lose consciousness, but did in the subsequent ones. Has had twelve attacks between last December and July of this year. They were all confined to the right side, beginning with twitching of the fingers. This gradually spread upward, and then the patient lost consciousness. Her friends informed her that on two occasions the convulsions became general. After the third attack (last January) the right arm became paralyzed and felt numb. At the present time dynamometer shows right hand 25, left hand 85. The sensation in the arm is normal. This patient was placed on antisyphilitic treatment; she has improved except when recovery was interrupted by her devotion to the bottle and failure to take medicine regularly. I saw her again about a year later, and all the symptoms had disappeared.

The symptoms in this case are those of typical syphilitic cortical epilepsy, due in all probability to a gummy meningitis, and the patient was treated with pachymeningitis in this region. Such a lesion should always be suspected in every case of repeated unilateral convulsions, which always run the same course, especially if the attacks are preceded by an aura on the same side of the body as the convulsions, and if paralysis of the same side gradually supervenes after a number of seizures. In many instances also it will be found that each convolution
THE MEDICAL RECORD.

April 26, 1884.

is followed by a partial loss of power in the parts subject to spasms, but this paresis disappears in a period varying from four to eight hours, to several days. Even if no history of syphilis can be elicit, in such cases it will be well to institute an antisyphilitic course of treatment.

Case IV.—J. O., aged thirty-three years, admitted to Randall's Island Hospital, September 19, 1884. She has been a hard drinker; had six children, all of whom died at the age of two to four years; denies venereal. Two years ago, diplopia developed, with burning in right eye; then the face around the right eye began to swell, with shooting pains in eyeball and head, and the parts have remained swollen ever since. At the outset noticed anesthesia of right side of face; at end of six months marked hyperesthesia of upper half of right side of face and anterior half of right side of scalp; this still continues. Pain and ringing in right ear from the start; more or less deafness in this ear for past two to three months. About a year ago the legs, particularly the right one, began to grow weak; two months ago the right arm grew so weak that patient had to give up work.

Present condition.—Marked swelling of right side of face from lower border of the malar bone to upper part of right side of scalp and forehead. Perceptible dragging of right leg around the right side of the body. Ptosis of right side of face. Eye normal. Dr. Cocks states that the right optic nerve shows evidences of neuritis. Taste and smell; markedly diminished on right side. Motion; considerable loss of power in right arm; dysmetria of right arm; 22, left hand 40. Slight paresis of right lower limb.

Sensation.—Marked diminution of tactile sensation in right upper and lower limbs, and abolition of sensation in tips of fingers and toes. Slight diminution of sensibility on right half of trunk; abolition on right cheek below a horizontal line drawn from lobe of ear; exquisite hyperesthesia above this line. Cutaneous reflexes abolished on right side.

Diagnosis.—Syphilitic (?) periotics of the cranium and face, corresponding to the tumefaction; endarteritis of left middle cerebral artery, producing softening of interior capsule. Ordered: Kali. iodid., gr. xv., and hydrargyri bichlorid., ss gr. t.i.d. Marked improvement in two weeks.

October 13th.—Sharp shooting pains in left leg, which kept on increasing.

October 20th.—Increased cutaneous reflex in sole of left foot; with exception of nip-joint, the joints of left leg are tender when pressed together. Tenderness over transverse processes of left side, middle of dorsal region to upper border of coccyx. Marked hyperesthesia over left side of trunk, beginning above at middle of dorsal region, and also over left lower limb. Tumefaction on head rapidly disappearing. Dose of antisyphilidea doubled, and actual cauterity applied, every second day, over transverse processes of spine on left side.

November 8th.—Iodide of potassium increased to 3 j. t.i.d.

November 12th.—Pains in limb have disappeared; patient markedly improved, except special senses, which remain in status quo.

December 2d.—Patient discharged.

The symptoms which developed late in the left leg may be attributed to spinal pachymeningitis below the middle of the dorsal region. In this case no direct history of syphilis could be obtained; but the occurrence of periotics without any known cause, the irregular distribution of the cerebral and spinal lesions, and the prompt response to antisyphilitic treatment, justify the assumption of the existence of constitutional syphilis.

In this connection I am happy to be able to quote such an eminent authority as Buzzard, who says: "I should not take much account of this absence of evi- dence if there were other reasons for strongly suspecting syphilis, for we are continually meeting with cases in which the symptoms caused by lesion of some part of the nervous system constitute of themselves the only testimony to the specific nature of the disorder, and experience shows these to be quite as pathognomonic as affections of the skin."

BULBAR SYphilis.

Case V.—December 18, 1883, Julius L.,—forty-seven years of age; has been a heavy drinker at times; had gonorrhoæa; has a very suspicious pigmented eruption over both lips, and some cicatrices over the chest and back, which I consider indubitable evidences of syphilis. Considerable headache for past three years. Beginning of July, 1883, was affected by heat (?) ; went back to work on next day. July 26th suddenly complained at night of severe pain in left arm, and at twelve o'clock was seized with a fit which began with twitching in left hand, spreading to left side of face, when he lost consciousness; convulsion limited to parts mentioned and lasted about two hours. Since that time has been unable to work, except one week. Has had about nine fits of character described above, the leg never being involved. At last one was accompanied by delirium, and patient delirious, and was kept in a straight-jacket until morning. Speech almost lost for an hour after the attacks, but patient knew what he wanted to say. Has had a large number of attacks of twitching of left arm or left side of face without loss of consciousness. Last week had similar attacks in right arm. Yesterday and to-day right half of face and arm twitched (eight or nine times). Two weeks after he was taken sick had intense pains in soles of feet, lasting about three weeks. They began about 3 p.m., and lasted during the night; then had a peculiar dread come over him, as if something were going to happen. After the pains disappeared memory became normal very promptly, but right arm felt very strange. Would sometimes walk around room all day, fumbling in his pockets as if looking for something. At times spoke incoherently.

Present condition.—Special senses normal; arms equal in strength, but rather weak for a man of his strong build; walks normally. Upper facial movements normal; lower muscles appear partially paralyzed only part of tongue appears to act rather slowly; memory very much impaired; cries very easily; expression of face dull and lethargic. Tongue freely movable, except upward and downward, which is almost impossible; slight twitching of tongue on protrusion. Speech slow, thick, and hesitating; this has increased during past week. Sensation normal throughout.

On first examination urine contained large amount of sugar and considerable albumen. December 19th, 4 qts. urine, 10 grs. sugar to the ounce; December 24th, 2 qts. urine, 2 grs. sugar to the ounce. December 17th, the patient was ordered iodide of potassium 3 j., t.i.d.; December 20th, 3 iss., t.i.d.; December 24th, 3 iss., and bichloride of mercury gr. ¼, t.i.d. December 29th, sugar disappeared permanently; January 10th, considerable albumen; January 15th, no sugar or albumen. Has had no spells since December 26th; speech has improved very markedly, so that nothing is noticeable now, and memory improved to such an extent that he has returned to business. On February 23d I made another examination of the urine, and found no sugar, but a large amount of albumen. The mercury and iodide of potassium were then discontinued and the patient placed on digitalis and acetate of potash.

March 1st.—The quantity of albumen in the urine has diminished very much, but a moderate amount is still present.

March 8th.—Less amount of albumen present than at last examination; no casts; urine otherwise normal.

March 25th.—At 2 a.m. the patient, while asleep, was suddenly seized with a general convulsion, attended with...
loss of consciousness. He rose early and dressed himself, but was then seized with another convulsion, and a third one at 9:45 A.M. I saw him at 10:30 A.M.; he was unconscious, the pupils were moderately contracted. Convulsive movements were noticeable in the left part of the face, involving the right side of the face and the tongue, which kept twitching from left to right. The coma persisted until the next morning, when the patient became violently delirious, and attempted to jump out of the window, choke his brother, etc. During my visit in the afternoon, consciousness was partially restored for a few minutes. On the following day the patient was entirely rational, and complained of nothing except a general feeling of soreness. During the period of coma I ordered rectal injections (the patient was unable to swallow) of a drachm of iodide of potassium dissolved in an ounce of water every two hours. After the attack, albumen reappeared in large quantities in urine (nearly a quarter by volume), but this is gradually diminishing. For the past three weeks mercurial treatment has been used exclusively, and the patient is now in better condition than before the attack, even with regard to memory; he is now attending regularly to business.

In this case the lesion, in part at least, is evidently situated in the region of the medulla oblongata, and probably consists of small spots of softening due to endarteritis of some of the small vessels. The absence of symptoms except a general feeling of soreness may have been due, perhaps, to slight changes in other vessels of the brain.

The case is interesting on account of its extreme rarity, and Fournier, despite his enormous experience, has never observed a case of diabetes in cerebral syphilis. In my opinion the albuminuria is due to the same lesion, as, I think, a renal affection may be excluded by the non-existence of casts (a large number of careful examinations were made), and the absence of cardiac hypertrophy or other signs of Bright's disease.

SPINAL SYMPHILIS.

CASE VI.—A. C., aged forty-six years; in November, 1880, had a sore throat which lasted until the beginning of March; had alopecia in the summer of 1881. In April, 1882, noticed that when the right foot was put on the floor the matting seemed very warm; then had soreness of the skin of the right side of chest, belly, and back, and this kept on increasing until pain became intense, especially over the right arm and hand. Then noticed a little loss of power and stiffness of the left leg; at the same time was unable to pass water freely. Under the use of iodide of potassium the pains disappeared almost entirely, but he became unable to hold his water. After a few weeks the lameness of the left leg again appeared, and grew gradually worse until August, 1882, when he became unable to walk. The present condition—Head and arms normal; about three-fourths inch atrophy of left leg and thigh. Almost complete paralysis of left toes; slight power of flexion of ankle and knee. Sensation in this limb fair, but patient does not differentiate very distinctly the head and point of a pin on the sole of the foot. Right limb shows a fair amount of power; is not quite up to the normal (possibly from poor general condition of the patient). Tactile sensation markedly diminished over entire limb, also moderate amount of analgesia. The anesthesia extends up the right side of the abdomen to the floating ribs, and posteriorly as high as the middle of dorsal spine; no distinct zone of hyperesthesia above the region of anesthesia. Severe pains in the back and lower part of the chest, particularly at night. Very little control over bladder; has had several involuntary evacuations from the bowels. Examination of urine showed existence of cystitis. Patient had violent attack of gastric catarrh, with a temperature of 104°. After this disappeared under ordinary treatment, a mixture was given of iodide of potassium, tincture of belladonna, and ergot, 3d. t.i.d. The latter was increased to one drachm, but discontinued at the end of a month. Kali. iodid. gradually increased to

3 liss. t.i.d., and October 15th combined with hydrarg. bichlorid. 3 gr. t.i.d., and increased gradually to 5 gr. At the beginning of October, strychnina 1 gr., gradually increased to 3 gr. t.i.d. Dry cups were applied to the back in the morning for three weeks, followed by intermissions of a week.

The power of the limb slowly improved, but at the same time spastic symptoms developed in both limbs, particularly the left. Enormous increase of patellar and Achilles tendon reflexes, also on tapping the front of tibia. Frequent twitching of the limbs at night. Improvement in few hours after application of plasma and Bouillaud's solution; for two weeks when patient had a marked relapse on account of disobedience of orders concerning the amount of exercise taken), with the exception of the rigidity of the limbs, particularly the left one.

During the past month the patient has been placed on an exclusively mercurial course (bichloride of mercury, gran. t.i.d.) and the rigidity of the limbs and intensity of the tendon reflexes have diminished very considerably.

This case is an interesting example of the rare form of disease known as spinal hemiplegia (more properly, in this instance, hemiparaplegia) and is undoubtedly due to a myelitis limited to the left half of the cord in the middle dorsal region. The symptoms and signs would seem to indicate that the circumscribed myelitis has been caused by the pressure of a gummy pachymeningitis in this region. I am sorry that lack of time has prevented me from entering more fully into the details of this case.

PRIMARY CRURAL ASYMMETRY.

BY HENRY LING TAYLOR, M.D.

NEW YORK.

There is a natural equilibrium between the two great and opposing biological forces, namely, the centripetal one of heredity, tending to preserve the type, and the centrifugal one of variation, tending to modify it. In studying the evolution of the human form we find that civilization and refinement come in as disturbing factors, favoring variation.

It has long been known that the human form is not strictly bilaterally symmetrical. We are right- or left-handed, i.e., the right or left side of the body is more powerful, more skilful and larger than the other. Photographers and portrait painters accept the fact that the lateral halves of the face differ in form and expression, and pose their subjects accordingly. I have somewhere seen curious statistics concerning the relative lengths of the index and ring fingers on the two hands, showing that in some persons the index fingers were longer, in others the ring fingers, while many had a longer index finger on one hand and a longer ring finger on the other. The caminero of a few hands will show any one that there is no uniformity about it. A gentleman to whom I spoke of this subject, gave a singular illustration on his own person. He said he had always been annoyed in wearing spectacles by the circumstance that one of his ears was so much higher than its mate that the frame never rested evenly on his nose.

Although these or similar facts have long been known, the medical profession was quite taken by surprise when it was announced, a few years ago, that it was not very uncommon for persons, not the subjects of disease or injury, to have lower extremities of unequal length.

This discovery was made by some of the surgeons of the Pennsylvania Hospital while studying parasitical results in the measurement of both legs after fractures of the femur.1

The fact has been known and recognized in the treatment of cases by Dr. C. Fayette Taylor (from whose practice I shall draw my illustrations) for about fifteen years, having been observed by him independently of its discovery by others, and while studying quite a different class of cases, namely, those of lateral curvature.

Before going further, I wish to emphasize the fact that, far from being a simple matter, the accurate measurement of the extremities, even where there is free joint motion, is extremely difficult. Sufficient proof of this is afforded by the frequent instances of wide differences in the results obtained by even eminent surgeons in the measurement of the same case, and I could adduce curious and striking examples of this, if it were worth while.

In undertaking to measure the lower extremities of a recumbent person, the first object must be to level the pelvis. We must see that a joining the anterior spines of the ilium cuts the median plane of the body at right angles, and this relation must be preserved while the measurement is being made. Merely to drag down by the feet and observe whether the soles are on a level, gives one no information whatever. It follows that an assistant to hold the pelvis straight is desirable, if this method be employed. The hope for many years has been that something more satisfactory, even when proper precautions are taken, and a number of instruments have been devised to take its place.

No instrument, however, can obviate the main difficulty, namely, the absence of definite corresponding points between which to measure. Sir James Paget, with his usual directness, wrote a letter to the Lancet, dated February 5, 1875: "I very rarely use measuring tapes or anything but the eye. The eye is surely more exact."1

Dr. Taylor has employed for many years the following method, which is at least as accurate as any other, and perfectly easy to apply. The patient, barefooted and without clothing, is placed on his back, with the examiner in a seat at the head. Care is taken that the heels are near together and the knees straight. If, after careful inspection of the contour of the hips and loins, which alone will nearly always reveal the presence or absence of crural asymmetry to the trained eye, while the patient stands upright, the edges of two equally thick rulers, or the radii edges of Medical Science, are pressed against the trochanters and the just above and, guided by the iliac crests, any difference in their level will be easily appreciated. If there be a difference, its amount may be determined by placing increasing thicknesses of thin pamphlets, or similar objects, under the foot of the short side, until the two hands of the examiner, pressing against the iliac crest with a light touch. Now that the thickness of the pamphlets be measured, we shall have quite an accurate notion of the amount of shortening. This method presupposes that the acetabula and ischia are vertically symmetrical, and I believe they approximate nearly enough to this standard not to invalidate results obtained in this way, and, at any rate, the amount of pelvic obliquity is the really important point to be ascertained. This method is not equally applicable in all cases, but it is simple, convenient, and sufficiently accurate for the cases uncomplicated by joint troubles or paralysis, which we are now considering.

The measurements which I shall now proceed to give were mostly found by this plan, though some were obtained with the tape in the usual way, and in a few cases both methods were employed. I, myself, have seen and measured a good proportion of the cases given, the others are taken from notes scattered over the last six years. The notes were not systematically taken, and the cases given do not include a great many seen where no note was kept. Many of the cases have been under observation for several years, and have been repeatedly measured. A dozen or more have been photographed, and here the lateral tilting of the pelvis is easily apparent, and also the improvement of the form when the pelvis is horizontalized. I have taken no account of differences of a fourth of an inch or less.

The cases have been drawn from all parts of the United States and Canada, and represent the well-to-do class.

[Since compiling the above table, two months ago, I have seen two cases of primary crural asymmetry in females of sixteen and twenty-five years of age. The left leg was half an inch shorter in the former and an inch and a quarter in the latter.] P e e n t s will be seen by the table this study has been mainly directed to young people (mostly girls) in the growing period. Of the thirty cases whose ages are known, all but three are under twenty years of age, and of the entire number all but six are females.

The left leg was shorter in twenty-eight cases, the right in four. This is a very striking result, and one directly opposed to that of Dr. Wight and others. It will have a bearing in the discussion later on.

Another striking result is the large size of the difference found in most cases. It is not a question of eighths or fourths of an inch; in sixteen cases the difference is over half an inch, and in six it is an inch or more.

Crural asymmetry does not seem to depend on the rate of bodily growth. Some of the patients tabulated had grown rapidly, others slowly, while many had developed at about the average rate. No. 21, a young man of sixteen, whose left leg is an inch shorter than its mate, rather more than less, is only fifty-eight inches tall. The majority of these children compare well with others of the same age and circumstances, in respect to general health and development. Many of them, however, have imperfect and asymmetrical chests, partly due, in many cases, to changes secondary to pelvic lateral obliquity. Out of a few measurements made, I have found a difference in the length of the arms, measured from the tip of the acromion process to the end of the middle finger, in two cases. In Case 12, the left arm was 8 inches shorter than the right, and the mother had noticed that

1 Dr. T. M. L. Chrysis remembers a particular case of this kind in Dr. Taylor's practice, in which case it was 9 inches, and the patient was then reclined. Dr. Chrysis and other cases were shown by Dr. Taylor's office before.  
2 Wide-The Medical Record, August 6, 1871, Dr. T. M. Howgate; Am. Jour. of Medical Science, 1879, Dr. Stacey B. Collins; Lancet, April 27, 1878, Charles Roberts, F.R.C.S.  
4 Dr. Frank Hamilton found the left limb longer in most cases (letter to Dr. Wight). Proceedings Medical Society Country Kings, quoted in the Lancet, April 6, 1870, page 306.  
5 Dr. Charles Roberts, in the Lancet for April 27, 1878, says: "The limb in these cases was the left, and the right limb shorter in the majority of their cases. These results were obtained in males, and all but Dr. Morton's mostly in adults.  
6 Out of 623 cases reported by Drs. Cony, Wight, and Morton, there was asymmetry in 390 cases, but this amounted to more than half an inch in only twenty-eight cases.
in fitting dresses for her daughter she had always been obliged to shorten the left sleeve. In Case 13, the right arm was found to be 8 inch shorter than its mate, though the left leg was the shorter.

Accurate measurements of the length of the arms are even more difficult than those of the legs, which is the less to be regretted, as moderate inequality in the lengths of the upper extremities is of no practical importance. I have noticed that in a few of these cases there seemed to be a general ill-development. The chest and loins were asymmetrical and the former flat or narrow (I am not now speaking of the effect of secondary lateral curvature), the whole form devoid of grace of line and movement, and the circulation poor, as shown by cold feet and hands, bluish skin, and “goose-flesh.” These were apt to have particularly intellectual parents.

How do these cases come under the notice of the practical physician? What do they come for? In most instances the parents’ attention is attracted by some of the evidences of a lateral spinal bending, due to the pelvic obliquity. It is a drooping or bulging shoulder, a peculiar attitude of the body or head, or an abnormally curved spinal column that leads the patient’s friends to seek a physician’s advice.

In other cases it is a peculiar or awkward gait, or an undue tendency to stand on one leg. In Case 30, a single lady of thirty, the simple question was, “Why do I tire so easily in walking?” The 44 inch difference in the lengths of the lower extremities found answered the question. It is not easy to walk constantly along a side hill. In spite of this considerable difference this lady had no lateral curvature.

This brings us to the practical core of the matter. Crural asymmetry is chiefly important from the pelvic obliquity which it necessitates, giving as it does a strong bias in the growing period, when there is increased flexibility of the spinal column, toward a lateral curvature. I say a “bias,” because if the spinal column and muscles be exceptionally strong this tendency will be resisted, and the patient once tided over the vulnerable period—pubescence—the danger is over. The accompanying figures (1, 2) show how a lateral curvature must ensue (Fig. 3), which, as it necessitates the carrying of the head and shoulders toward the opposite side, to preserve equilibrium, enables the patient to stand and walk with a straight back. The following case walked and stood in the manner described: No. 31, aged forty-three, the father of a little patient under Dr. C. Fayette Taylor’s care for hip disease. While Dr. Taylor was examining the little girl one day, she suddenly exclaimed to her father, a large, well-developed man, “Why, papa, you walk with one leg straight either!” On looking at the gentleman Dr. Taylor detected pelvic obliquity, and on examination discovered an inch difference, yet there was no lateral curvature and the gentleman had been entirely unaware of his abnormality.

Pelvic obliquity, however, in the vulnerable period is a threat against the symmetry of the spinal column, and it is to be diligently guarded against. The simple remedy is to place sufficient extra sole under the shoe of the short side to level the pelvis. In cases taken early, before there is any permanent curvature, i.e., when, the spine can be as easily bent and rotated in one direction as the other, levelling the pelvis until growth is attained is often sufficient to prevent deformity, though not always so, as children without a latent lateral curvature. When a permanent curvature is already present, levelling the pelvis should be only accessory to mechanical means, and is never in itself sufficient. After the patient has attained her growth, the danger of lateral curvature is passed and the high sole may be discarded, unless, from excessive difference in the length of the limbs or from a susceptible pelvic system, the unnatural walking be too great a tax on the strength.

There is a common and ignorant prejudice, that the wearing of a high sole will tend to make the leg still shorter. It is hardly necessary to observe that the leg cannot be driven into the body like a pin into a potato, and it is hardly reasonable to suppose that a pelvis which, by restoring pelvic horizontals, puts the muscles into their proper relations and permits of the leg being used to the greatest advantage, would involve a retardation of growth. But what is more to the purpose, I can adduce an instance of the contrary effect.

Case 3 came at twelve, with a difference of over three-fourths inch. She wore the high sole for a considerable time. At seventeen years of age the difference had so diminished as to be barely perceptible. Similar instances have been observed. Secondary crural asymmetry due to joint or bone disease, or paralytic retardation of growth, of course, involves pelvic obliquity and its accompanying dangers. Many of the points made above apply with equal force to these cases.

In concluding, I must urge the importance of determining the presence or absence of pelvic obliquity as a necessary preliminary to the treatment of every case of lateral curvature of the spine.

There is an almost uninterrupted procession of these cases coming to our office, who are wearing or have worn plaster jackets or mechanical appliances to straighten the spine when the attempt was about as hopeful as that of the traditional individual who tried to lift himself over a stone wall by pulling at the straps of his boots, unless the sloping pelvis was first made level.

I also wish to call attention to the light which these cases throw on the etiology of lateral curvature, though I have no time to develop this subject here. Dr. C. Fayette Taylor estimates that half the cases of lateral curvature, as met with in his practice, occur with a sloping pelvis. In these cases, certainly, the primary curve is in the lumbar region, and he believes this to be equally true of all ordinary cases.

Does not the large preponderance, in the table, of instances where the slope is to the left, explain, partially at least, the long-recognized fact that in the majority of cases of lateral curvature the convexity of the dorsal curve is to the right, the lumbar to the left?
A CASE OF DISTORTION AND CICATRICIAL STENOSIS OF THE TRACHEA, FOLLOWING THE PROLONGED USE OF A TRACHEOTOMY TUBE.

BY GEORGE M. LEFFERTS, A.M., M.D.,
PROFESSOR OF LARYNGOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

During the past two or three years attention has been so frequently, forcibly, and I may be permitted to add, so rightly, called to the dangers incident to the prolonged sojourn of a tracheotomy tube within the walls of the trachea after the operation, and the subject is in itself one of so much importance, that it is hardly receiving as yet, if we may judge from the published reports of even recent tracheotomies, the general attention that it merits, that the following practical illustration of these dangers will not be without value as a warning.

Literature concerns itself mainly with the immediate— as far as the trachea is concerned—bad results of the operation, or, perhaps better, its dangers, viz., granulation tumors, granulation stenosis, prolapse of the tracheal walls, atrophy of the muscles of the glottis, and certain, as yet undefined, reflex nervous disturbances of trachea and larynx; while but few cases of the remote effects attributable to the same primary cause, and only discovered afterward, as a rule, by the aid of the laryngoscope, are on record.

The present case will therefore, on this account alone, not be without interest. I submit it without comment, so well does it tell its own story.

A medical student, aged twenty-five, consulted me incidentally in regard to a peculiar whistling noise that he made during inspiration, especially after exertion, and a difficulty that he at times experienced in clearing his throat of accumulated mucus. The conditions were old ones, and gave him no particular annoyance. Time had established tolerance.

The laryngoscope showed, to my own surprise as well as his when I informed him of the condition, a stenosis of the upper trachea to the extent of at least two-thirds of its normal lumen; the lesion was evidently of long standing.

Bear in mind that the patient was a strong, well-developed young man, with a bright, fresh color, who had never been conscious of any respiratory difficulty. A striking example, then, of the curious tolerance developed by nature, in cases of slowly developing stenoses of the upper air-passages, to the obstruction to the respiratory current and consequent diminished supply of oxygenated air to the lungs.

The stenosis was due, as is shown in the drawing that I made at the time of examination, first, to a marked depression inward of the anterior arch of the cricoid cartilage; second, to a lateral prolapse of the tracheal wall; and, third, to strong cicatricial bands—several in number—which ran, in an antero-posterior direction, from and below and posterior to the depressed portion of the cricoid cartilage to the posterior tracheal wall. The opening for respiratory purposes thus corresponded to less than one-half of the normal glottic opening.

When three years of age the student was tracheotomized for the relief of so-called diphtheritic cough. The tube was worn without interruption, except for cleansing purposes, for nearly eight years. Why it was not removed earlier, he cannot tell me. A depressed and irregular cicatrix over the cricoid cartilage, nearly in the median line of the neck, marks the site of the operation.

TRACHEOTOMY IN A DIPHTHERIA CASE UNDER TWO YEARS SUCCESSFUL.

BY NATHAN MAYER, M.D., F.

The initiatory history of the case runs like this: On December 28th last, Mrs. S., whose mother I had been attending for an acute bronchitis, called my attention to her little girl Bessie, a well-developed child, aged one year and ten months. The child had been depressed and sleepy for several days, with loss of appetite and considerable fever. The probabilities of worms and difficult dentition were discussed, and as no special organ could be fairly held responsible for the condition, the babe was left alone for the present. On the day after the same state was found, but somewhat more pronounced. A little accompanied retching attacks. Next day patches appeared in the throat, a clearly margined ulcer on one side, and an extensive but thinner membrane covering the other tonsil and the soft palate. At the same time the cervical glands under the angle of the jaw were swollen and painful. Tincture of iron was used in the Jacobi manner, and the throat gently brushed twice a day with a solution of sulphate of iron in glycerine. The following day the slough had come away from the one tonsil, leaving a bare granulating surface, and in addition to the membrane on the other side, some irregular patches were perceptible on the pharyngeal wall. The voice was entirely gone, but breathing did not seem much impeded. The steam chamber with thin vapors was added to the treatment, with pentastine applications to the throat. Next day I was summoned early, and in anticipation of the state of the case, took with me chloroform and a small rubber tracheotomy tube. When I arrived the child was in a state of approaching asphyxia. The eyes dull, the lips blue, the face livid, extremities cold, and only an occasional inspiration, which was forced with all the energy of the muscles of the chest, throat and countenance. The father, a lawyer and a gentleman of great decision, said: "Do something to relieve her, even if she doesn't get well. Open her throat." I at once seized the child and carried her into next room, placed her on the washstand with her head hanging down toward the window, and tore open her clothing. She began some faint struggles, so that I gave her a few whiffs of chloroform and prepared to operate. One moment I paused, thinking she was dead. Then I made a quick incision from the base of the larynx almost to the stenum, and spreading the skin with my fingers rapidly endeavored to free the trachea. I seized the tongue and throbbed to steady it, and hesitated once more, thinking the child moribund. Then opening the trachea, and indifferent to the rather free hemorrhage from the parts around, I introduced my dilating forceps, and between the branches pushed in the canula. A spray of blood responded, and the whistling respiration, which I assisted by manual pressure on chest and abdomen, was attended by similar spray from the tube for some minutes; and for several hours bloody froth was thrown out occasionally with the expiration, and always with the cough.

The rest is very simple. In a few hours the child seemed to regain regularity and ease of breathing. It lost the livid and blue tinge, coughed frequently, expectorating through the canula, and, though feverish, with a high pulse and temperature, yet attained a certain degree of comfort. Alimentation by the rectum was undertaken, but caused vomiting which nearly dislodged the canula, and brought out the only redness of membrane which were voided that way. If any loosened previously and were coughed up they must have been swallowed, as children are almost continually doing. Medicine and brandy were continued by mouth, and swallowed with some difficulty, as well as very small portions of milk.

Immediately after the operation the child was returned
to the steam cabinet, and kept there for the next fortnight. In about five days the temperature and pulse subsided; more milk, beef-juice, and a little egg were swallowed, the iron was discarded, and bits of crackers were taken daily. The cough proved frequent and troublesome at this time, mucus of a certain thickness and tenacity being presented at the mouth of the tube, and drawn back several times before ejection. Frequent cleanings and withdrawal of the inner canula became necessary. The wound around the mouth of the canula looked well, never exhibiting distinct signs of diphtheritic supervision. On the tenth day the tube was experimentally withdrawn, and the parts joined together with a plaster. The child seemed uneasy and struggled as if it did not get air enough, and when the experiment was continued, began to look a little blue. At the same time no sound issued from the larynx. So the tube was introduced once more. The parents were directed to make frequent trials by withdrawing the inner tube and stopping the outer, which was fenestrated so as to permit the current of air to pass through the larynx. These experiments gradually accustomed the organ to the performance of its usual functions, evoked moisture, and when two days after the tube was again withdrawn and the opening plastered up, the little patient breathed easily, and got along so well that on the eleventh day it was taken off. Finding the wound well contracted, and the canula difficult of re-introduction, I left it out, and matters went on very smoothly. On the sixteenth day I heard the little one say, "papa" and "mamma," and knew that the cure was complete. In the last seven days the appetite had increased, the usual playfulness returned, and one day I found that I could interest the little one deeply by boring a hole in the throat of a toy elephant, and inserting the inner canula. On each succeeding visit I was presented with the elephant to carry out the same operation.

It is unfortunate that the temperature was not measured, on account of the restlessness of the little patient, and the urgency of the other symptoms. The pulse ranged at 130, and during the critical days was beyond counting.

The lessons of this case are to me: that, though authors do not commend late operations or those performed on children under two years, yet such may be successful if the parents are in accord, should be attempted. In this connection, I may refer to the case of Dr. G. F. Shady, a successful tracheotomy on a child of eleven months, and also to eight more all under one year, which he cited in his report of that case two years ago (Medical Record, vol. xxii., p. 514). These nine are seemingly all that are known to literature at present. The canulae used in these cases must have been smaller than any ordinarily found in the market.

**Pilocarpine in the Treatment of Deafness.**—For all recent cases of deafness due to labyrinthine disturbances, what is the primary cause may have been, Politzer tries the subcutaneous injection of a 2 per cent. solution of the muriate of pilocarpine. He injects four drops at first, and gradually increases the dose to ten drops daily. He gets fairly good results in about one-half of the cases. I have seen three cases of persons totally deaf, who, after being treated in this way, could hear and understand loud speech spoken at the distance of a few inches from the ear; and Politzer has had one case of perfect recovery of the hearing after it had been absent for three years, and several other very satisfactory results, following the use of this drug. He is about to publish the results of his experiments, with the history of some of the cases. It is not known how much of the benefit derived from its use is certainly great in some of them. Vienna Correspondent of Berlin Med. and Surg. Journal.
counterbalanced by the large number of phthisical patients who congregate there during the season, and the almost daily deaths, which exert a depressing influence, morally, upon other patients not phthisical. If a sea-board resort is deemed desirable in some cases, such should be sent on the Gulf coast to a place like Cedar Keys or Tampa; both are protected from the northerly which prevail on the Atlantic side, and the air of the Gulf is milder and more balmy.

The changes that occur on the Atlantic coast are aptly illustrated by the following brief note: St. Augustine, Sunday, December 16th, ice; Tuesday, December 18th, thermometer 75° in the shade; Wednesday, December 19th, thermometer 80°; January 6th, thermometer 24° above zero, pump frozen. The breezes sweeping across Florida from the Atlantic to the Gulf assume at times the character of high winds, another reason why this climate is not suited to advanced stages of pulmonary disease.

The question when to come to Florida, and where to go, must be answered according to the requirements of each individual case; but, as a general rule, no case in which the cachexia has made its appearance—and I have seen such here frequently—will have sufficient general health to allow the affected organ to profit by the climate. It is best for the patient to consult a competent physician; he will be able to judge of the extent of the visceral complications dependent upon weather or mi-asma, and such cases are much better off at home, surrounded by comforts, friends, and under skilled medical attendance. The old panacea of “going South” has of late years too often been synonymous with getting rid of a hopeless disease, and the patient has died, or is gradually becoming alive to the fact that there is more oxygen in mountain air than in low districts, whether seaside or inland. To what range of diseases then, is a southern climate adapted? To a comparatively limited one. First of all, to rheumatics and cases of confirmed neuralgia, then to all cases whose general health is sufficient to stand the climate, and who have been obliged to consult the skin and emunctories—notably in gout, arthritis deformans, and syphilis. Such patients, by guarding against exposure, remaining indoors and keeping warm during the cold and rainy weather, derive great benefit during the warm days, as the skin is kept in a gentle action and the elimination of morbid process can be aided by drinking the sulphur and alkaline waters from the numerous wells in Florida, and by bathing in the same. The writer has in mind a case of chronic rheumatism radically cured by a visit of some weeks at the Green Cove Sulphur Springs, on the St. John's River. The remarkable point in this particular case is, that after taking the baths an abscess developed, and ran the regular course, upon the left thigh of the patient. Two years have since elapsed, this being the only abscess he has ever had.

Interesting cases in other diseases could be given at length; but let us pass on for a moment to the tractus respiratorius, for it is with this that Florida has become inseparably linked in the minds of many.

Those will derive benefit from a sojourn here during the winter months who from family history may become phthisical; those, provided they are not too advanced in years, who are subject to bronchitis, bronchial catarrhs, laryngitis, to bronchial and laryngeal troubles generally, at different seasons of the year, more especially during the cold months and early spring. To phthisical cases in the latter stage, too, it may be mentioned here in the second stage, who, unable to withstand the influences of the climate, now depressing and then exhilarating, pass more rapidly into the third stage than if they had sought the mountains, or even remained at home. The climate of Florida as a prophylactic is perhaps more valuable than as a palliative—curative I do not believe it to be—that is, as a prophylactic in cases where the bronchial or lung disease may for scientific reasons be anticipated. Patients of this class are not only able to spend most of their time out of doors, but also reap the advantages of having the mind diverted by moderate exercise, walking, fishing, shooting, etc. The scenery of Florida, which is unique and beautiful, also the diet, into which oranges fresh from the trees enter largely, are important factors in treatment.

Those in health who come simply to escape the cold weather of the North, should remember that a summer in the North followed by a winter in the South, is equivalent to a year of perpetual summer, and consequently the system is kept below par; having been deprived of the bracing influences of winter, it is thus more susceptible to diseases of the respiratory organs upon returning to northern latitudes. This is also noticed in laryngitis. A gentleman who came South a few years ago for a slight affection of the larynx, enjoyed relief from all inconvenience while remaining in Florida, but upon returning North, early in the summer, suffered a relapse, and has been obliged to consult his doctor. This is the history of many. The climate is palliative, not curative. This much is certain, that a southern climate renders the system, be it in a physiological or pathological condition, more sensitive to cold.

In closing this paper it will be observed that the views expressed with reference to Florida as a resort for inva-lid are somewhat connected from those popular and entertained about this portion of the “sunny South”; they are, nevertheless, based upon personal experience, individual observation, and inquiry.

To get beneficial influence from a southern climate the party must be first an invalid, and secondly, have sufficient general health to withstand the changes from warm to cold, from dry to damp, and from humid to dry. As the cold is never intense and can be easily guarded against, it is rheumatoid patients and cases of chronic neuralgia, syphilis, and gout that will do best in Florida, and it is to these that the climate is suitable rather than to phthisis.

St. Augustine, Fla., January 19, 1884.

ARTERIO-VEINous ANEURISM OF THE COMMON CAROTID ARTERY AND INTERNAL JUGULAR VEIN.—Dr. Lewis A. Stimson reports, in the April number of The American Journal of the Medical Sciences, a case of traumatic communication between the left common carotid artery and the internal jugular vein. The point of communication was between the two vessels appeared to be more than three-fourths of an inch below the bifurcation of the artery, and perhaps not more than half an inch, and therefore the application of a ligature to the common trunk on the distal side of the opening, in addition to the necessary one on the proximal side, seemed too hazardous to be undertaken. The alternative of placing the second ligature upon the internal carotid, with or without a third upon the external carotid, was also rejected, and Dr. Stimson determined to tie the artery at one point only, and that as near to the opening on the proximal side as possible, hoping either that the distal clot would extend far enough to close the opening, or that the reverse current through the internal and external carotid would prove too slight to cause inconvenience. Seven weeks after the operation the thrill was recognizable only over the seat of the opening, and could be arrested by moderately firm pressure at that point, or by deep pressure behind the angle of the jaw; it was steady and continuous. The appearance of the anterior temporal artery visible on the side of the forehead was notabily enlarged, and pulsated strongly; its pulsation was arrested by distal pressure.
Progress of Medical Science.

CORTICAL LESIONS OF THE BRAIN.—While anatomical study, demonstrating a connection between various organs of the body and definite regions of the surface of the brain, may furnish grounds for a priori reasoning as to the function of those regions; and while physiological experiments upon animals may afford valuable suggestions as to the probable effect of limited brain disease in man, an accurate determination of the subject of cortical specialization can only be reached by a study of clinical cases. The appreciation of this fact has led Dr. M. Allen Starr to collect, in the April number of The American Journal of the Medical Sciences, the cases on record in American journals, in which a limited area of disease of the cortex, whose position was determined by a careful autopsy, had given rise during life to definite symptoms. From the comparison and classification of these cases with the foreign cases collected by Charcot, Ferrier, Nothnagel, Exner, Wernicke, and others, certain general conclusions, which are of great practical importance, have been reached, and it is now possible to refer many symptoms occurring in the course of brain diseases to the destruction of a definite area of the surface. In reviewing the cases of lesion of the frontal region, it is noticeable that decided mental disturbance occurred in one-half. This did not conform to any one type of insanity. It is rather to be described as a loss of self-control, and a resultant change of character. The other symptoms were chiefly negative. The absence of disturbances of motion and sensation, and of the special senses warrants the statement that the motor and sensory areas of the cortex do not lie in the frontal region, and that the diagnosis of lesions of the frontal convolutions must rest upon the presence of general symptoms of cerebral disease and of mental disturbance, and also upon the absence of motor and sensory disturbance. Lesions of the temporo-sphenoidal lobes may exist without giving rise to any local symptoms. Symptoms of disturbance of the special senses of hearing and smell, and loss of memory of perceptions acquired through these senses, may be caused by lesions of this region; odors being probably perceived in the inner sphenoidal convolutions, and sounds in the first temporal convolutions. The areas connected with motion, with general sensation, and with vision, do not lie in the temporal lobes. The importance of a careful examination of all the special senses in any case of suspected brain disease is enforced by the probability that some of the sensory areas lie in this region; but that the symptoms produced by their destruction pass quite over the sensory region. The most constant local symptom of lesion of the occipital lobes is a disturbance of vision—blindness. Absence of motor or sensory disturbance is also noted. A study of the cases warrants the conclusions that the visual area lies in the occipital lobes, and that the areas governing speech, motion, general sensation, and non-visual sensory impressions, lie elsewhere.

VERATRIA IN MUSCULAR TREMOR. According to Dr. Feris, after small doses of veratrum each muscle, when stimulated, reacts more vigorously, and the contraction lasts longer than in the normal condition. The increased duration of the single contraction is shown not only by the greater length of the myographic curve, but also by the fact that while sixty stimuli per second are needed to set a normal frog’s muscle into tetanus, some ten suffice to tetanize a veratrumized muscle. The tremors of alcoholism, of central nerve-degeneration of fever, and of febrile paralysis are due, according to the author, to a condition of muscular contraction in which the impulses are not sufficiently rapid to give rise to tetanus. This may be owing to defective innervation as well as to muscular degeneration. Dr. Feris has used veratrum in such tremors, giving it in pills of half a milligramme each (1/100 gr.), of which four were taken daily at intervals of an hour. Of thirteen patients so treated ten were suffering from alcoholism, two from disseminated sclerosis, one from sequele of typhoid. In all the tremors disappeared entirely in five to fifteen days. Improvement appears after the first day, as is shown by making the patients write before and (one hour) after each pill. The treatment should be kept up for ten days at least, or relapse may occur. The cases continued well for two months at least after the veratrum was stopped.—The Practitioner.

THE DIAGNOSE OF TYPHUS FEVER.—Dr. A. Randolph Mott, in the April number of The American Journal of the Medical Sciences, gives an analysis of 108 cases which were mistaken for typhus fever and sent as such to the Riverside Hospital, New York, during a period in which 771 cases of typhus fever were treated there. These patients had been seen by one or more physicians, and in certain half the number the unqualified diagnosis of typhus fever was made; the rest were considered to present symptoms sufficiently suspicious of this disease to warrant isolation for further development, and were, therefore, admitted to the quarantine wards of the hospital. The revised diagnosis showed nearly every disease which writers have considered as like typhus fever. For instance, the frequency with which any disease was mistaken does not indicate the comparative closeness of its resemblance to typhus. Thus, there were three cases of erythema, and but one of measles, yet all writers declare that the latter is sometimes distinguished from typhus fever with much difficulty. Dr. Mott makes no allusions as to how he arrived at this erroneous diagnosis, which led to the errors of diagnosis, which, in the case of small-pox, for instance, caused 8 cases to be sent to the hospital as typhus, and 13 cases of typhus to be sent as small-pox; and in the case of typhoid fever, 2 cases proved to be typhus, while 12 cases of supposed typhus turned out to be typhoid.

A NEW METHOD OF REMOVING NAJAL POLYPUS.—Dr. Bell, in the Canadian Med., February, 1884, describes in certain half of treating polypus which he has practised with the very best results in several cases. He claims that it obviates any trouble from hemorrhage, which is frequently the case when the forceps or hook are used, that it is painless and very simple. He gets his patient to blow strongly through the affected nostril, and while this is going on, he begins to find fine hair which is brought down so that it can be easily seen through the external nares; then, with the hypodermic syringe charged with a solution of tannic acid in water (of the strength of twenty grains to the fluid drachm), he pierces the polypus with the needle, and injects ten, fifteen, or half a dozen minims of solution, according to size of tumor. In a few days, it comes away without any trouble or pain, and looks like a clot of dried blood, the patients usually removing it by blowing the nose or by their fingers.

NEPHRITIS AFTER VARIICELLA.—In a recent number of the Berliner Klinische Wochenschrift, Professor Henoch relates briefly four cases which have come under his notice, in which varicella was followed by nephritis. The patients were aged respectively ten, two, five, and four years. In each the urin. was generally abundant, and was accompanied by fever; and, at the end of the period varying from eight to fourteen days from the appearance of the eruption, there was oedema, with nephritic urine. In three of the cases, recovery took place in a few weeks, under the use of diaphoretics, with Biliun water or acetate of potash as a diuretic. One, a girl aged two years, in whom the patient was generally a good blood-donor, and after death there were found oedema of the lungs and hypertrophy of the left ventricle. Dr. Henoch has not been able to find any record of varicellar nephritis in medical literature. He regards it as analogous to the nephritis which attends other infectious diseases, especially scarlatina.
IRRITATION OF THE SEXUAL APPARATUS AS AN ETOLOGICAL FACTOR IN THE PRODUCTION OF NASAL DISEASE.—The evil effects of undue excitation or disease of the generative apparatus upon the organs of sight and hearing are well known to specialists in these departments. In the April number of The American Journal of the Medical Sciences, Dr. John N. Mackenzie quotes authorities to prove the fact that immediate indulgence in venery may lead to derangements of sight, was familiar to Aristotle, and that the fathers of medicine recognized some mysterious connection between the ear and the reproductive functions, and that the intimate relationship between the genital organs and those of the throat and neck attracted the special attention of the ancients.

While historical facts point to the early recognition of the relationship between over-indulgence of the sexual powers and morbid conditions of the eye, ear, and throat, the special part which it plays in the production of nasal disease seems to have been heretofore overlooked. Dr. Mackenzie points out the intimate physiological relationship between certain portions of the reproductive system and the erectile nasal tissue. Clinical observation has shown him that far from suffering from nasal affections, the disease is greatly aggravated during the menstrual epoch, or when under the influence of sexual excitement. 2. Excessive indulgence in venery seems to have a tendency to initiate inflammation of the nasal mucous membrane, or to aggravate existing disease of that structure. 3. The same is true in regard to the nasal mucous membrane. The coexistence of uterine or ovarian disease exerts sometimes an important influence on the clinical history of nasal inflammation. These observations, therefore, encourage the belief, if they do not establish the fact, that the natural stimulation of the reproductive apparatus, as in coitus, menstruation, etc., when carried beyond its normal myelitic agent, is of the sexual apparatus, as in certain diseased conditions, or as the result of their over-stimulation from venereal excess, masturbation, etc., are often the predisposing, and occasionally the exciting causes of nasal congestion and inflammation. Whether this occurs through reflex action, pure and simple, or as the sequel of an excitatory, and perhaps of the erectile structures of the body participate, the starting-point of the nasal disease is, in all probability, the repeated stimulation and congestion of the turbinate erectile tissue of the nose. It is highly probable that this erectile area, so sensitive to reflex-producing impressions, is the correlative of the urethral gland of the spinal cord, which, in its phrenic innervation, serves as a nucleus of the nasal nerve-fibril system.

ACUTE MYELITIS IN SYPHILIS.—Dr. Déjerine describes two cases of rapidly fatal acute myelitis in syphilitic subjects, remarkable for the early period in the course of the constitutional disease that the spinal lesion appeared, as well as for the nature of the latter.

For although chronic disease of the spinal cord is no doubt often genetically allied to the syphilitic taint, and notably posterior spinal sclerosis, yet such lesions are late manifestations. But just as occasionally cerebral syphilis appears early, so the author contends may "spinal syphilis," and the cases are contributed as evidence in support of this. The first case occurred in a coal miner, fifty-one years of age, who contracted syphilis thirteen months before, having had no other manifestations beyond the primary chancres, which ulcerated anew five months after its cicatrization. He had taken mercury for two months on each occasion. The nervous symptoms commenced with headache and irritability of the bladder, only to recur as the result of the dental caries; followed in a few days by complete paraplegia, the absolute loss of power occurring suddenly. He was admitted into La Charité under Professor Vulpian, when, in addition to the motor paralysis, there was found to be complete anesthesia from the umbilicus downward, incontinence of urine, headache, and commencing sloughs over the buttocks. The course of the case was rapid, the gangrene involving also the heels and the abdominal walls (from the application of a poultice), and death occurred from pulmonary oedema twenty-eight days from the onset of the paralysis. The post-mortem examination revealed acute central myelitis, extending from the lower part of the cervical to the lower part of the lumbar region, with commencing ascending degeneration traceable to the medulla. Marked degenerative changes were present in the anterior nerve-roots and in the cutaneous nerves supplying the abdominal wall at the seat of the sloughs, but the posterior nerve-roots were intact. The second case was that of a man thirty-eight years of age, who a year previously had contracted syphilis, followed by secondary lesions, rapidly disappearing under specific treatment. A week before his admission into the Maison Municipale de Santé he had experienced pain in the spine, and paraplegia began on the day before his admission, with no pain or altered sensations in the legs, but a 'girdle-pain' around the abdomen and back, in the part of the chest. The extremities were completely paralyzed in the lower limbs, and anesthetic to the level of the margin of the thorax; reflexes abolished; paralysis of sphincters; no interference with respiration, but inability to expectorate. On the sixth day a large superficial slough appeared on the sacrum, diarrhoea set in, and death occurred eight days after the onset of the disease. In this case the gray matter of the lower half of the dorsal and upper half of the lumbar region, with degenerative changes in the corresponding anterior nerve-roots, but none in the posterior. Dr. Déjerine, who gives a minute histological description of the spinal cord in these cases, points out that they in no respect differ from the cases of acute spinal syphilis, but he does not believe that the absence of distinctive syphilitic lesions is sufficient to negative the idea that syphilis was the exciting cause of the myelitis. It often happens in syphilitic subjects that organs are the seat of a chronic interstitial inflammation which does not bear any specific anatomical characters, but which is indubitably due to the action of the syphilitic virus. As to acute inflammations, the broncho-pneumonia of measles cannot be distinguished anatomically from other forms of broncho-pneumonia; and we refer to measles as the cause, just as we refer to diphtheria as the cause of its paralytic sequelae, because of the frequency with which the local affections follow upon the general. The same applies to spinal syphilis; the relative frequency of chronic myelitis in syphilis impels the acceptance that the former is often due to the latter, and, although acute myelitis is rare in syphilis, it is a relatively rare disease in itself; and when the myelitis supervenes, as in these two cases, so closely upon syphilitic infection, there is ground enough for accepting the existence of an acute syphilitic myelitis. At the same time Dr. Déjerine guards his argument by stating that, although syphilis may excite the spinal inflammation, there is no doubt a special disposition or proclivity to the local disease in the subjects who are attacked by it.—The Lancet, February 9, 1884.

REMOVAL OF SPLEEN FROM A DOG WITHOUT PRODUCTION OF ANY BAD SYMPTOMS.—Dr. Wm. H. Mercur, of Pittsburg, Pa., writes that, in 1875, Dr. W. J. Asdale, of that city, successfully removed the spleen from a one year old black poodle dog, weighing about fifteen pounds. The dog continued about the house as a pet. It showed no change in disposition, grew rapidly, until it weighed twenty-five or thirty pounds. Its skin was smooth and free from red patches. The dog got no ill effects from the diseased organ. On post-mortem the organs were perfectly normal, except for an enteritis. There was no vestige of a spleen. Dr. Mercur does not speak of any development of the bone medulla, the thyroid or the lymphatic glands.
GOVERNMENT IN ITS RELATIONS TO QUARANTINE.

We noticed last week a bill before the Public Health Committee of the House of Representatives, entitled "A Bill to Protect Public Health," and discussed that clause which provides a "United States Board of Health," to supersede the present National Board of Health. There is another feature of this bill which, we learn from the pamphlets before us, was discussed before the Public Health Committee, and which, from its importance, deserves the attention of all health authorities of States and municipalities of the seaboard which have quarantine duties to perform.

The bill provides that "such board shall have full power to make such regulations as may be necessary for the government of the quarantine service of the United States and the protection of the public health." Section 4 is as follows: "That the United States quarantine service shall hereafter be conducted and managed by the said Supervising Surgeon-General of the Marine Hospital Service, acting under the direction of the Secretary of the Treasury."

The objects sought to be accomplished by this measure, as appears in the discussion, are twofold, viz.: First, to prevent the enactment of a law that will revise the law of June 2, 1879, which expired by limitation in 1883; and second, the ultimate inauguration of a national quarantine system under the Surgeon-General of the Marine Hospital Service, which shall supersede the present State and municipal quarantines. Let us briefly examine both branches of this subject.

The law of 1879, entitled "An Act to prevent the Introduction of Contagious and Infectious Diseases into the United States," was passed during the extra session of Congress of that year, and in anticipation of the immediate outbreak of a yellow fever epidemic. It was the subject of much discussion by the ablest men of both Houses. The point of contention was its tendency to invade the rights of the States. The bill was finally perfected and made acceptable chiefly by General Garfield and Senator Harris. A clause limiting its operations to four years was added on its final passage. This law was a long step in advance. Congress recognized for the first time the duty of the general Government to aid the States in the suppression of wide-spread epidemics.

To the National Board of Health was assigned the duty of administering the law. The essential feature of the law was the duty of the National Board to co-operate with and aid State and local boards in the prevention of the introduction of epidemic diseases into the United States, and their spread from one State into another.

This act of the National Legislature created an era in the history of sanitary reform in this country, for it completed and perfected a national system of public health administration. We now had the local boards of health in every community protecting and promoting the health of the individual and the family; the State Board cooperating with the local board to suppress and prevent the spread of domestic pestilences; and finally, the National Board ready to bring the resources of the general Government to the aid of local and State boards in the suppression of the great foreign epidemics which so often invade our shores, and spread from State to State. The practical results which followed, during the four years of the existence of this law, were of the most valuable and lasting character. The great epidemic of yellow fever of 1879, which immediately followed the enactment of the law, was grappled with by the united forces of the local, State, and National Boards, and brought under control as it had never been before; the quarantine defences were everywhere strengthened; refuge stations for the cleansing and disinfection of infected vessels were established; the sanitary inspection of steamboats and railroad cars was enforced at infected places; rules for securing the best sanitary condition of ships were issued, and, as far as practicable, applied; information as to the health of the seaport towns of the world was weekly issued to all health officers and consuls; and, finally, an effective system of inspection and vaccination of immigrants.

We do not exceed the bounds of a rational estimate of our public health service in asserting that, during the existence of the law of June 2, 1879, it was the most complete and effective, in all its details, of any yet formulated. In allowing this law to lapse Congress made a great mistake, which can only rectify by enacting a law containing similar powers and duties. A bill embodying the essential features of that law is now before the Public Health Committee, and is opposed by the promoters of the scheme of centralizing all quarantine powers in the Marine Hospital Service.

If now we turn to the bill before us which is designed to supersede the law just noticed, we find an entirely new phase of the question presented. Instead of aid and co-operation by the general Government with local and State authorities, all powers and duties are to be centralized in the Washington establishment. Though we are not prepared to assert that a national quarantine system might not be organized and administered by the general Government, which would be more effective than the present, we do say that the plan proposed in this bill will not accomplish that object. The board that is to be clothed with the "full power to make such regulations as may be necessary for the government of the quarantine service of the United States," is to be composed of officials who have no practical knowledge of quarantine rules and regulations. Quarantine belongs to the external sanitary police of seaport towns, and hence has always been under the jurisdiction of municipal or State authority.
Neither the Army, Navy, nor Marine Hospital Service have had any functions to perform, in connection with quarantine, except to obey the regulations of the particular seaport town which they happened to enter. We believe, therefore, that when the general Government determines to enter upon the management of the quarantines of the United States, it must appoint a board of control composed of representative men from the great commercial centres.

And we fail to see any special fitness in the agent selected in this bill to conduct the quarantine service of the United States. The Marine Hospital Service is devoted to the care of sailors in port, sick of other than contagious and infectious diseases. The very diseases among sailors, for which quarantine regulations are to be enforced, that Service has never taken care of, but has always turned the sick over to the local authorities and carefully abstained from personal contact. At the port of New York, sailors sick of small-pox, yellow fever, or cholera, are not sent to Marine Hospitals, but to the appropriate hospitals of the city and of the State quarantine. The ordinary operations of that service, therefore, do not qualify its officers for quarantine duties, and if "the United States Quarantine Service" is to be conducted by the Surgeon-General, another staff of officers must be created specially qualified for these new duties. If any such measure as this is to be inaugurated, we would suggest that the Surgeon-General of the Navy be selected to conduct the quarantine system, for his officers have at least had experience in ship sanitation, and the senior medical officers might be usefully detailed to such duties.

But all such immature schemes for securing the control of the quarantines of the country as this bill embodies, are unworthy the serious attention of Congress. They only illustrate the traditional ambition of the minor Bureaux at the Capital to increase their power, and thus magnify their importance.

ANÆSTHESIA BY THE RECTAL METHOD.

M. DANIEL MOLLÈRE, in the Lyon Medical, has described a very novel method of administering ether, and claims for it advantages which, if sustained by further trials, will in a very literal sense revolutionize the usual procedure.

He writes that while showing a Danish physician, Dr. Axel Yversen, through the wards of the Hôtel-Dieu at Lyons, that gentleman asked how he administered ether, by inhalation or by the rectum! Further conversation elicited the fact that in Dr. Yversen's experience anaesthesia could be advantageously induced by giving the anesthetic in the reverse of the ordinary way.

Next day Dr. Mollère began to experiment. A young woman, twenty years of age, was to be operated upon for a tumor of the parotid. The ether was injected into the rectum by means of a Richardson's atomizer. Absorption took place very slowly, but at the end of ten minutes the patient became incoherent, and could taste the ether in the mouth. A few drops were then placed near her nose, and upon inhaling them she fell at once into a profound sleep. The operation was then performed without any trouble. The patient had taken some soup just before the operation, and she vomited it upon recovering from the anesthesia. Apart from this she felt no disturbance.

In a second case the ether was given in a different manner. An india-rubber tube of the size of the finger was introduced into the rectum, and connected with a flask of ether which was itself placed in a jar containing water heated to a temperature of 50° C. The ether entered the tube boiling. In five minutes the patient became incoherent; a few whiffs of ether then produced complete anesthesia. The operation was for the removal of a tumor from the antrum of Highmore, and was much facilitated by the fact that no ether cone had to be kept over the face. The patient came out from the anesthesia without any trouble and suffered no nausea.

In a third case, the administration succeeded equally well, the patient suffering no nausea.

The fourth patient was a robust man who had been a hard drinker. He was anesthetized like the others, without any preliminary period of excitement except that the procedure "greatly excited his hilarity."

Two other operations were performed, in which the ether was administered in the same way and with the same success.

M. Mollère thinks that anesthesia by the rectal method is destined to be of great service in many cases. It suppresses the period of excitation; it permits one to regulate the dosage very exactly; it reduces to a minimum the amount of ether needed; it allows the surgeon opportunity to operate upon the face; it is a more agreeable method to those patients to whom the odor of ether is nauseating and objectionable.

Some better method of injecting the ether may be devised, but at present M. Mollère thinks that the introduction of a flexible tube and connecting it with a flask of ether placed in hot water, at a temperature of 40° to 60° C., is the best method.

MEDICAL LEGISLATION IN CONGRESS.

House Bill 1340, "To Establish and Maintain a Bureau of Labor Statistics," which was considered in Committee of the Whole House on Saturday last, contains, among many things pertaining to labor statistics, the following provisions: "The number and ages of children, nature of their occupation, their attendance at school and church; the sanitary, educational, social, and religious condition of laborers; the average duration of life; accidents incident to employment; insanity; epidemics; factory, mill, mine, and dwelling inspections. The Commissioner of Labor Statistics shall obtain all possible information upon the various subjects specified from the different foreign nations, and shall have authority to issue circulars to United States Consuls asking them to obtain the information desired," etc.

Mr. Blount, of Georgia, opposed the bill, and referring to the provision of the bill with reference to strikes said: "We are probably to be treated to essays on strikes, their causes, effects, and remedies. Why do we want to pay persons for getting up essays on those subjects? We created a Board of Health and made an appropriation for it, and then we found that a large portion of the funds of that Board were utilized to pay friends of its
members for getting up essays on various diseases." etc.

Mr. Hopkins, of Pennsylvania, in answer said: "The gentleman says we inquire into their sanitary condition when we do not propose to remedy it. Congress has proposed to regulate the general health at times, and established a National Board of Health for that purpose," etc.

The discussion took a wide range, and several amendments were made, among them the following: After the word occupation (referring to children) insert the words, "the effect of the different kinds of labor on their growth, development, and health." After the word classes insert the words, "the condition of tenement-houses for operatives and the rental thereof."

Much opposition to the passage of the bill was made by Mr. Bland, Bayne, Aiken, and others, but on a call of ayes and nays the bill passed by a vote of 183 ayes to 19 nays; 120 not voting.

A resolution authorizing the House Public Health Committee to "inquire into the extent and character of the adulteration of food and drugs imported into the United States, or exported therefrom," and appropriating $2,000 to defray the expense of such inquiry, was presented by the chairman of the committee (Mr. Beach, of New York), who moved to suspend the rules and pass the resolution. Mr. Mills, of Texas, demanded a second on the motion to suspend the rules, whereupon Mr. Beach asked unanimous consent that a second be considered ordered. To this Mr. Mills objected, and tellers were appointed, who reported 93 ayes and 51 nays. The rules being suspended, debate followed, and Mr. Beach made a speech in favor of the resolution, as did also Mr. McComas, of Maryland. The resolution was opposed by Mr. Mills, of Texas, who said he was "opposed to this constant interference on the part of the law-making power of the Government with the habits, food, and customs of the people at home. There is too much sumptuary legislation," etc. He continued, "Suppose some butter is presented for examination before this committee, and they have an expert to pass upon it; how can he know what is coming in at New York on that day or the next day, or what is going out? The proper plan would be manifestly not to deputize the committee, but to authorize the Secretary of the Treasury to take such steps as in his wisdom may be necessary to have an examination made through the Custom House, and make his annual report to Congress. Therefore there is no necessity for the passage of this resolution."

No other members participated in the debate, and the motion to suspend the rules and pass the resolution was not agreed to—ayes, 64; nays, 80. Mr. Beach then called for the ayes and nays, but only fourteen voting in the affirmative, the ayes and nays were not ordered, so the resolution was defeated.

Mr. Blount, of Georgia, introduced Bill No. 6672, to reduce the internal revenue tax on brandy distilled exclusively from apples, peaches, or grapes grown in the United States, to ten cents per gallon. Referred to Committee on Ways and Means and ordered printed.

Mr. Parker, of New York, introduced Bill No. 6708, to tax the manufacture and sale of oleomargarine. Referred to same committee and ordered printed. Mr. Parker also introduced Bill No. 6709, to regulate the exportation of articles made in imitation of butter and cheese. Referred to Committee on Commerce.

Mr. Scales, of North Carolina, under suspension of the rules, moved to pass the joint resolution authorizing the public printer, whenever he receives "a sufficient number of orders for copies of the 'Report of the Tenth Census,' or 'Compendium of the Tenth Census,' or for the 'Medical and Surgical History of the Rebellion,' or for the 'Rebellion Record,' accompanied in each case by the cost price thereof, with ten per cent. additional, to warrant, in his opinion, the expense of putting the plates to press, he shall cause an edition or editions thereof to be printed; provided the number of copies thus at any time printed shall not exceed the number ordered and paid for in advance of publication." This resolution was agreed to.

Mr. McPherson, of New Jersey, presented "a petition of many citizens of New Jersey, praying that all qualified physicians be made equal before the law in the Government service of the United States," having reference, he explained, "to all grades of physicians and all classes, as allopathic, homoeopathic, etc.," and moved its reference to the Committee on Military Affairs. So referred.

Mr. Cameron, of Wisconsin, presented "a petition, numerously signed by residents of Wisconsin, praying for the passage of Senate bill 1223." The bill refers to the employment of different schools of medicine in the Government service, and the petitioners ask that their petition be referred to the Committee on Civil Service and Retrenchment.

The President of the Senate said similar petitions had been referred to the Committee on Military Affairs, under the impression that most of those surgeons are employed in the army. The petition was then referred to the Military Affairs Committee, but afterward changed to Committee on Civil Service and Retrenchment.

Mr. Hawley, of Connecticut, presented the petition of ex-Governor Win. T. Minor and one hundred and seventeen other citizens of Connecticut, to the same effect, and moved its reference to the Committee on Civil Service and Retrenchment. Motion agreed to.

Mr. Cullom, of Illinois, presented sundry petitions of citizens of Chicago and other cities in Illinois, Iowa, and Minnesota, praying Congress that homoeopathic physicians be given the same opportunities as allopathic physicians to enter Government service. Referred to Committee on Civil Service and Retrenchment.

Mr. Harrison, of Indiana, presented a petition from Dr. T. C. Hunter and sixteen other citizens of Indiana, and four other petitions of citizens of Indiana, praying for the passage of bill 1223, to secure to the medical profession equal rights in the service of the United States. Referred to same committee.

Mr. Cockrell, of Missouri, presented a similar petition to above from citizens of Missouri, also memorial of the faculty and students of the Homoeopathic Medical College of Missouri, protesting against the discrimination that is made in favor of one class of physicians alone in Government employment in all the offices except the
Pension Office, and recommending the passage of Senate bill 1233, and asking it be referred to the Committee on Civil Service. So referred.

If the above petitions relative to the homeopathics were introduced in the Senate on the 21st instant, showing a determined effort to secure legislation in their behalf.

Mr. Palmer, of Michigan, presented resolutions of the State Board of Health of Michigan in favor of legislation for the prevention of the introduction of infectious diseases into the United States. Referred to the Committee on Epidemic Diseases.

HOW INFECTION IS IMPORTED.

Of the many unpleasant aspects of the defective medical service on ocean steamships, to which attention has been directed in recent issues of The Record, that of greatest moment to the public at large is the facility afforded for the introduction of infectious disease.

A competent medical attendance may become necessary to all who face the vicissitudes of ocean transit, and is eminently desirable for the physical well-being of immigrants to this country, but of even wider importance as affecting every member of the community is a reliable sanitary administration on ship-board, for without it, and without the co-operation of the ship-surgeon, our quarantine arrangements offer no security against the importation of epidemic disease.

As the constant recipient of immigration from almost every part of the world, and from peoples among whom small-pox, scarlet fever, typhus, and other infectious fevers are more or less endemic, the United States is singularly situated, and has need of especial caution in this regard. Absolute protection can only be secured by the rigid enforcement of quarantine proper, that is, the detention at a safe distance of every foreign vessel during the longest incubative period since possible infection.

This, however, is attended with such heavy commercial loss, and inconvenience to travellers, that nothing short of urgent emergency would justify its adoption. Nor does it seem necessary at present, since it would appear that the first spread of infection is almost invariably a consequence of defective structural arrangements and neglected sanitary precaution on ship-board, and that the usual method of its dissemination here is by persons who have themselves contracted the disease during the voyage hither, but in whom symptoms have not appeared until after the quarantine examination had been passed.

In another column we publish a letter from Dr. J. A. Irwin, in which this evil is fully elaborated, and illustrated by an example which will astonish many of our readers.

On "the steamer belonging to one of the reputedly safest trans-Atlantic lines," which recently carried small-pox to this port on two successive voyages, the hospitals are so located that isolation is absolutely impossible, since the only exit for infectious germs is through the inhabited part of the vessel. To deal with such cases is one of the objects of the bill now before Congress, but we fear that no legislation will prove effective in this regard which does not hold the medical officer directly responsible for sanitation on ship-board, and render him so independent of the owners of the vessel that he will be enabled to co-operate with our quarantine authorities without first consulting their interests, or else forfeiting his position.

News of the Week.

THE OUTCOME OF ETHICAL INTOLERANCE.—Dr. Allan McLane Hamilton, of this city, sends us the following remarkable communication:

"At the suggestion of several medical friends I send you for publication a fact which may have some interest for those who are concerned about the preservation of the Code of Ethics. Some weeks ago I was the recipient of a letter from the Secretary of the Section of Practical Medicine of the American Medical Association, inviting me to read a paper at the coming meeting, and at the same time to take part in the discussion of a paper by Dr. Pepper. I accepted, and heard no more of the matter until this morning, when I learned from Dr. Shoemaker, the chairman of the section, that the committee had refused to allow my name to be used in the discussion because I favored the new code."

MEDICAL PARIS.—The session of the Académie de Médecine, on April 8th, was chiefly devoted to a lively discussion upon M. Luys' proposition regarding the mobility of the brain in different attitudes of the body. M. Béclard opposed the view of Luys, and stated that it was not only not proven but impossible. M. Luys reiterated his opinion, which was in part sustained by M. Guérin. M. Colin said that at the previous meeting he had opposed Luys' view, but now he would defend it, having observed the phenomenon in a living animal. On the whole the discussion was rather in M. Luys' favor. M. Mahuet, of Caen, read a paper upon the "Danger of Employing Purgatives in the Third Stage of Typhoid Fever." The author thought that purgatives were useful and necessary at the beginning of the fever, but absolutely dangerous later on.

MEDICAL VIENNA.—At the meeting of the Royal Society of Physicians, March 28th, Dr. V. Hacker presented a woman upon whom Billroth had successfully operated for carcinoma of the pylorus on February 26th. He also related the history of a case of a large lympho-sarcoma of the spleen, in a woman aged forty-three, upon whom he had successfully operated, the spleen being entirely removed. This was the thirty-sixth case of extirpation of the spleen. Prof. Adamkiewicz read an elaborate paper upon "Compression of the Brain." At the annual meeting of the Vienna Medical Dottoren-Kollegium, Prof. Schmerling was elected president.

DELEGATES TO THE AMERICAN MEDICAL ASSOCIATION.—Delegates to the American Medical Association may obtain excursion tickets from New York to Washington, from May 5th to May 8th, and returning until May 12th, on application to Dr. J. G. Adams, Park Avenue Hotel. Price of tickets, $5.80. Trains leave Desbrosses and Cortlandt Street Ferries at 1 P.M., 7 P.M., and 12 NOON. Most of the roads to and from Washington agree to give special rates and round trip tickets on presentation of certificates of delegatship.

THE SIMS MEMORIAL LIST, which is unusually long, is unavoidably crowded out of the present issue.
EIGHTEENTH ANNUAL SESSION OF THE
MEDICAL AND CHIRUGICAL FACULTY OF MARYLAND.

Held at Baltimore, Tuesday, Wednesday, Thursday, and Friday, April 23, 24, 25, 26, 1884.
(Specially reported for THE MEDICAL RECORD.)

FIRST DAY, TUESDAY, APRIL 22D.

The Medical and Chirurgical Faculty of the State of Maryland met in annual session, in Hopkins Hall, Johns Hopkins’ University, Baltimore, Tuesday, April 22d, at 12 M. A large number of members was present from the city and counties, and also delegates from the Baltimore Academy of Medicine, Baltimore Medical Association, the Medical Society of Maryland, Medical and Surgical Society of Baltimore, and the Allegany County and Cecil County Medical Societies.

The meeting was called to order by the President, Dr. Richard McSherry, who delivered his address.

ABSTRACT OF THE PRESIDENT’S ADDRESS.

He would not attempt to review the progress of medicine since the organization of this Faculty, though it had been very remarkable. We have seen many changes and not a few improvements. We are bound to watch the former and use the latter. The ideal physician should take cognizance of everything; winnow the wheat from the chaff, and add to his stock, already very varied, all that modern science may offer him for the benefit of his fellow-man. He must get what he can from the Kohns, the Pasteurs, the Listsers of the day, without giving up what has come down to us from the days of Hippocrates, or without depreciating his own well-earned experience.

The changes in medicine are often very perplexing, so much so that some of its ministers themselves become very skeptical. One of the most brilliant members of the profession is reputed to have said that if the whole materia medica in the world were cast into the sea, it would be all the better for mankind and all the worse for the fishes. But Dr. Holmes put in the qualifying clause, “as now used” — which is equivalent to saying, as now abused or misused; and when any physician looks over the cure-alls advertised in the daily papers, and sees how many people swallow drugs, good in themselves, it may be, but with all chances of misapplication, he will not dispute the corrected dictum of Boston’s favorite son.

It is scarcely a matter of surprise, however, that people swallow all kinds of nostrums so readily when they see them endorsed not only by ignorant dupe, but also by ministers of the Gospel, who ought to be very chary of using their influence where it may do so much injury. I have been informed by a well-known minister that compounds of quack medicines frequently offer a bonus or percentage to ministers for the use of their names. Our own profession, too, is sometimes offered bribes, the ingenious parties making such offers being unaware that their acceptance would ruin a physician’s standing with his professional brethren.

ETHICS.

We have a Code of Ethics not appreciated by the public, but which is necessary to our own peace and self-respect. The regular profession, while always ready to add to its resources, cannot consistently make any compromises with irregular practice in any of its forms. We believe in our system, which though not perfect is the best now known, and we will therefore adhere to it, leaving all devious forms of practice to their deluded partisans. This Faculty happily has frankly expressed its determination to adhere to the American Code, which is in accord with the best tone of the profession all over the world.

POLITICS AND MEDICINE.

It scarcely becomes physicians, as such, to become active politicians, but in many things we should call upon legislators to hear and heed us. In everything pertaining to public matter; in whatever bears upon purity of air, water, food, or medicines; in school hygiene, while we see so many children in purest family and physically by unwise courses, miscalled education; in all matters pertaining to medical jurisprudence; in the drainage and sewerage of cities, and in some respects in matters of public morals, physicians should properly take an active part, which should have a potent influence. There is a fell destroyer abroad which reaches from dens of infamy but too often into the purest families; medical control might often be given to save the virtuous from such detestable contamination. Furthermore, physicians in public and private should be among the foremost advocates of the superlative virtue of temperance—“temperance in all things.”

ACCOMMODATIONS.

Our Faculty has now a respectable library of over four thousand volumes, which is constantly growing. We have an immense number of medical journals, published at home and abroad, for the greater part of which we are largely indebted to the generosity of the proprietors of the Maryland Medical Journal. We want increased accommodations; a good house, or at least a suite of rooms, that is, a large public hall which shall contain the library, with room for public sessions, a social hall, a committee room, and proper apparatus. The Executive Committee has been endeavoring to obtain such accommodations, but so far without success.

SECRETARY’S REPORT.

The Treasurer, Dr. W. F. A. Kemp, presented his report. Total receipts for the year $3,318.97; disbursements, $1,780.98, leaving a balance in the treasury of $528.99. Total assets, $9,792.99, viz.: library, valued at $9,000 (insured for $7,000); amount to credit of building fund, $500; cash on hand, $28.99; dues from members in arrears, $264. Liabilities, $247.55. Loss in membership, two died, seven resigned; gain, seven new members.

EXECUTIVE COMMITTEE’S REPORT.

The report was read by Dr. P. C. Williams, Chairman. It announced that Professor Wm. Pepper would deliver the annual oration, on “Some Practical Views on Dietetics in Disease,” to-morrow at one o’clock. That earnest efforts had been made to secure better quarters for the accommodation of the Faculty, but without success. That accommodations had been provided for the increase of the library for the next two or three years, etc.

LIBRARY REPORT.

Presented by Dr. B. Bernard Brown, Chairman. The report sketched the rapid growth of the Library during the last ten years. The total number of volumes was 6,646, of which 277 are duplicates. Number added during year, 673. The most noted additions were complete sets of the new Sydenham Society’s publications, and London Obstetric Society’s Transactions. Four elegant new dictionaries were presented by Dr. John Morris. Among the most valuable additions is the Glasgow diploma of the first President of the Faculty, Dr. Upton Scof, deposited by his great-grandson, Dr. C. Birnie. One hundred and nineteen medical journals are regularly received. It was announced that members can now obtain books from the Surgeon-General’s Library, Washington, by requisition through the Librarian of the Faculty.
EXAMINING BOARD.

Dr. S. C. Chew, Chairman. The following were recommended for membership: Drs. J. B. Browner, Emmitsburg; F. Donaldson, Jr., S. J. Fort, Baltimore; G. H. Hocking, Mt. Savage; W. S. Maxwell, Still Pond; Arthur Williams, Elkridge Landing.

PUBLICATION COMMITTEE.

Dr. G. Lane Tanyhill, Chairman, reported that 500 copies of the Transactions for 1884, and 300 copies each of the President's and annual address had been distributed. Total cost of above publications, $430.30. It had also, in accordance with the instructions of the Faculty, printed 1,000 copies of the "Medical Annals of Baltimore," an octavo of 275 pages by Dr. J. R. Quinan, of Baltimore. Cost of this work, including advertisement, $417.55.

THE COMMITTEE ON MEMOIRS.

Dr. Eugene F. Cordell, Chairman, gave sketches of the lives of Drs. Judson Gilman, late Treasurer, and E. Gover Cox, both of Baltimore, deceased during the year.

The resignation of Dr. F. D. Gavin was received and accepted.

SECTION ON SURGERY.

The Report on Surgery was by Dr. J. Edwin Michael, Chairman. Dr. Michael said the principles of antiseptic surgery are now so thoroughly established that the question of to-day is simply, WHAT ANTISEPTIC SHALL BE PREFERRED.

The elaborate apparatus of Lister would be inapplicable in country practice or in places like the Soudan. Lister himself has shown that the essentials might be both portable and cheap. He admits that the spray is not necessary and recommends irrigation or sponging with sublimate solution (1 to 1,000). Efficient antiseptics are dangerous and require careful watching.

BRASS ONS.

The tendency to operate is on the increase. Axillary involvement is no contra-indication. Repeated operations are to be commended in cases of relapse. But Gussenbauer's extreme views— to operate when the supraclavicular glands are involved—are not to be accepted. Billroth keeps hopeless cases asleep under morphia.

WIRING FRACTURED PATELLA.

This operation, introduced by Lister, will no doubt be valuable in old ununited cases with wide separation and loss of function, in compound cases, also, perhaps, in cases where there is extensive comminution and great distortion of the joint. Recent simple cases will continue to be treated by splints and other measures free from danger and accompanied with sufficiently good results.

Sir H. Thompson's operation of digital exploration was next described; this surgeon has had thirty-two such cases with satisfactory results.

In deep urethral strictures external perineal urethotomy is considered by Dr. Michael as much safer than any of the internal divulsing or cutting operations.

SECTION ON PRACTICE.

The Chairman was not prepared to report, but a supplementary report was made by Dr. Robert W. Johnson on CRYPTOCHIDISM.

The author had collected from various sources 89 cases, 65 of which were over fourteen years of age; 9 had no testicles on post-mortem; in 18 both testicles are stated to have been in the inguinal canal; in 8 one testicle was in the canal, the other was not discoverable; in 15 the semen was examined microscopically, in 3 of which spermatoza were discovered; 10 are stated to have had children. Heredity was observed in one, where a monorchid brought forth a cryptoorchid child. The above figures show that whilst human cryptoorchids are not necessarily sterile, the great majority of them are, and the question must be determined in each case by an examination of the semen.

Dr. Johnson then exhibited an illustrative case of the above condition. The patient is a robust sailor, white, thirty-three years of age, always very lascivious, and twice married, with one child by his first wife. Four years ago he had gonorrhoea, with apparent right orchitis. Three years ago, after exertion, felt something give way on the right side, after which he put on a double truss. Signs of virility marked, except that scrotum is smaller than usual, on left side empty, and on the right contains only a bag projecting half-way into it from the groin; this bag disappears when he lies down, and nothing like testicles can be felt on either side. When he stands and coughs occasionally, the testicles descend into the scrotum; they appear slightly smaller than natural. The semen is thinner and more translucent than normal, and is devoid of spermatoza.

SECTION ON OBSTETRICS AND GYNECOLOGY.

The Chairman of this Section was not ready to report, but Dr. W. A. B. Sellman presented a supplementary report on THE EFFICACY OF IODOFORM IN PREVENTING UTERINE COLIC AND PELVIC INFLAMMATION FOLLOWING THE INTRA-UTERINE APPLICATION OF NITRATE OF SILVER.

Dr. Sellman stated that he had found the latter agent (gr. lxxx. to the ounce) the most effective of any in intra-uterine inflammation, but he had had some troublesome cases of colic, and even peritonitis and ovaritis, after its use. He had found, however, that the immediate application of iodoform prevented this unpleasant sequel. He generally applies it within the cervix by means of cotton and an applicator, but external to the os if the canal be too much contracted by the first agent to admit of the second introduction of the applicator.

SECOND DAY, WEDNESDAY, APRIL 23D.

Dr. F. W. Patterson offered the resignation of his membership, which was accepted.

Drs. J. G. Jay and A. A. Hanna, of Baltimore, and J. W. Williams, of Lonaconing, were recommended for membership by the Examining Board.

SECTION ON PRACTICE.

A paper was presented by Dr. A. B. Arnold, chairman. He spoke of the recent development of A NEW DEPARTMENT OF MEDICINE, PHARMACOLOGY, and of the services it had rendered and was capable of rendering. Pathology could never serve as the basis of therapeutics, and such a belief is utopian. The morbid changes of tissues and organs could never be completely understood; art could not be separated in medicine from science, and personal qualities are essential to successful therapeutics. Roser and Wunderlich had been champions of the high science idea, but the latter had found it necessary to make concessions in favor of rational empiricism when he became a medical teacher. The English have always taken experience as their guide, and it is claimed that they have been successful practitioners in consequence. Bronunism obtained no foothold among them. The fallacies to which false experience, or experience misinterpreted, may give rise, were illustrated by the history of venesection, while physiology, or rather physiological toxicology, must be relied on to furnish an exact scientific basis for our therapeutics. Clinical medicine must supply the final test.

The paper concluded with a reference to the neurotic theory of fever and the use of antipyretics.
THE ANNUAL ORATION
was delivered by PROF. WILLIAM PEPPER, of Philadelphia, on
SOME PRACTICAL VIEWS ON DIETETICS IN DISEASE, OR
THE RELATION OF DIETETIC ERRORS TO DISEASE.

Successful treatment depended chiefly or exclusively on proper diet and regimen. The scientific adaptation of dietetics to special morbid states constituted the greatest triumph of the medicine of the near future. Far too much importance was ascribed to climate and overwork, too little to diet and personal hygiene. If the English who go to India and Australia were to adopt suitable diet and regimen, the characteristic health and energy of the race would be preserved there. The typical characteristics of the American (sallow complexion, tall, thin figure, ceaseless energy and activity, dyspeptic tendency) were due, not to climate, but to temporary influences, as malaria, damp soil, bad whiskey, tobacco, strong tea and coffee, the constant resort to the frying-pan, the soda-baking-powder, the patent purgative pill, etc.

There was no more favorable climate than ours on earth. Neurasthenia in his experience was a rare condition. With the correction of the evils referred to there was gradually being developed a new type of American, harking all the best qualities of his foreign ancestry. This result may be promoted by the introduction of the study of hygiene and physiology in the schools.

The enduring capacity of a man is measured like the chain, by his weakest link. Patience and self-restraint enable him to spare the weak point. In considering the results of indigestion we confine our ideas too much to the process of digestion itself. We are not concerned with the processes which take place from the reception of the food to its complete digestion and assimilation.

Lithemia or suppressed gout, a very common affection in this country, but not always associated with arthritic trouble, was one form of indigestion.

The author referred to the hot-water mania and to hydrotherapy, and said that many popular mineral waters owe their virtues purely to the water they contain, the mineral ingredients being inert. Water may be of use by taking the place of objectionable liquids. He illustrated the lengths to which patients will go in seeking relief from real or imaginary ills, by reference to a patient of his, who sought relief in a German schloetter cure, in which she was subjected to a dry diet alternating with stimulants, the result being an artificial fever, great constipation, and loss of flesh. Unquestionable benefit accrues in some diseases from this method. A lady suffered with extreme dyspepsia and fatty degeneration of the heart was diagnosed; her weight was greatly increased; a diet diminished her size and effected a cure. A case of periodical albuminuria occurring on exertion but disappearing during rest, was related, in which good diet and regimen produced a cure; also a case of eczema cured by the same means.

The body weight diminished at various rates. Too great a diminution might be harmful, as in a case related, where a lady had an ulcerated tongue, which was supposed by her friends to be of a malignant nature and was attributed to the dieting. It disappeared, however, by improving the diet. Bismarck's trouble was lithemia, and was relieved by regulation of diet.

A VOTE OF THANKS
was passed to Dr. Pepper, whose address was listened to by a crowded audience, and he was nominated for honorary membership.

Dr. R. S. SULLIVAN presented his credentials as a delegate from the Pennsylvania Medical Society.

SECTION ON OBSTETRICS AND GYNECOLOGY.

DR. P. C. WILLIAMS presented a report, as chairman, on THE USE OF ERGOT IN OBSTETRICS.

He took grounds in favor of this remedy and in opposi-
tion to Engelmann and A. H. Smith, who denounce its use under all circumstances in obstetric practice, on the ground that serious accidents, rupture of uterus, lacerations, etc., result from its use. With regard to the two cases of rupture reported by Engelmann in the Medical News, and ascribed by him to ergot, he rejected the first as not being described with sufficient care. The second case was a shoulder presentation without medical assistance for three days, then freely dosed with ergot and version unsuccessfully attempted. Dr. Engelmann first saw the patient on the fourth day after rupture had occurred. The child was removed by disarticulation, and the woman died in two hours. Disaster in such case was inevitable.

The speaker had used ergot in most of his labor cases since 1874, with the view of preventing post-partum hemorrhage, and has not had a single case of the latter. Of two hundred and ten of these cases he has records. In seventy of these forceps were used, and in nearly all chloroform. Two hundred and fifteen children were born, eight of whom died, one in twenty-seven; five of the mothers died, one in forty-two.

He believed ergot had nothing to do with deaths in any of these cases. Ergot should never be given in shoulder presentations, nor in any malposition unless it is to be followed by forceps, unless the case is desperate. It should be given in any stage where the head was too large, without immediate use of forceps. It should never be given in either stage unless the soft parts were dilated or dilatable, but might be given without hesitation if this condition be present and there be no disproportionate or mal-position, and especially if it is a breech delivery or a transverse lie. Wherever the head does not descend, or fails to recede in the intervals, it is absolutely necessary to apply forceps and terminate labor.

Dr. Williams gives chloroform in nearly all his labors, believing that thereby he shortens their duration and prevents exhaustion, and he precedes by ergot whenever the latter is not contra-indicated, thus maintaining pain and obviating risks of hemorrhage.

SECTION ON MATERIA MEDICA AND CHEMISTRY.

The report was presented by Dr. A. ATKINSON, who described several preparations lately introduced to the profession, viz., salicylate of iron, hydroiodic acid in the form of syrup (syrup of the bromide of nickel), saccharated oil of laurel-palmneto, coumarin, lozenges of chlorodyne, and pellotine.

Among novelities suggested were citric acid in drachm doses in morrhagia, which the author declared to be followed by wonderfully good results; the combination of tincture of digitalis with chloral hydrate, one grain to one minim, to prevent the heart depression sometimes consequent on the use of the latter alone, and boric or boric acid in erysipelas and the local inflammations.

SECTION ON SANITARY SCIENCE.

A report was presented by the Chairman, Dr. C. W. CHANCELLOR, the title of which was THE SANITARY NEEDS OF THE POOR.

In the absence of the author it was read by title and referred to the Publication Committee.

A supplementary report was read by Dr. JOHN MORRIS, upon

SOME SANITARY STATISTICS OF BALTIMORE IN THE PAST.

Dr. Morris recalled some humorous details of his subject, and pointed out the remarkable changes in the occurrence of diseases since the beginning of the century. An amusing instance of ignorance was a death certificate of hystitis in a male. The statistics indicate gradual but marked improvement.

(To be continued.)
Dr. Janeway presented a specimen of post-partum acute diphtheritic dysentery involving the entire large intestine.

It was accompanied by the following clinical history:

Dora S., twenty-three years of age, married, domestic, admitted to Ward 20, March 20, 1884. Patient was delivered of her first child at the Emergency Hospital on March 18th, at six P.M. The labor was in every way normal, and lasted only about six hours. The day following her delivery her temperature was 99°. She was then transferred to Ward 20. At this time her uterus (which had contracted down well after her delivery) had increased to a large size, extended above the umbilicus, was flabby, and her uterine sounds could be felt retreating from the vagina, which was somewhat colored, and which was increased upon pressure upon the uterus. There was no perceptible odor. She was given an intra-uterine douche of 1 to 2,000 hydragr. bichlor. Her temperature gradually fell after this, until the following morning (21st inst.) it was 99°. In the afternoon it rose again rapidly and at 7 P.M. was 102°. She was given another intrauterine douche, and temperature fell until at 3 A.M. (March 22d) it was 104°. At 2 P.M. temperature 103°. Was given an intra-uterine douche again. At 11 P.M. temperature 101°. During the night of 22d and 23d she had three large diarrheal movements.

March 23d.—This morning patient is in almost a state of collapse. Hands and feet cold, skin clammy, pulse imperceptible. Had three large diarrheal movements during the morning. Was ordered opium suppositories and these checked diarrhea. Discharge from vagina still considerable. Examination of urine: Cloudy, acid, 1.024; small amount of albumen; large number of hyaline and granular casts. At 6.30 temperature 103°; temperature 103°; 101°; 105°; 106°; 105°; skin during much of the day; temperature 101°. Removed to the Post-natal Ward.

March 24th.—Has had two large diarrheal movements. Has remained in condition of semi-collapse since yesterday morning, when her diarrhea commenced. At 1 P.M. she died, five days and eighteen hours after delivery. Treatment: quinine, gr. 30, each day; last two days, ext. ergot f. 35, q. 3 h.; morphia; whiskey.

An interesting point in the clinical history was the fact that although the temperature was high, and the heart beat with a fair amount of force, the pulse at the wrist was imperceptible. A point of pathological interest was the fact that the diphtheritic lesions were much more marked in the large intestine than in either the vagina or uterus. This fact also showed that the intra-uterine douche will not reach the whole of these cases. Again it may seem that the case is one of diarrheea, when in reality it may be one of dysentery. From the appearance of the discharges in this case, containing as they did merely a small amount of shelly matter, easily enough accounted for by the existence of lochial discharge, there was nothing to indicate the presence of dysentery.

Dr. J. Lewis Smith asked Dr. Janeway if he believed the diphtheritic colitis to be due to the same cause which produces diphtheritic pharyngitis.

Dr. Janeway thought it difficult to say; but probably it was different. It seemed to him that perhaps the uterine, vaginal, and intestinal changes appeared at about the same time, and the lesion was quite recent, because the epithelial cells still showed their nuclei when the autopsy was made. Probably the process had begun in the large intestine when the patient had the diarrheea, and the specimen was especially interesting because it showed how varied the lesions may be, and that no one would have suspected such severe dysentery from the clinical symptoms. There was no tenesmus; the patient merely having an urgent desire to have an evacuation from the bowels, followed by a large discharge. The history was such as would lead one to suppose that the symptoms were due to ergot; especially the sudden desire and a large stool. The lochias were not febrile.

Dr. J. L. Smith remarked that it was well known that women when exposed to diphtheritic poison in childbirth die without the occurrence of any inflammation of the fauces, but with diphtheritic inflammation of the uterus and perhaps the vagina.

The specimen reminded him of a case which he saw a few years ago, and in which there was undoubted diphtheritic colitis. Diphtheria had occurred in one of the children of a physician, who, soon afterward, was taken sick with obscure symptoms, and it was supposed he had typhoid fever. But after a protracted sickness he passed a cast, nearly a foot long, of the large intestine. The patient never fully recovered; there was great narrowing of the colon, when all hope of recovery was given up. In that case it was probably due to the same poison which produced the diphtheritic pharyngitis in the child.

Dr. Janeway said his patient had not been exposed to diphtheria at all.

Dr. Ferguson asked Dr. Janeway if he thought the reduction of temperature was due to the intra-uterine douches, or was it due to some other periodical reduction?

Dr. Janeway replied that the temperature fell after the first two douches, and after that it continued elevated. It would be difficult to say exactly what the reduction was due to, as very many of these cases have a periodical rise and fall of temperature.

Death from Peritonitis Following Perforation of the Appendix Vermiformis.

Dr. J. Lewis Smith presented a specimen with the following history. On March 16th he was called to a woman of about twenty-five years, fleshly, and of robust appearance, whose history was as follows: Her parents were deaf, and by strict economy, and hard work as a farm MECHANIC, she had supported herself and her family and children. Her conduct and character were such as to win the praise and sympathy of the neighbors. During the two or three months preceding the present attack she had complained of a dull aching pain low down in the abdomen on the right side and in the pelvis. At the time of Dr. Smith’s visit the pain had suddenly become more severe, and it extended over the entire abdomen, but the tenderness, though general over the abdominal cavity, was most severe in its lower part, especially on the right side in the iliac region. She said that the pain extended even to the right shoulder. With these grave symptoms Dr. Smith was surprised to find the temperature taken under the tongue normal, and the pulse not one-fourth grain of sulphate of morphia was given every three hours. On the following day the symptoms were about the same. The temperature taken under the tongue was still not elevated.

On the third day she stated that she had vomited occasionally; the temperature was elevated, but not more than two or two and a half degrees, and subsequently it did not rise above 102.5°. The pulse was about 100. Her monthly flow had now commenced, which was about one week before the usual time. Its early appearance was attributed to the poulcicing. She stated that similar
pains had always accompanied her catamenia, though perhaps not so severe.

Her features now began to show more serious sickness than before, and the doctor became anxious as to the result, so that she was visited twice daily, though he was not apprehensive of her immediate death. It seemed to him that she had inflammation in the region of the right ovary with some surrounding peritonitis, and he thought of perforation of the appendix vermiformis, but was not prepared to accept the diagnosis of a general peritonitis from the history of the case and the symptoms. The flow of blood continued, and the patient remained about the same, with occasional vomiting and the aspect of more serious sickness than at first, till the afternoon of the sixth day, when she suddenly went into collapse, and died. The physician who saw her at this time, in the absence of Dr. Smith, believed that she had sustained an internal rupture of some kind.

Autopsy.—Twenty-three hours after death, the body having been surrounded with ice; no appreciable meteorism, or distention of abdomen; abdominal walls thick from fat; on opening the abdominal cavity very foetid pus escaped, filling the room with an offensive odor; general recent peritonitis with agglutination of the intestines, peritoneum of a pink color and readily stripped from the intestines.

The inflammatory lesions were most marked in the right iliac region, and in this locality, extending down into the pelvis and reaching the ovary, the walls of the abscess could be made out, especially upon the parietal surface of the abdomen. The appendix vermiformis, at first, and subsequent to the peritonitis, was of about the size of the little finger, of a slate color, as were also the adjacent surfaces, probably from long contact with pus, and firm or solid to the feel from inflammation. Near its middle was a perforation large enough for a slate-pencil to pass. On account of the offensive odor of the pus, he did not search for the foreign body. The uterus was not opened, but it was normal in size and appearance.

It seems evident, from the lesions and history, that some foreign body had lodged in the appendix vermiformis, probably three, perhaps four months before death, and that when this body by ulceration had reached the peritoneal covering of the appendix, perityphilitis occurred, causing the abscess. Rupture of the abscess and escape of foetid pus and the foreign substance into the abdominal cavity caused the fatal peritonitis. Usually, peritonitis, when acute and general, can be readily diagnosed, but in some instances, as in the present case, a clear and certain diagnosis cannot be readily made. He once attended a young woman in her confinement, who immediately after the birth of her child, had intense general peritonitis, of which she died in a few days. At the autopsy he found that a similar abscess, produced by the perforation of the appendix by a baked bean, had ruptured. Were such a case without an autopsy reported at any of our medical meetings, nowadays, it would undoubtedly be said that the patient died of peritonitis, and the neglect to wash out the uterine cavity would be deplored.

It appears from the history of this case, and of others, that in a considerable proportion of instances perforation of the appendix does not cause immediate death, but gives rise to perityphilitis and an abscess, which so long as it does not rupture into the peritoneal cavity is not fatal. If the physician be consulted before the abscess rupture, it seems probable that he might, as a rule, save the life of the patient by opening it externally. Life thus, in one instance that had been reported to him, had been saved in this way.

Dr. Ferguson referred to a case in which impaction of faeces produced necrosis of about one-half of the vermiform appendix. In four or five cases he had found the last inch of the appendix involved by the necrotic process. In one case he found the appendix normal except at its very tip, where there was a very small opening, and a bean was found in the peritoneal cavity so large that he was unable to push it through the opening without using considerable force.

Dr. Janeway remarked that the symptoms in some of these cases are very obscure. And even when an abscess has formed it does not necessarily kill directly. He then referred to a case in which an abscess was found in the right iliac fossa with perforation of the appendix that had probably existed for three or four months, as there remaining only a small cheesy focus. Besides this there were found multiple abscesses of the liver and brain.

The President thought there was no doubt that, if the diagnosis had been made, the patient in Dr. Smith's case could have been relieved by the usual surgical operation.

Dr. Scott had seen a few cases, but he was unable to find, at autopsy, the foreign body which caused the perforation of the appendix. He inquired whether ulceration and perforation might not occur without the presence of a foreign body.

Dr. Janeway had seen ulceration and perforation of the appendix in typhoid fever, and without the presence of a foreign body. On the other hand, it has been supposed that when the vermiform appendix was invaded by foreign bodies ulceration always occurred. He had seen two cases, however, in which there was enormous enlargement of the appendix, without ulceration, in one as large as a child's head, in the other as large as a bologna sausage. One was found in the body of a woman, the other in the body of a man. The largest contained mucus and debris with white flakes which were degenerated epithelial cells, the other clear serum.

The President referred to a case of perityphilitic abscess in which rupture took place into the rectum, and the patient recovered. The Society then went into executive session.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 17, 1884.

Horace T. Hanks, M.D., Vice-President, in the Chair.

DUPUYTREN'S FINGER-CONTRACTION—ITS NERVOUS ORIGIN.

Dr. Robert Abbe read a paper on the above subject, in which he first alluded to the deformity as described by the French surgeon Dupuytren, and then gave the anatomy of the palmar fascia. He also directed attention to the history of the disease, as found in the writings of Sir Astley Cooper, Grevy, Dr. A. S. Storer, of New York; Dr. W. W. Keen, of Philadelphia; and Mr. Adams, of London. Throughout the literature of the subject Dr. Abbe had found little reference to the associated pain, and though he was aware that many of the cases were without it, there were many where it was an important symptom. Dr. Abbe then gave the history of ten cases, ending with the following conclusions: First: All there was a decided prominence of nervous manifestations, in the majority of cases resembling spinal reflex action, and he would venture to assume the following working hypotheses as capable of explaining fully the symptoms observed in this disease.

First.—A slight traumatism, often entirely forgotten.

Second.—A spinal impression produced by this peripheral irritation.

Third.—A reflex influence to the part originally hurt, producing insensible hyperaemia, nutritive tissue disturbance, and new growth, shown in the contracting bands of fascia and occasional joint-lesions resembling subacute rheumatism.

Fourth.—Through the tense contractions a secondary series of reflex symptoms, neuralgia, and general systemic disturbance. If these could be proved it would
give an agreeable substitute for the now commonly ac-
tcepted theory of gout, a blood disorder, as a cause.

Dr. Abbe then alluded to the disposition of the pro-
fection to regard any joint implication of an acute or 
subacute form as of rheumatic or gouty character, and 
direction was given to the nerve theory of acute rheuma-
tism, as stated by Dr. J. K. Mitchell, of Philadelphia, in
1831 and 1833; also the views of S. Weir Mitchell,
concerning spinal arthropathies, followed by the views 
set forth by Charcot concerning the essential nature of 
the same affection.

There was in his mind little doubt that the local con-
traction was responsible for many of the symptoms 
which had been attributed to a gouty origin; but it 
might be asked why does it so often occur where no 
traumatism can be assigned to start the trouble? On 
the contrary, Dr. Abbe referred to two cases among his 
number where traumatism preceded the contraction, as 
well as in the first case which Dupuytren reported.

The favorite method of operating is that of multiple 
subcutaneous incisions, practised by Adams, of London,
resorting to just as many as are needed to break up the 
continuity of the contracted band. With reference to 
the number, Dr. Abbe thought it made little or no differ-
ce if they were carefully made, as antiseptic dressings 
would protect from all danger. From Dr. Abbe's expe-
rience of operating he advised to do all possible not to 
do not keep the hand over-stretched after cutting, by 
binding it too tightly on splints. He believed the gen-
eral fascial inflammation following is due to nerve irrita-
tion incident to this, and that we should do better to 
keep the hand only so far extended at first as not to give 
pain. He had not operated by the method practised by 
Busch, of Eisenach, of making a flap in the palm and 
dissecting out the contracted bands and allowing 
the wound to granulate, but regarded Adams' method 
as one which left nothing to be desired.

Dr. R. F. Weir said he had noticed the nervous symp-
toms which were present in this form of contraction of 
the fingers, and had become pretty thoroughly converted 
to the view of the nervous origin of the trouble. He 
believed that the difficulty, however, might originate in 
traumatism. He fully agreed with the author of the paper 
as to the advantage of multiple incisions, and thought the 
remark made, not to stretch the fingers back to their per-
fectly normal position at first, was a wise one.

A. C. Poir said his attention was directed to this 
subject some twenty years ago, and perhaps was the first 
American surgeon to bring it before the profession in this 
country. Of late years he had not been in the habit of 
seeing many cases. He never could understand why 
surgeons should suppose had supposed the contraction was 
one of the flexor tendons instead of contraction of the 
fascia. In the cases which he had operated upon, open 
incisions into the integument were made, dividing the 
contracted bands, and he thought there was little danger 
attending either method. There had been no difficulty 
in extending the hand after the operation, but there had 
been difficulty in developing normal power of flexion, 
and the after-treatment was attended with a good deal 
of pain. When he thought of the recovery, from the first 
result had been satisfactory. He believed a traumatism 
had occurred in all the cases which he had seen, often 
due to the patient's (who had previously been engaged 
in some lighter occupation) taking unusual exercise, as 
in rowing or playing ball. He did not know that any 
of his patients had been affected with gout or rheuma-
tic affections, but never have the several cases related to 
the cause of the ring or little fingers, sometimes 
the second phalanx, and very rarely the distal. In one 
in which the sheath of the flexor tendon was involved, 
and its division was followed by more than the usual 
amount of inflammation.

Dr. Frank H. Hamilton said that when Dupuytren 
first made his observations he tried his method of treat-
ment, but not with great satisfaction. So far as the 
theory which the author had propounded was concerned, 
it had occupied his mind for a great many years, namely, 
that the malady was primarily of neurotic origin; that 
photic changes had occurred, which were due to certain 
lesions of the nervous system. A similar condition took 
place in a ligament when the latter was subjected to 
traumatic origin, but believed some were due to disuse 
of certain fingers in the occupation of the individual. 
That disuse or permanent position might cause the disease, 
he had little doubt. This would also account for the 
hand and ring fingers being most commonly affected, as 
these were more frequently subjected to a fixed position.

Dr. L. A. Sayre said he could give the theory of 
the neurotic origin of the disease his hearty concurrence. 
Most of the cases which he had seen had been accom-
panied by pain, the pain commencing even before con-
traction took place, and continuing perhaps for months. 
He believed all the cases which he had seen had had 
traumatism. Since he had adopted Mr. Adams' method 
of operating he had not observed any. The suggestion 
which had been made by Dr. Hamilton with reference to 
atrophy, seemed to him an important one, and pointed out 
the necessity for manipulation after the operation. 
Indeed, some of the best re-

Dr. V. P. Gibney could bear testimony to the painful 
and distressing neuroses which many of Dr. Abbe's 
patients had suffered. He had had similar cases himself 
which were attended by symptoms pointing to implic-
ation of the nervous system. It seemed to him there was 
an analogous condition in certain cases of club-foot in 
which he had, during the course of treatment, divided con-
tracted fascia, which enabled him to get better and more 
permanent results. The question as to the neurotic 
origin and traumatism in connection with Dupuytren's 
contraction of the hand, he thought had been very satis-
factorily set forth in the paper.

Dr. A. L. Ratcliffe said he had seen a few years ago made a num-
ber of dissections of the hand, for the purpose of de-
termining whether or not any fasciculi of the palmar fascia went to the thumb, and he had in each instance 
been able to find some, although not numerous. He had 
evertheless doubted the assumed rheumatic or gouty origin 
of the disease, and was disposed to consider it due to a 
nervous lesion, although he did not think we need exclude 
entirely the possibility of influence of gout and rheuma-
tism. He could easily comprehend how the disease 
might take place without a traumatism. Position alone 
might give rise to nervous lesions leading to such symp-
toms, as was illustrated in "writer's cramp," which was 
now regarded by all as of nervous origin. Pressure upon 
the palmar nerve at the wrist is very common, but to a com-
monly had rest upon that part, might go to account in 
part for the greater frequency of the lesion on that 
side of the hand, and also for the fact that it occurred 
more frequently among men than women. The slow 
progress of the atrophy in the fascial bands might be 
accounted for by the gradual implication of the nerve-
ous fibers in relation to the motor root of the corresponding part in the opposite hand was due to 
a lesion in the centre of nervous supply of those parts 
becoming affected by sympathy with their fellows.

Dr. R. W. Amidon had seen several of the cases nar-
rated by Dr. Abbe, and since then had observed in 
in which the contraction of the fingers was accompanied by 
certain other peculiar nervous phenomena. The man 
had had two attacks of complete loss of power in both
legs, lasting for some hours, and then passing entirely away, and unaccompanied by loss of consciousness. He had also lost partial appetite and power for two years past.

Dr. Post suggested that one reason why the deformity occurred in the ring and little fingers more commonly than in the others, was the fact that traumatism took place on this side of the hand more frequently than on the other, the thenar eminence directing the blow to the inner side of the hand.

In the course of the discussion, exhibited some patients whom operations had been performed, and remarked, concerning massage, that in some of these cases, and in many reported by other gentlemen, massage had been practised for months and perhaps years without any benefit. Massage, however, was preferable to stretching.

The Academy then adjourned.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

London, April 11, 1845.

The out-patient difficulty continues to excite discussion. It is undeniable that at most, probably nearly all, of our hospitals apply for and receive out-patient relief who are capable of paying a moderate sum for medical attendance. The loss to the hospitals is twofold: first, in the time of its out-patient medical officers; second, in the cost of the medicines supplied. At some hospitals the out-patients attend in such hordes that the work in the out-patient departments is really very severe, occupying, in extreme cases, not the hours twice a week of the time of each physician and surgeon. There is also always the danger that important cases may be slurred over among such a crowd. What can be expected when two or three hundred patients are seen in four or five hours, even though the physician or surgeon be an able general clerical and surgical practitioner?

On such a scale, too, the cost of the medicines is no trifle. The injury to neighboring practitioners is certainly real, and the remarks made in the recent discussion in the Medical Record are as applicable to London as to New York. In our metropolitan hospitals there is not absolutely a "free clinic" system, as in most of them patients are required to get "letters of recommendation." This is a slight check, and moreover, the pecuniary circumstances of patients are at any rate nominally open to investigation. Only a few hospitals dispense with "letters." Many special hospitals and dispensaries have adopted the "pay system" for out-patients. In some a fixed sum is paid for a week's or month's attendance, in others a sliding scale is in force, and patients pay according to their means. The "occupation" of the patient is often taken as the basis from which to adjudge the weekly sum to be paid. These payments vary greatly in amount. At the special institutions they average from one to two shillings a week. "Pay patients" are not required to procure "letters," so this system, advantageous though it may be for the finances of the institution, is still more injurious to private practitioners. I have known out-patients at special hospitals pay ten shillings a week, and frequently five shillings.

Ordinary out-patients at the large general hospitals are a heavy tax though. A good deal is said about "clini- cal material." But even from this point of view these departures are not so valuable as might be imagined. The patient gets his advice and medicine and goes on his way, perhaps never to attend again, although he may have gone to considerable trouble to get a "letter." The proportion of patients who attend only once is surprisingly large; still larger is that of patients who attend a few times, and then come no more. The most vexations part of it is that it is generally the interesting cases that disappear.

The annual meeting of the British Medical Association at Belfast is not to be all sweetness and light. Discontent and jealousy has already arisen, and there is likely to be more. This is partly from the fact that, of the Irishmen chosen to be officials at the coming meeting, about one fourth of them, when Sir Bell to Belfast or its immediate neighborhood. Dublin has been practically ignored, and the Dublin doctors feel aggrieved. Dublin, being the capital, certainly seems to have some claim to be fairly represented.

It is supposed that Sir William Jenner will soon vacate the presidential chair at the College of Physicians, and that choice of his successor is a topic of the day. Sir Henry Pitman, Sir Andrew Clark, and Sir William Gull are all spoken of as likely candidates. The first-named of these gentlemen is the Registrar of the College, and as such might be thought not to be in a very suitable position from whence to be elevated to the Presidency. Sir Henry Pitman has, however, been once for all rejected as a candidate, viz., when Sir Risdon Bennet was elected. Sir Henry Pitman then obtained a good many votes. The next election (that of Sir William Jenner) was unopposed. For the coming election, then, Sir Henry Pitman may be said to stand a very good chance.

Clark and Gull are both well-known men, and are both physicians with enormous practices. Sir Andrew Clark has long been a sitting-room every morning at half-past eight, and even then he cannot be seen without making an appointment in advance. After seeing his "morning patients" he drives out on his rounds, and only returns home to dine toward eight o'clock. Although conducting so large a practice, Sir Andrew is frequently to be seen at societies, and almost as frequently heard, as a competent and able speaker. Of late years he has come forward with a special advocacy of temperance.

Sir Andrew Gull is as well known and probably nearly as large a practice as Sir Andrew. As a baronet of longer standing he has probably a more intimate connection among the leading men of the medical body. The upper story of it is, as frequently in passing, are not as a rule, the best patients, and generally only give the sovereign without the accompanying shilling.

Gull is an able man, but not very popular among his fellow-physicians. He got into hot water over the Bravo trial some years ago, and more lately fell foul of Dr. Pav, one of his colleagues at Guy's Hospital. That gentleman frequently brought him before the Censors' Board of the College, who let him off with a milk and-water remand. The same fate befell him over the Bravo episode. He is, in fact, overbearing and not sufficiently considerate of others. He has offended so many that I shall be much surprised if he is chosen.

A question which has already been somewhat a burning one in London, has recently received a fillip in one of the courses of lectures recently delivered at the College of Physicians. The lecturer was Dr. Clifford Albutt, now well known as one of the most original men among our provincial physicians; his subject, the nerves, nerves, nerves of the Viscera. Dr. Albutt maintains that a very large number of nervous diseases may be accounted for by the nervous system in origin, and that their cure is to be sought in treating them as neuroses, and not as local disorders. The lecturer specially referred to uterine disorders, and narrated numerous cases in which wondrous affections which had received
no benefit from special treatment were promptly ameliorated when they were recognized as neuroses and treated on general principles. Dr. Albutt proceeded to 'have a flier' to the gynaecologists. It is an old tale that they are ready to see uterine mischief in every case, however remote the diseased area may apparently be from the pelvic organs, and the Leeds professor but emphasized the opinion of most general physicians when he protested against this view.

Another course of lectures just delivered at the College was by Dr. Hughlings Jackson, F.R.S., Physician to the London Hospital. Dr. Jackson, who is well known on one side of the Atlantic as the other as an able and laborious writer on nervous diseases. He is a careful physician and painstaking with his cases, but somewhat abstuse and difficult to follow as a writer. He has frequently been misunderstood by his contemporaries when they have undertaken to criticise some of his written or spoken utterances, and had to explain himself afresh. In his recent lectures he chose as his subject "The Evolution and Dissolution of the Nervous System." They are rather tough, but here and there the lecturc enlivens his subject by a happy illustration. Thus, referring to epilepsy, Dr. Jackson says that the cases arise when one of the enemy, the navy officials becomes occasionally insane. "Then, by issuing foolish orders to lower officials, 'discharging downward,' he produces widespread and yet slight disturbance in the navy. But by wrongly advising his colleagues, 'discharging collaterally,' he leads them to issue foolish orders to lower officials; leads them to 'discharge downward,' thus to a complete and universal collapse, the whole navy is severely and universally convulsed. The officials who, in the case of loss of one of their colleagues, work more to compensate that loss, are compelled, when one becomes insane, to co-operate in his excess."

The other course of lectures at the College of Physicians was given by Dr. Andrew, of St. Bartholomew's Hospital, who selected "The Etiology of Phthisis" as his theme. Dr. Andrew avowed himself at the outset an anti-contagionist. He considered that consumption was a specific disease which occurred in both the acute and chronic forms, having a special affinity for the apices of each lobe, and, descending in levels, it attacked the upper part of the middle lobe of the lung, the lower lobe of the upper lobe. It was not "a mere catarrhal inflammation, a peribronchitis, a chronic apex pneumonia," but a disease as distinct as scarlatina or gout. Dr. Andrew considered at great length the historical evidence for and against the contagiousness of phthisis, but throughout showed himself an uncompromising opponent of the "contagion" doctrine. Many of his arguments were perhaps not novel, but, as he remarked, "an advocate would surely do his duty in a strange fashion who omitted to state an argument because it was an old one and hitherto unanswered." In these days when it is so customary to refer to many ailments to the influence of bacteria and bacilli, it is quite refreshing to hear a hearty outpatient opposing these views.

Sir William Jenner has, after all, allowed himself to be re-elected president of the college. The Medical Council has just concluded a session of eight days. No one knows why they need have sat at this time of year, with a bill before Parliament which will virtually disestablish and disendow them. The present position of the Council is that of a helpless ulcer. They can do nothing except get through their routine work. However, they are paid by the day, and perhaps they thought they might as well spend the money in hand on a visit to London. The city corporation has just taken steps for securing the notification and isolation of cases of infectious disease, arriving on this port. The Port Sanitary Authority of London is the first one which has made regulations to this effect; but as the acts of Parliament under which the regulations are made are dated 1866 and 1875 respectively, great praise for promptitude cannot be awarded the city.

Dr. Allen Thomson, late Professor of Anatomy in the University of Glasgow, has recently died, aged seventy-four. Dr. Thomson is well known by his scientific writings. He had the rare distinction of being professor successively in three out of the four Scottish universities. Mr. Peter Squire has also just died, aged eighty-six. Mr. Squire was not a medical man, but a well-known pharmacist, and the author of "Squire's Companion to the British Pharmacopoeia," a work which is perhaps more widely known than the "Pharmacopoeia itself, and has reached the thirteenth edition.

OUR PARIS LETTER.

(From our Special Correspondent.)

THE DIAGNOSTIC VALUE OF TUBERCLE BACILLUS—EXPERIMENTAL RESEARCHES ON CHRONIC ALCOHOLISM—ALCOHOL AS A PREVENTIVE OF TISSUE WASTE—BICHROMATE OF POTASH AS A REMEDY IN CATARRHAL DYSEPSIA.

PARIS, April 15, 1882.

At a recent meeting of the "Société Médicale des Hôpitaux," Dr. Grancher read a very interesting paper on the diagnostic value of the bacillus of tuberculosis. Without wishing to depreciate the value of the presence of bacilli as a means of diagnosis in pulmonary phthisis, he thought too much time and labor were devoted to the searching of this new sign, to the prejudice of the other time-honored and classical methods of investigation. He was led to make these remarks from several cases which had come under his own personal observation in his hospital and private practice, and from those of other physicians in which there were unequivocal signs of pulmonary tuberculosis, and yet no bacilli could be detected, notwithstanding the most careful search for them by the classical methods of investigation. There is no question, he added, that when once the presence of bacilli in the sputa is established, this sign would be of greater value than all the signs furnished by percussion and auscultation. This fact, however, should not be allowed to supplant the other means of diagnosis. The bacilli make their appearance rather tardily in the sputa, that is in ordinary cases of tuberculosis, and not before manifested by a rapid ulcerative process; and to wait for the appearance of this sign to institute a course of treatment would be to commit a grave and culpable error. Moreover, the difficulties attending the searching of the bacilli are almost insurmountable, and if to this fact be added the time taken up by the investigation, Dr. Grancher did not think that the neglect of the other means would, in any way, be compensated for. The following is a summary of the conclusions as formulated by Dr. Grancher: "The discovery of the bacillus of tuberculosis should not in any way supersede the practice of auscultation and percussion. In cases of doubtful tuberculosis, the presence of bacilli in the sputa would furnish, as it were, an additional element of uncontestable certainty. But to make an early diagnosis, it is always auscultation that it would be necessary to have recourse to."

I may, however, here observe that the above declaration does not quite tally with that made by Professor Koch, of Berlin, Professor Germain Sée, of Paris, and others, who, it was believed, found the bacilli in the spu-
bility of the alcohols, also to the elevation of their atomic weight. But as it was objected that the experiments performed on dogs were not comparable with what takes place in man, the experiments were directed on pigs, and the following is the result of those experiments, which Dr. Dujardin-Beaumetz lately communicated to the Academy of Medicine: The researches were carried out on eighteen pigs, covering over a period of three years. These new researches confirmed the results previously obtained with the dogs, that is to say, the alcoholic phenomena varied with the kind of alcohol administered. The different derangements during the life of the animals and the lesions observed at the autopsy, were the more accentuated according to the impurity of the alcohol ingested. For instance, non-rectified alcohol of grain, beet-root, and potatoes, determined, all things being otherwise equal, grave accidents, whereas the same alcohols, properly rectified, produced but very little disturbance, whether functional or anatomical.

After these experiments, Dr. Dujardin-Beaumetz was induced to extend his investigations further, in order to ascertain the modifications that alcohol underwent in the organism. It has often been asserted that rectified alcohol is rejected unchanged from the system, as believed by M. Maurice Perrin and others, or whether it is consumed in the body. Dr. Dujardin-Beaumetz admits that the question is extremely difficult to resolve. Nevertheless, he thinks that when alcohol is ingested in small doses, it is transformed first into acetic acid and then into formic acid of soda. Thirdly, acetic acid, one portion of it enters the blood unaltered, and it is in passing through the lungs where, placed in contact with the oxygen of the air, it is transformed into acetic acid. In large doses, the alcohol dissolves the hemoglobin; it produces hemorrhages; the transformation of the alcohol into acetic acid does not take place; the alcohol is diffused through the entire economy and passes out of it unaltered. To sum up, Dr. Dujardin-Beaumetz stated that alcohol may be considered an aliment, but an aliment of a special character, that is, one that prevents the waste of tissue ("aliment d'épargne"), as instead of hastening the process of combustion it retards the latter, in withdrawing a certain quantity of oxygen from the blood-globules; hence the antiseptic property of alcohol, which attains its maximum by the ingestion of toxic doses, as there is then destruction of the hemoglobin and even of the globules themselves. Besides this property, alcohol has a direct action on the nervous centres, sometimes determining tonic effects, at other effects of intoxication, according to the doses administered.

The use of alcohol as a medicament has been employed principally as an external remedy; its administration internally has not hitherto produced very satisfactory results, it has been set aside as a therapeutic agent. Professor Vulpian, however, has studied its therapeutic action when administered by the stomach. He has ascertained that the bichromate of potash produces good effects in certain cases of dyspepsia, particularly in that form connected with a catarrhal or gouty affection of the stomach, presenting a certain analogy with the phenomena attended at the commencement with the development of epithelium of that organ. Professor Vulpian administered the bichromate in the form of pills in preference to solution, never exceeding ten centigrammes, or about two grains, a day, and he never noticed any toxic effects produced thereby.

At the last meeting of the Biological Society of Paris Dr. Quinquaud read a short note from Dr. Philippeaux, in which the latter states that the best manner of preserving dead bodies is to cover them over with a layer of bran and fill the coffin with charcoal powder. The body of an acquaintance preserved thus was found at the end of fifteen months mummified and without any odor.

The average consultation fee in New York is ten dollars, the maximum, twenty-five dollars.

NEEDED REFORMS IN TRANSatlantic MEDICAL SERVICE.

To the Editor of The Medical Record.

Sir: Infectious disease is the only foreign enemy which threatens, and may one day invade and decimate the United States. The danger is not visionary. Small-pox and other zymotic fevers are practically endemic in many of the larger European cities, but being usually confined within narrow bounds seldom excite public attention, yet there are times when, even in England, the pestilence stalks forth from the slums to scatter disfigurement and death among the wealthiest and the highest.

Why may it not do so here? New York sanitation is notoriously far from perfect. Lesser outbreaks are of frequent occurrence throughout all the conditions, atmospheric or otherwise, which occasionally break down all limitations of infection are more or less undetermined who can question the possibility of our being brought face to face with the national disaster of an uncontrollable epidemic?

This much is certain: the present defective sanitary administration on steamships offers easy ingress to infection, which existing quarantine arrangements are powerless to oppose.

When, as not unfrequently occurs, zymotic fever appears on shipboard during the transatlantic passage it is evident that many of the persons in such necessarily close proximity to the sufferer are likely to contract the disease, and to infect the healthy, unless immediate steps are immediately enforced. It is equally certain that when the period of incubation is unfilled at the time of disembarkation, neither will these persons have been of any inconvenience to the ship officials while on board, nor can the most careful examination at quarantine distinguish them from the healthy. They are therefore permitted to tarry at the port of arrival and to proceed to their destinations, where to become centres of possibly definite dissemination.

That this actually happens, and frequently, is proven by the fact that almost every appearance of zymotic disease in any part of the United States is—as the present outbreak of small-pox at Easton, Pa.—directly traceable to the recent advent of immigrants.

The reasons are not far to seek: the medical officers of steamers are appointed by the owners without due regard for their fitness for the post, and remain dependent upon persons whose first, if not only care, is to make the voyage with as little expense and inconvenience as possible; they are not allowed a particle of independent administrative authority in even the most purely sanitary matters, and the ship's officers are not likely to combat disease; and lastly many of the vessels employed are so constructed that the isolation of infectious disease is absolutely impossible.

A recent example is from many points of view interesting: A steamer, belonging to one of the reputedly safest transatlantic lines, arrived at this port some months ago with a saloon passenger on board suffering from small-pox, and shortly after arrival another case was discovered in the steerage.

The vessel was granted pratique, discharged her passengers, returned to England, and in due course arrived here again with another consignment of passengers, and another case of small-pox;—this time a steward who had served on the ship during the previous voyage, but who only developed symptoms of the disease thirty-two days after the former cases had been removed.

There are persons, and apparently in authority, satisfied with the assumption that cases of infectious disease following thus closely one upon another are unfortunate coincidences for which no one may be held responsible. In the public interest more careful inquiry would seem to be desirable.

The interval of time precludes the possibility of this steward having been infected directly by either of the former cases or during his stay in this city. It is highly im-
probable that he contracted the disease from an independent source at Liverpool, since small-pox was not prevalent there. Remaining is the intestine of the cases, and variola germ surviving not less than sixteen days after the supposed disinfection (?) infected this man during the latter days of the eastward passage; or, there were a succession of small-pox cases on board this vessel, which were not recognized, or were intentionally concealed from the health officer of this port, and from the public.

A visit to the ship strongly confirmed the last supposition. The hospitals for infectious disease were situated not upon the upper deck, but between the decks, in the foremost part of the vessel, opening off, and ventilated exclusively into, a covered-in passage running through the first-class saloon the entire length of the vessel. In fact if the builders had set themselves the task of constructing and locating these hospitals so as to disseminate throughout the inhabited part of the ship every germ of infection coming from within, such an end could scarce have been more skilfully attained. And this is not an isolated instance of the total disregard of sanitary law on ocean vessels.

Within five months dating from January 11, 1882, no fewer than twenty vessels infected with small-pox entered the port of New York. Upon four only was even partial quarantine enforced. The remaining sixteen were granted pratique as soon as the passengers and crew had been vaccinated. In doubt it was better to vaccinate than do nothing, but under the circumstances vaccination cannot be regarded as affording protection, since it is admitted that it does not even modify small-pox, previously contracted, unless it has been so timed that the maturation of the vaccine vessel shall precede the period of variolous invasion.

In order by which the surgeons of transatlantic steamers are required to vaccinate the steagage passengers within twenty-four hours after starting is in most instances practically ignored, seldom complied with during the time specified, and when attempted, with what results may be judged from the report of the health officers.

One surgeon reported two hundred vaccinations of which not one proved to be successful, another two hundred and fifty with but two successes, and so on.

But even if this order were carried out to the letter it would be at best but a choice of evils—and I think the wrong one. That the medical officer of a crowded steamship should neglect other more pressing duties to vaccinate steagage passengers during the first day or even days of the voyage would be manifestly inexpedient for the public welfare. On other grounds it would be both cruel and unscientific: cruel, as unnecessarily disturbing persons already miserable, many of whom would be in the throes of sea-sickness, and might claim at least to be let alone; unscientific, and calculated to discredit this most valuable of prophylactics, as challenging an epidemic of erysipelas under conditions combining to favor its development and spread.

Thus is quarantine administered in the United States, and thus is the country sown broadcast with foreign infection which will assuredly one day take root and flourish.

Is it wise to wait until the panic of that day shall call forth extreme precautions in measures repressive of convenient travel and healthful immigration?

Surely it were better that Congress should now by moderate legislation guard the country against pestilence, and insure the protection of intending citizens during the ocean transit.

This may be secured by: (1) requiring all persons coming to the United States to show evidence of having been vaccinated not less than fourteen days previous to embarkation; (2) by insisting that vessels carrying passengers shall provide proper hospital accommodation, and necessary assistance for the care of the sick; and (3) by establishing a competent service of marine medical officers, who being independent of interested influences, and responsible to Government for the discharge of their duties and intelligent co-operation with the quarantine authorities, would be some guarantee that the laws should be observed throughout the voyage.

I am, sir, your obedient servant,

J. A. IRWIN, M.A., Cambridge, Eng., M.D.,
Lady Physician to the Manchester Southern Hospital for Women and Children.

365 FIFTH AVENUE, N. Y.
April 26, 1884.

Army and Navy News.

Official List of Changes in the Stations of Duty of Officers serving in the Medical Department, United States Army, from April 13, 1884, to April 19, 1884.

NEWTON, R. C., First Lieutenant and Assistant Surgeon. Relieved from duty at Fort Sill, Indian Territory, and ordered to Fort Elliott, Tex., for duty. S. O. 77, par. 1, Headquarters Department of the Missouri, April 14, 1884.

PILCHER, JAMES E., First Lieutenant and Assistant Surgeon. Assigned to duty at Camp Poplar River, Montana, S. O. 36, par. 2, Headquarters Department of Dakota, April 7, 1884.

CHAPIN, ALONZO R., First Lieutenant and Assistant Surgeon. Relieved from duty at Fort Douglas, Utah, and ordered to Fort Laramie, Wyoming, for duty. S. O., 35, par. 2, Headquarters Department of the Platte, April 15, 1884.

WALEs, PHILIP G., First Lieutenant and Assistant Surgeon. Ordered to report to the Commanding General Department of the Columbia, for assignment to duty. S. O. 84, par. 11, A. 0. O., April 11, 1884.

WALLES, P. S., Medical Director. To continue on duty as member of Ration Board.

WELLS, H. M., Surgeon. To special duty at Hot Springs, Ark.

PECK, GEORGE, Medical Director. Ordered as President of Board of Medical Officers, detailed for special duty at Coaster's Island, near Newport, R. I.

GORGAS, A. C., Medical Director. Member of Board of Medical Officers detailed for special duty at Coaster's Island, near Newport, R. I.

WISE, I. C., Surgeon. Member of Board of Medical Officers detailed for special duty at Coaster's Island, near Newport, R. I.

An Interesting Tree.—At a recent meeting of the Berlin Medical Society, Professor Virchow showed photographs of a gigantic plane-tree in the island of Cos, under the shade of which Hippocrates is said, by tradition, to have held medical consultations. The tree now stands in the market-place of the town of Cos, on the east side of the island. The branches, which spread over nearly the whole of the market-place, are supported by marble pillars.

ERRATA IN DR. HERMANCE'S ARTICLE.—Page 431, 5th line from top, binding should read "dividing." Page 431, 20th line from bottom, should read Dr. Ward. Page 431, 30th line from top, should read intemperance, not "internal," and 26th line from top should read graver, not "gross." In the next to the last paragraph in the article the word brains should be "overties."

MORTALITY STATISTICS OF NEW YORK CITY FOR 1883. Dr. Nagle has sent us the following interesting statistics: The deaths in New York City during the year 1883 were 34,011, which is a decrease of 3,913 compared with that which occurred during the preceding year, and represents an annual death-rate of 25.8 per 1,000 of the population, which was estimated in the middle of the year at 3,171. Of the total number of deaths 9,011 were ascribed to syphonic diseases, 7,575 to constitutional diseases, 13,949 to local diseases, 2,150 to developmental diseases, and 1,326 were due to violence. The deaths from some of the most prominent causes are as follows: small-pox, 12; measles, 716; scarlatina, 744; diphtheria, 1,009; membraneous croup, 644; whooping-cough, 327; erysipelas, 175; typhus fever, 15; typhoid fever, 471; cerebro-splinal fever, 287; scarlet fever, 476; malaria, 81; tuberculosis, 1,633; aneurism, 81; marasmus, tabes mesenterica, and scrofula, 831; hydrocephalus and tuberculous meningitis, 560; meningitis and encephalitis, 749; convulsions (infantile), 514; sunstroke, 83; cirrhosis of liver and hepatitis, 350; all diseases of the brain and nervous system, 2,810; apoplexy, 636; enteritis, gastritis, gastro-enteritis, and peritonitis, 838; Bright's disease and nephritis, 1,854; cyanosis and atelectasis, 248; deaths by suicide, 161; premature and preternatural births, 753; drowning, 45; surgical operations, 39; deaths of persons seventy years of age and upward, 2,425; deaths of children under one year old, 8,671; deaths of children under two years of age, 11,315; deaths of children under five years of age, 15,856. The deaths for the year 1883, compared with the previous year, show a decrease of 3,411 in the syphonic class, 258 in the constitutional, 172 in the local class, 22 in the developmental class, of 50 in the violent deaths. The average age of those reported to have died during the year from small-pox was twenty-seven years, eight months, fifteen days; from measles, two years, six months, eleven days; from scarlatina, four years, three months, twenty-one days; from diphtheria, four years, four months, twenty-eight days; from croup, two years, nine months, fourteen days; from whooping-cough, one year, five months, eight days; from typhus fever, twenty-eight years, fifteen days; from typhoid fever, twenty-six years, three months, twelve days; from cerebro-splinal fever, seven years, twenty-two days; and from malignant fever, twenty-five years, four months, seventeen days. The number of deaths from measles in tenement-houses was 515, and in houses containing less than four families 97; from scarlatina 520 deaths were reported in tenement-houses and 187 in "private" dwellings; 627 deaths from diphtheria were reported in tenement-houses and 338 in "private" houses; 464 deaths were reported in tenement-houses and 144 in "private" houses; 240 deaths from whooping-cough were in tenement-houses and 69 were in private houses; 186 deaths from typhoid fever were in tenement-houses and 115 in private houses; 147 deaths from cerebro-splinal fever were in tenement-houses and 127 in private houses; 172 deaths from malariac fever were reported in tenement-houses and 211 in private houses. Nearly all the deaths from small-pox and typhus fever were in institutions, as these cases are sent to the Hospital for Contagious Diseases, unless they can be properly isolated and cared for. The total number of deaths during the year 1883 in institutions was 61,917, and the deaths reported in tenement-houses 18,359, and in private houses 187.

NEPHRITIS AFTER VARICELLA AND AFTER MUMPS.—Henoch has recently reported four cases of post-varicella nephritis. He regards it as analogous to the nephritis after other infectious diseases. We have elsewhere referred to the case of post-parotitis nephritis. These are both rare pathological forms.

ALOEs IN PREGNANCY.—Aloes is very commonly given to pregnant women in this country, hence the following letter from Dr. William J. Mackie to the British Medical Journal will be of much interest. He says: "In the British Medical Journal of January 5th, page 41, is a letter from Dr. J. Balch, of New York, which appears advisable in the administration of aloes in pregnancy and suspected pregnancy. While admitting that the general fear of bad effects in pregnant women from moderate doses of aloes is, to some extent, excessive, yet I may say, on behalf of those who observe considerable caution in its employment in such cases, that I knew a lady (now dead) who took aloes in pregnancy, with good results; but I cannot think that the widespread caution observed by medical men in the employment of aloes during the period of gestation is based upon tradition and prejudice alone."

LIGHTING DOCTORS' GIGS WITH ELECTRICITY.—An apparatus for lighting doctors' gigs or broughams by electricity has been successfully used in England. The Swan light is used, and a portable battery.

GO EAST, YOUNG MAN.—Dr. T. W. Kay, writing to the Medical Chronicle from Beyrouth, Syria, strongly advises his readers who want to rise in the profession to go East. "The East," he says, "is the place for a man who wants work in the medical line, and who really wants to find where his gruel a small amount of good. There you can have any amount of work and in any line that you like, except ovariotomy. Civilized communities seem to particularly claim this specialty."
ON ETHERIZATION BY THE RECTUM.

BY WILLIAM T. BULL, M.D.,
SURGEON TO THE NEW YORK AND ST. LUKE'S HOSPITALS.

Since April 15th, when I read M. Mollière's note in the Lyon Medical, of March 30th, a notice of which appeared in The Record of April 26th, ether has been administered by the rectum to patients in my service at the Chambers Street and New York Hospitals. Dr. J. B. Hunter has furnished me with notes of two etherizations from his service at the Woman's Hospital. The mode of administration was the same in every instance. The ether (Squibb's) was contained in a bottle, which was connected by a rubber-tubing (eighteen inches to two feet in length) with the vaginal nozzle of a Davidson syringe. The tube was introduced into the rectum, and the bottle placed in a vessel containing water at a temperature varying from 120° to 140° F. The ether boiled actively when the bottle was first immersed, and its vapor was given off freely; but at the expiration of five or ten minutes, when the temperature of the water had fallen several degrees, the boiling almost ceased, and it was found necessary to add hotter water to reproduce it. Some patients were prepared by withholding food for six or eight hours, and in one or two the bowels were moved by enema before etherization. In the following table, where these precautions are not mentioned it may be inferred that they were not observed.

For convenience of reference I have placed in the left hand column the data, the sex, age, and occupation of the patient, the operation, the time required to produce complete anesthesia, the time during which the etherization was continued after that stage was reached, and the quantity of ether used. In the right hand column will be found only facts relating to the patient's condition before, during, or after the etherization. The time which elapsed before complete recovery took place has not been noted.

I.—Healthy working-girl, eighteen years. Removal of carious carpal bones; anesthesia complete in six and one-half minutes; ether continued for ten minutes; quantity, 3 ij.

II.—Sailor, eighteen years. Amputation of two fingers; anesthesia complete in thirty-two minutes; ether continued twenty minutes; quantity, 3 vj.

III.—Laborer, forty-two years. Perineal section for extravasation of urine; anesthesia complete in fifteen minutes; ether continued with Allis' inhaler for ten minutes; quantity by rectum, 3 iij.

IV.—Laborer, twenty years. Amputation of finger; anesthesia complete in twenty-five minutes; ether continued for ten minutes; quantity, 3 vj.

V.—Laborer, thirty-three years. Removal of carious phalanx and metatarsal bones; anesthesia complete in ten minutes; ether continued for fifteen minutes; quantity, 3 lijjs.

VI.—A boy of sixteen years, who had been four weeks in bed with fractured femur. Application of gypsum splint; anesthesia complete in fifteen minutes; ether continued twenty-five minutes, when anesthesia was so profound as to cause alarm; quantity, 3 iiij. 3 vj.

VII.—Housekeeper, forty-eight years; robust. Removal of necrosed phalanx. Muscular relaxation in twenty minutes and no sensation in the hand; this partial anesthesia continued for fifteen minutes; quantity, 3 lijjs.

VIII.—Laborer, twenty-six years. Incision of meatus urinarius; anesthesia complete in twenty-three minutes; ether continued for two minutes more; quantity, 3 liij. Time, 9 P.M.

IX.—Female, twenty-four years; a steady drinker. Removal of wire sutures; had taken ether three or four times; anesthesia complete in seventeen minutes; ether continued for twenty minutes; quantity, 3 v. Time, 2 P.M.

X.—Laborer, eighteen years. To examine abdomen and bladder; anesthe-
sia complete in five minutes; ether continued for ten minutes; quantity, 3 iss.

XI.—Laborer, fifty years; tall and muscular. Ligation of hemorrhoids; anesthesia completed with aid of inhaler in twenty minutes; continued by rectum for ten minutes, then by mouth for ten minutes; quantity, 3 iv. to 3 iv. 

XII.—Clerk, twenty-five years. Incision of cold abscess of thigh; anesthesia complete in eleven minutes; ether continued for forty minutes; quantity, 3 iv. Time 3.30 P.M.

XIII.—Female, forty-five years. Incision of ischio-rectal abscess; anesthesia complete in ten minutes; ether discontinued; quantity, 3 iss.

XIV.—Laborer, twenty-four years. Rupture of ankylosis of wrist-joint; muscles relaxed in twenty minutes; anesthesia complete in thirty minutes; ether continued ten minutes; quantity, 3 ivs.

XV.—Laborer, sixty-five years. Excision of epithelium of lip; by the rectum for twenty minutes; duration forty minutes; quantity by rectum, 3 iv.

XVI.—Female, twenty-four years. Curettage uterus, by Dr. Hunter; anesthesia complete in eight minutes; ether continued in six and one-half minutes; continued for fifteen minutes; quantity, 3 iss.

XVII.—Female, thirty years. Curettage uterus, by Dr. Hunter; anesthesia complete in eight minutes; ether continued for twelve minutes; quantity, 3 iss.

Several phenomena, which have not been noted, have been common to all these cases. The first "new sensation," experienced has been the distention of the bowel with the gas, but this has not generally been painful, nor given rise to straining. The gas has frequently escaped pretty freely beside the tube. At the expiration of three or four minutes the odor of ether has been detected in the breath. The face has then become flushed, the breathing a little slower and deeper, the patients have yawned a few times, and then, when no stage of excitement has ensued, have gradually lost consciousness, breathed stertorously, and all sensation and reflex action have been suspended.

I have hastened to make public these observations, while they are still too few and too superficial to permit any close study of this method of etherization, because of the one symptom which cannot escape observation, the diarrhoea. Seven out of seventeen patients have had loose passages, containing blood in two instances. In these seven patients the duration of the etherization has varied from ten to forty minutes, and the quantity of ether administered from three to five ounces. There has been little or no pain or tenesmus and no constitutional disturbance accompanying this diarrhoea, which has ceased without the aid of medicine. But its occurrence in a large number of cases is a matter of concern. My conclusion that ether may be very dangerous when employed in this way, and should not be administered recklessly. In even smaller quantities than any of my patients have absorbed it might in young or enfeebled persons produce death from diarrhoea and collapse.

"M. Mollère thinks that anesthesia by the rectal method is not to be credited. He says: 'It suppresses the period of excitement; it permits one to regulate the dosage very exactly; it reduces to a minimum the amount of ether needed; it allows the surgeon to operate upon the face; it is a more agreeable method to those patients to whom the odor of ether is nauseating and objectionable.' These advantages, which are claimed for the rectal etherization, are not all confirmed by my experience. I find that it does not suppress the period of excitement, and that as a rule a much longer time is required to produce complete anesthesia than with any of the inhalers or the "towel cone." In several cases it has been impossible to etherize without the aid of the cone. The manipulations are likely to be disagreeable to patients of delicate constitution, and the apparatus cumbersome. It certainly requires less ether, and patients are free from the disagreeable odor and the still more disagreeable sense of strangulation; it unquestionably leaves the face free for operations; but it is a dangerous irritant to the intestine.

In view of these facts I cannot regard the rectal method as a substitute for inhalation, but I shall still consider it a valuable addition to it. To avoid the odor and strangulation one can begin with the rectal administration of a small quantity (3 iss. to 3 iii.) and then continue with the inhaler; and in operations on the face this order can be reversed. So far as the quantity of ether is concerned, this can be reduced to a minimum by the use of Clover's or Ormsby's inhalers, and with Allis' inhaler the suffocation is very trifling.

I should add that Dr. Curtis and Dr. Jessup, at Chambers Street, Dr. Spencer, Dr. Stephens, and Dr. Phelps, at the New York Hospital, have rendered me much assistance in recording these cases.
OPERATION FOR THE RELIEF OF BILIARY FISTULA RESULTING FROM GALL-STONE—REPORT OF A SUCCESSFUL CASE. 1

By CHARLES W. ALLEN, M.D.,
NEW YORK.

The interest always attached to the escape of gall-stones through unusual or abnormal channels has during the past few years been much increased by the advances made in abdominal surgery, and especially in the surgery of the gall-bladder.

Cholecystotomy (χόλη, gall; κύστης, bladder; and τόμης, incision) has now a sufficient number of successful cases to its credit to take the place it deserves among the recognized surgical operations. We have learned that many cases can be saved by operation which otherwise would surely be lost.

The cases which formerly were left to nature and ended fatally are probably more numerous than is generally known, for we find that in the cases which result favorably the diagnosis is rarely made, and probably many fatal cases pass unrecognized or never find their way to the surgeon.

Although many cases have been reported where gall-stones of various sizes and in varying numbers have passed through fistulous openings in the abdominal walls, yet I consider the subject of sufficient interest and importance to the profession to add to the number, and in reporting a case to collect such others as have not previously been published together.

The following case is reported with the kind permission and assistance of Dr. W. B. Bliss, of Washington, D. C., in whose practice it occurred and with whom I saw it on several occasions.

The patient was Mrs. A——, eighty-three years of age. Until the age of sixty she had enjoyed excellent health, with one exception, which was chronic rheumatism. A few years after this she sustained a severe injury to the left hip and thigh from a fall, which caused her to lead a very sedentary life on account of the pain and difficulty of locomotion. She was quite stout.

In September, 1877, she had a sudden attack of severe pain in the epigastrium, believed at the time to have been caused by the passage of a gall-stone. Intestinal obstruction covering a period of four days followed the attack. Relief was finally obtained by the introduction of a stomach pump tube through the rectum into the colon and the injection of an emollient solution. Three weeks later there was a second attack, with symptoms of passage of gall-stones, relieved by hypodermic administration of chloroform and ether internally, which was followed by nausea and severe retching. The next day a constant and severe pain localized itself in the right hypochondrium and continued with more or less severity for about three weeks, when Dr. Bliss was called, who found the following conditions: On a line with the umbilicus and fourteen centimetres to the right of it was a swelling covering an area seven or eight centimetres in diameter. There was great tenderness on pressure and pain on motion, and fluctuation revealed the existence of fluid. The bowels were obstinately constipated, the only relief being found in enemata.

The tumor was opened at once in its central and most prominent instigation. The tumors and thick cream-colored pus, of a peculiar and extremely offensive odor, were discharged. Two or three days later five biliary calculi passed through the opening; they were dark brown in color, of the size of cherry-stones, triangular in shape, and all having the characteristic polished facets. They were composed of cholesterine, with an excess of bile-pigment. Calculi continued to be discharged at intervals with the pus, but the external opening tended to heal and became so contracted as to prevent the free passage of the discharge and calculi, and although the opening was enlarged several times a pus cavity formed below, the pus burrowing between the muscular layers.

An opening was made about ten centimetres below the original one, and pus having the same characteristics was freely poured out. I first saw the case with Dr. Bliss in August, 1881, when it was decided to enlarge the original opening, explore the cavity, remove any concretions that might be found, and endeavor by keeping the orifice well open and maintaining thorough drainage of the lower cavity to allow the wound to close.

This was done. After enlarging the original wound both Dr. Bliss and myself passed the finger well into the abdomen in the direction of the gall-bladder. The smooth walls of the cavity could be felt, but no calculi could be found nor the probe reached. Drainage tubes were inserted into both upper and lower cavity and into the fistulous tract by which they communicated. The lower cavity healed completely. The upper orifice again became so contracted that an occasional stone would have to be extracted. In July, 1882, a red spot appeared at the free border of the ribs, and a spurious discharge began to escape from the original opening and a little to the inside of it. One stone came out with the discharge, making twenty-nine in all removed or discharged. Bile has been observed in the discharge on two or three occasions, but always in small quantity. There was none at first. There has never been any jaundice, and the stools have always been bile-stained, never dark.

Notwithstanding the age of the patient and her other infirmities she has remained in fairly good health, not being confined to her room; her appetite has been excellent. The bowels, at times constipated, are promptly relieved with a preparation of buckthorn bark.

Since January, 1885, there has existed a large abdominal hernia, measuring thirteen centimetres in diameter, occupying the situation of the original pus cavity, due to the destruction of the muscular walls of the abdomen in this situation.

The hernia is retained by an improvised pad and bandage, a truss which was made for the patient giving too much discomfort and interfering with the discharge. The patient was seen by the writer (May, 1883), the conditions were much the same as they had been six months previously. There were two discharging sinuses, one about eight centimetres above the other, the intervening space to the right being occupied by the hernia. To the left is a thickened mass of indurated tissue into which the sinuses run. The probe passes into the lower one; the orifice of the upper sinus will not admit the probe; its margins are red and tender, and attempts to pass a small-sized probe cause pain. Both sinuses constantly discharge a thin fetid ichor. Although this condition is not at all a common one, quite a number of cases are found recorded, some with an almost identical history.

Thudicum, in his work on gall-stones, published in 1863, brings together forty-five cases of biliary fistula; eleven collected by Soemmering in 1705, twenty by Fauconneau Dufane in 1851, eight by himself, three by Walter, and several by Oppolzer.

Dr. G. W. H. Kemper, of Muncie, Ind., has kindly sent me his pamphlet, published in 1879, entitled "The Affections of the Gall-bladder Tending to Cutaneous Biliary Fistula," in which he gives eleven cases, including one of his own. Of these eight were female and three male. The youngest was forty-one, the oldest

---

1 Read before the Manhattan Medical_and_Surgical Society, April 5, 1884.
sixty-nine years of age. In six the abscess opened spontaneously, one opened after the skin was blistered, two half opened with the knife, one after Vienna paste had been applied. All the cases recovered but one, five of them within five months.

I have collected twenty-seven cases, mostly from reports in journals of recent date, but including a few not found in former collections. I have taken only such cases of gall-stone as have resulted in abdominal fistula, or have had operations done for their relief. These, added to the cases previously collected and to the case I now report, make a total of eighty-four cases, each adding in some way to our knowledge of the condition and aiding us to devise means for its prevention or cure. In nine of the twenty-seven cases the opening, through the abdominal walls occurred spontaneously, but in four of them some cutting operation was subsequently done.

Case I. resembles a case reported by Alexander Mackindy and mentioned by Thudichum in the length of its fistulous tract, the formation of a sac in the iliac region, and the existence of a single stone. Both patients were females advanced in years. The patient, aged fifty, had a periodical pain of excruciating severity, which lasted for days. At times a large flat tumor always appeared in the right side. A discharge of a greenish-yellow mass from the navel would accompany the cessation of pain. This discharge would increase during several days and then cease until a new attack. The patient died after three years of suffering. The tumor was removed from the umbilicus to near the right iliac crest, where it formed a small sac; from here it followed the colon ascendens to the border of the right lobe of the liver, thence along the border, ending in the cystic duct. It was surrounded throughout its whole course by very strong and apparently old adhesions. The gall-bladder was much thickened and contracted. It contained a stone which measured two and one-fourth inches in its greatest circumference. The common duct was much contracted. In this case nature had made an unsuccessful attempt to expel the stone. The symptoms were severe, the condition distressing, and the result unfortunate. It is in precisely this class of cases, where nature's efforts are already unsuccessful, that the task made by the ancient surgery of to-day is called upon to give relief. We will bear this and similar cases in mind when we come to consider operative measures.

Case II.—Female, aged twenty-eight. In May, 1871, had pain and swelling to the right of the umbilicus. In April, the stone passed through the free border of the ribs and remained until seen by Dr. H., March 3d. He found a painless tumor reaching from the free border of the ribs to near the navel. It was considered an exudative deposit. May 3d two openings occurred in centre of tumor, discharging a little serous-like fluid and blood. They were joined by an incision, forming one large opening through which the finger passed into a cavity the size of a walnut. May 15th a stone passed through the opening. Fifteen others were discharged during the month. With the last stone came a flow of bile-colored fluid, which continued for several days. During this time the stools were clay-colored. The wound soon closed, and six days later the stool was again bile-stained.

Case III.—Male, aged sixty-five. In August, 1877, he complained of pain over a circumcised spot in right side. Had noticed pain in same spot on bending forward for past two years. Skin dusky, but no jaundice. September 8th an abscess burst one inch below and a little to the right of navel. Discharge was fetid and contained twenty or thirty friable gall-stones, from size of pea to that of large pea, and one weighing one drachm. September 14th a dozen calculi were loosened with probe and extracted. Probe passed in a distance of four inches. After probing the discharge contained bile. A fistula remained, but health improved and symptoms disappeared.

Case IV.—Female, aged sixty-three. Had repeated attacks of hepatic colic. Several fistulous openings formed in the abdominal parieties. One of these was dilated by Dr. Auger and about a hundred small gall-stones extracted. The patient's health improved after the operation.

Case V.—The protective agency of the peritoneal adhesions which form around these fistulous tracts, and the cur which should be exercised in exploration and operation not to injure them, is exceedingly well illustrated in this case, related to Prof. Flint by an eminent surgeon. A large number of stones had passed through a spontaneous opening which would admit the finger into the gall-bladder. It was ascertained in this way that all the stones had escaped. Another surgeon wishing to verify the diagnosis by exploring the tract, after withdrawing the finger a loop of intestine protruded, and fatal peritonitis supervened.

Case VI.—Female, aged fifty-six; first seen in October, 1879. Two months previously she had noticed a swelling in the right side of the abdomen, which was poulticed and broke in September. The following day gall-stones of her own description broke off. Two of the stones had been an attack of acute pain in the hepatic region in 1873, and dyspeptic symptoms for past five years. The sinus opened five inches below the navel and a probe could be passed six or seven inches upward and to the right through inflammatory thickening. In February Mr. Lister and Dr. Yeo slit up this sinus, divided it around which was a wound measured two and one-fourth inches in its greatest circumference. No gall-stones were subsequently discharged and the secretion ceased.

Case VII. is noticeable on account of the age of the patient, who was a female aged twenty-one, first seen July, 1880. About three years before this she had a severe pain in the right side, again one year later, and a third attack three months later. There was no jaundice. A tumor now appeared on the right side below the free border of the ribs. At the end of six months the skin became red; tumor was poulticed and discharged about four ounces of mucoid material through several pin-head openings, all within the diameter of an inch. Three weeks later it had disappeared, leaving a tender one, subsequently closed. When first seen the fistula had existed for a year, and there had been one attack of pain similar to those before its existence. In July a stone was detected in probing, and the sinus was slit up, and three stones extracted. In November the sinus had entirely closed.

Case VIII.—Female, age not given. First seen in November, 1881. There had been soreness and enlargement at the umbilicus for some time. Three months previously she had had an attack of "inflammation." The diagnosis was not established. The swelling was poulticed, and broke at the umbilicus two weeks after the doctor first saw her, discharging twelve gall-stones, ranging in size from a pea to a chestnaut. At date of report patient was in better condition than she had been for many years. In commenting upon the case the doctor says that authors consider the prognosis in these cases grave. In this I cannot agree with him, believing that the prognosis is good as regards life, and fair as regards recovery from urgent symptoms. I believe such an age at the present day so regard it.

Case IX.—Female, aged seventy-seven. Had, for ten years, been troubled with hepatic colic at intervals of a few weeks. Once, in 1878, it was attended with jaundice. There had been no colic for three years prior
to June, 1881, but she had experienced slight pain at times in the right hypochondrium. Swelling and redness now appeared, and an abscess burst, with a scanty yellow discharge. In December the patient noticed a hard substance at orifice of opening, and removed a gall-stone with the aid of a hair-pin. Several stones subsequently passed.

The explanation of the sudden cessation of attacks of colic in these cases, where no stones are found in the dejections to account for their passage, is to be found in the fact of their making their way through the walls of the duct, or bladder itself, and beginning the process of absorption or stone formation. In this case the stools were examined but no stones ever found.

In seven of the cases, besides the one I have reported, the abscess or tumor was opened—in five with the knife, and in two with cauteries.

CASE X.—F——, advanced in years. Had constant pain and discomfort in the epigastric and hypochondriac regions for several weeks, attended with vomiting. An abscess was opened four inches below the last rib, and three or four gall-stones were discharged. They were of a greenish-brown color, hard, angular, and highly polished. Eighteen or twenty more were discharged during the next few weeks, and the case ended in full recovery, there having been no jaundice and no urgent signs.

CASE XI.—Male, sixty years of age. Good health until 1859, when he had gall-stone colic without jaundice. In May, 1867, had severe pain and vomiting suddenly after dinner one day, and was sick for several weeks; pain continuing at lower border of the liver. In June an abscess was opened and a great number of stones were discharged, together with green pus. In October a sinus existed which discharged fluid like white of egg. Probe passed two inches. The sinus finally closed. A year later there were signs of adhesion of gut to under surface of liver.

CASE XII.—Female, fifty-three years of age; was admitted to Guy's Hospital in July, 1878. She had first noticed pain in the right side five years before. A tumor soon made its appearance, and three years later it was opened. The next year the tumor or abscess formed again, and two fistulous openings had since existed. The sinus was slit up between the two openings joining them. The discharge which at first was pus alone, subsequently contained bile. The abscess had almost entirely disappeared.

On October 8th, Dr. Bryant explored the wound under chloroform, and discovered a biliary calculus two inches from the surface. He enlarged the sinus in the direction of the gall-bladder, and extracted a stone one inch in length by one-half inch in breadth. Patient's health remained good, and parts were healed in about four months.

This case has been quoted and referred to by authors as a case of cholecystotomy. I am not aware that Dr. Bryant has so named it. I prefer to class it with the cases in which operation has been done upon the sinus resulting from the escape of the stone through the bladder walls. From the report of the case I do not understand it to be a true case of cholecystotomy proper.

CASE XIII.—Female, seventy-four years of age. In June, 1870, a tumor appeared resembling induration of the liver. Diagnosis not made. In July it was explored with a hypodermic needle, and opened four inches below and to the right of the umbilicus. Six ounces of pus escaped, and two or three days later a gall-stone. The opening soon closed and the tumor reappeared, and was again opened with the lancet. The same quantity of pus and another gall-stone escaped. No bile was noticed. By the middle of August patient had recovered.

Dr. Hughes asks, "Now, did I open the distended gall-bladder when I thought I was opening an abscess of the liver?"

I should answer "No." Nor do I consider that he thought rightly when he thought he was opening an abscess of the liver. We know that gall-stones can escape from the gall-bladder or substance of the liver, when adhesions have formed between these organs, and produce an abscess in it. Such instances are, however, extremely rare. Dr. Dundas had a case where an impacted stone caused abscess of the liver.

Dr. Alfred North, of Waterbury Conn., on September 8, 1881, aspirated a cyst of the liver caused by impaction of a gall-stone in the common duct, and drew off five pints of coffee-ground fluid. The patient was a male, aged forty-five, who had previously been in good health, with the exception of seven or eight bilious attacks. Death occurred on second day. It is unfortunate that we do not possess more details of the case. Considering, however, that there must have been an autopsy to determine the presence of the impacted stone, I have no doubt the cyst was plainly made out as one of the liver.

Trouseau gives two cases in which caustics were used; in one the orifice of a fistula appeared at the point cauterized, and twelve gall-stones were discharged. Both cases recovered, one completely.

He also gives a case of a male, aged sixty, in which the abscess was opened.

CASE XVII. is an interesting and instructive one, in which an operation was begun and abandoned.

Dr. Williams presented to the Society the specimen of the gall-bladder, ducts, portion of the duodenum, and abdominal walls adherent to fundus of bladder. A fistulous opening existed between the cavity of the bladder and the abdominal walls. The bladder contained twelve calculi the size of cherry-stones. The common duct was greatly dilated to within a few lines of its opening into the duodenum, and within it was enclosed a calculus much larger than those in the bladder. It could be freely moved backward along the dilated tube, but when pushed forward became impacted in the narrow portion, and occluded it.

The case was one of a female, aged thirty-five, a native of Madeira. In January, 1879, she had a severe attack of colic, followed in a week by a second, still more severe. She was much jaundiced, stools clay-colored. Urine loaded with bile. On the tenth day a tumor was detected three inches to the right of the median line, extending from the border of the liver to a little below umbilicus.

The tumor was aspirated February 22d, and sixteen ounces of very fetid, thick bile was drawn off, relieving pain at once. Little constitutional disturbance followed. The following day a large stool was passed, the first half of which was clay-colored, and the last half tinged with bile, the dividing line being very abrupt.

The diagnosis was made of calculus in common duct, which had in some way become dislodged, permitting temporary discharge of bile. An attempt was made with potassa fusa to produce adhesions between bladder and abdominal walls; but as no fluid could be detected by the hypodermic needle, after a few days, through the issue, the attempt was abandoned and the issue allowed to heal. Patient convalesced, but pain and great distention of bladder came on after a ride in a horse-car. Twelve ounces of thick bile were drawn off. No stone could be detected by probe passed through the aspirator canula. No relief was obtained, and the stools remained clay-colored. A few hours after aspirating an opening formed, just to the right of the navel, discharging bile mixed with a little pus. After two weeks a probe was passed from the spontaneous opening into the issue made in February. It is probable that the bladder adhered to the abdomen at this point. June 16th, an incision was made.
made through the eschar into the sinus, but patient was so weak and bore the ether so badly that nothing further was done. It was the intention to dilate gradually the passage into the bladder and reach the stone.

Death took place suddenly the next day, with violent pain in the region of the heart.

Heart was found flabby, but otherwise normal.

Dr. Martin Burke reports two interesting cases operated upon in his own practice. One was a male, aged eighteen; the other a female of fifty years of age. In the second case, fifty gall-stones were discharged. Both made full recoveries. This brings us to the consideration of cholecystotomy, an operation which seems to have suggested itself to the minds of surgeons many years ago, and to have been carried out in several cases of which we have some record. Schurigius, in his "Lithologia," says that J. Fabricius removed a biliary concretion from a living man by cutting. Petit seems to have suggested it in 1733. In his "Maladies Chirurgicales," 1790, he compares retention of urine and stone in the bladder with retention of bile and calculus, and suggests that as operation does so well in the one case it should in the other. He gives four cases which had been operated upon. They were supposed to be abscesses, and consequently do not deserve a place with the cholecystotomies of to-day. He began an operation himself and abandoned it.

His own and another case alone recovered; his with a fistulous opening through the abdomen, through which a calculus subsequently passed. He refers to the deliberate operation on the bladder, where the diagnosis is made. He says: "Before beginning puncture or opening of the gall-bladder, you must be assured that it is adherent to the intestines, and you know the situation of the adhesions," the idea being to operate where nature has paved the way. Thudichum said in 1859, in a paper read before the Medical Society of London, that gall-stones might be removed from the gall-bladder through the abdomen without danger or by the formation of a fistula. The priority of operation in our times is a matter of some dispute. Professor Bartholow claims to have been the first to puncture and explore the gall-bladder.

His case was one of hydatid cyst of the liver, in a man aged forty-five, reported in the Cincinnati Clinic, April, 1858, and in which there was no difficulty in finding the cyst. He found that he could pass a long probe through a canula fixed in the bladder, and explore it and the cystic duct. Patient died about four months after he first saw him.

As this was not a case of calculus, it is not included in this collection. Dr. Kemper claims priority for Professor Bollman of Indiana; in 1839, three cases was published or by the formation of a fistula. "Transactions of the Indiana State Medical Society, 1839."

He reiterates this claim in the Cincinnati Lancet and Clinic in 1879, and says that if it is not the first case, it is the first successful one on record. He operated in June, 1867, on a woman of thirty. Tumor had been growing for four years. They found five stones not made. When the tumor was cut down upon, a pedicle was looked for to tie, but none being found, the bladder was incised and several solid bodies of bullet size were discharged, with a quantity of limpid fluid. The bodies were not stated to have been gall-stones, but presumably were. The incision in the walls of the bladder were stitched, the external wound closed, and recovery was rapid. Although not a case deliberately undertaken for the relief of gall-stones, I believe it deserves a place among the operations for the relief of this condition.

I have found reported since 1856 eight cases of cholecystotomy and one case of extirpation of the gall-bladder for the relief of stone. Of these cases four were referred to by Dr. Kemper in his pamphlet, but not included in his eleven cases. I have therefore added them here to give them a little more in detail, and to make the collection as complete as possible for study.

Mr. George Brown's case is one of a female, forty-five years of age (first seen in March, 1877), who had suffered from biliousness, etc., for six years.

In February, 1877, after exertion, a painful tumor appeared in her side. Dr. B. diagnosed distended gall-bladder, and aspirated January 9, 1878, drawing off six ounces of yellow non-fetid pus. Patient remained weak, and tumor continued to decrease in size, but did not disappear. On January 22d he operated, cutting down and entering the peritoneal cavity. He then explored with the finger and tore down some adhesions on the side toward the tumor, but did not open tumor. The wound in the abdomen was sewed up. The next day there was a spontaneous discharge of bile-stained fluid. A fistula was formed which continued to discharge a small quantity of glycerin-like fluid until the middle of May, but by the end of May the fistula had healed, and the general condition remained good. The cause of the trouble was considered to be impaction of stone in the cystic duct.

If the tumor had continued to enlarge, he believes that the gall-bladder would have been ruptured into the peritoneal cavity, causing fatal peritonitis.

If Mr. Brown was following the advice of Troussseau (method of Bégien), endeavoring to produce peritoneal adhesions by cutting through to the tumor, but not making an opening before adhesions had formed, he certainly does not deserve the less credit because the tumor was ruptured before the usual twenty-four hours had expired. This, I believe, he has not made clear in his paper.

Dr. J. Marion Sims operated in 1878 (March) on an American lady, in Paris, forty-five years of age. In November of the preceding year she had had an attack of jaundice. In January, 1878, a tumor was discovered. There was intense itching of the skin. In March the distemper began, and the tumor, in the manner described, was made, and the tumor was aspirated as a diagnostic measure. Thirty-two ounces of a dark fluid were withdrawn. It contained no bile and no bloodhats hooks.

In April the symptoms became so severe that it was decided to make a permanent fistula through the abdominal walls, following the process of nature in similar cases, where the bladder and the cystic duct are in contact. Six ounces of dark-brown fluid were drawn out with a Dieulafoy's aspirator. The tumor was cut down upon and found to be the gall-bladder, and an incision, two inches in length, was made into it with scissors. Thirty gall-stones were removed. A portion of the hypertrophied wall of the bladder was amputated and the edges stitched to the cystic duct, and the bladder was packed with flannel. Sims acknowledges to have been a mistake, as it gives rise to considerable hemorrhage. The operation lasted an hour and a quarter.

Death occurred on the eighth day, from hemorrhage of the stomach (black vomit). At autopsy the abdominal incision was found perfectly united. Sixteen gall-stones were found, for diagnosis. The diagnosis was not made. When the tumor was cut down upon, a pedicle was looked for to tie, but none being found, the bladder was incised and several solid bodies of bullet size were discharged, with a quantity of limpid fluid. The bodies were not stated to have been gall-stones, but presumably were. The incision in the walls of the bladder were stitched, the external wound closed, and recovery was rapid. Although not a case deliberately undertaken for the relief of gall-stones, I believe it deserves a place among the operations for the relief of this condition.

I have found reported since 1866 eight cases of cholecystotomy and one case of extirpation of the gall-bladder for the relief of stone. Of these cases four were referred to by Dr. Kemper in his pamphlet, but not included in his eleven cases. I have therefore added them here to give them a little more in detail, and to make the collection as complete as possible for study.

In another case he says he would not delay operation after the diagnosis was established. It should be done.

before the bile acids have affected the blood to such an extent.

Dr. Keen, of Philadelphia, in November, 1878, performed cholecystotomy on a woman aged sixty years for tumour of the gall-bladder, and discharged a mass and fluid amounting to twenty ounces. Death took place on the third day. As far as Dr. Keen knew at the time his was the second operation of the kind, that of Petit being the first. He considers the operation justifiable in view of the severity of the symptoms and the certainty of a speedy fatal issue if left to itself. He intended to carry out the operation as described by Dr. Hanfeld Jones, to open the abdomen and by manipulation push into the intestine the stone obstructing the duct without opening the gall-bladder. He attributes death in this case to first, shock; second, secondary hemorrhage; third, debilitated condition of patient and age. He considers the dangers of permanent fistula not greater than those of continued obstruction.

A case of cholecystotomy for dropsy of the gall-bladder, due to impaction of a gall-stone, is reported by Lawson Tait. The patient was a female, aged eighteen, married, who in 1875 had suffered from spasmodic pains in the right side, aggravated by walking and lifting. In September a swelling appeared and increased slowly, and patient remained bedridden. An operation was postponed for two months. There was a heart-shaped elastic tumor without fixation, tender to the touch, over the region of the right kidney. No diagnosis was attempted.

On August 3d the abdomen was opened in the median line to the extent of four inches, and the tumor was found to be the distended gall-bladder. It contained two large gall-stones, one loose, and one impacted in the entrance to the duct. This one was removed with difficulty. The wound in the bladder was stitched to the upper edge of the abdominal incision by continuous suture, leaving free opening into the bladder. The abdomen was closed in the usual way. The operation was done aseptically under ether. There was a slight pyrexia, which continued until September 3d. On September 9th healing was complete, and on September 30th health of patient was restored.

Dr. Tait gives Hanfeld Jones the merit of first suggesting the operation and extending it, and Dr. Sims the credit of being the first to carry out the plan. He claimed this as the first successful case on record.

Dr. Tait performed the operation twice successfully. What he calls "a third successful case of cholecystotomy" was performed on a female aged twenty-eight, seen first December 20, 1881. Diagnosis of floating kidney had been made.

Patient had been under the care of Dr. Lycect since March, 1876, when he considered it a case of gall-stone. Dr. Tait's diagnosis was "an intubation of gall-bladder from occlusion of duct by calculus."

July 15, 1882, he opened the abdomen by a vertical incision over tumor, found gall-bladder distended, aspirated, removing a pint of thick cloudy mucus. Upon laying open bladder about eighty gall-stones were removed with curette. The largest weighed fifteen grains. The appearance of the bladder was carefully stitched to the abdominal wall as in previous case, but a drainage-tube was left in the bladder. Recovery was uninterrupted. Stitches were removed on eighth day, drainage-tube on twentieth, a small sinus was left, which discharged clear mucus until August 9th, when something seemed to give way and bile flowed freely. This Dr. Tait regards as indicating that the occlusion of the duct had been overcome, and considers that the complete functions of the organ may be re-established. To accomplish this he proposed to secure closure of the fistula by an operation. A precisely similar operation was performed by the same operator October 13, 1882. Mrs. B——, aged thirty-seven, had occasionally presented a tumor in the region of the gall-bladder. She had suffered at intervals from severe attacks of colic. The diagnosis of distended gall-bladder was clear. Sixteen gall-stones were removed, weighing from seven to forty-five grains. Drainage-tube was removed on third day. October 24th, stitches all removed. At date of report wound was almost healed.

Dr. Whittaker, of Cincinnati, O., publishes the case of a male, aged seventy-three, who had symptoms of total occlusion of the common duct, with jaundice, etc. On April 19, 1882, he fixed the gall-bladder by pressure from below and introduced an aspirator needle, withdrawing some bile. The following day he introduced the longest and finest of the Dieulafoy's aspirating needles, and struck a stone four and three-fourths inches from the surface in the direction of the common duct.

On May 3d Dr. Ranshoff operated on the case for him, removing two large stones weighing 138 and 172 grains respectively, one being firmly wedged into the cystic duct. There were also three small stones. Death occurred on following day.

Dr. Whittaker claims this method of exploration as his own, and considers it the simplest, safest, and surest method of detecting stones in the gall-bladder or ducts. He regards it as easy of accomplishment, and certainly was efficacious in the case reported, and is a method worthy of trial. It has recently been successfully employed in exploring the pelvis of the kidney for calculus. In one case in this city a large stone was detected, and the kidney extirpated. The exploring needle surely offers at present the best means of making a positive diagnosis. Whether it is entirely devoid of danger future experience will best prove. By its means many cases of impacted stone which now pass unrecognized might be discovered and operative measures instituted.

Blodgett claims precedence of Sims in operating in this country. In February, 1878, he cut down upon but did not open the gall-bladder. On post-mortem a cancer of the pancreas was found.

This I cannot consider a case of cholecystotomy, and it would not in any event be included in the collection, not having been performed for the relief of calculi. And had it been a case, those of Bobbs, Bartholow, and Brown precede it.

Langenbach advocates the extirpation of the gall-bladder in cholecistitis as well as in other pathological processes. He publishes a case in which he successfully performed it for the relief of chronic cholecystitis.

The patient was a male aged forty-three, who had suffered for sixteen years. The operation was done on July 15, 1882, and is of such interest that I give the different steps in it, as described by himself: A transverse cut is made corresponding to the anterior surface of the liver, near its lower border; then a longitudinal incision following the outer border of the rectus muscle joins the first so as to form a T. Each incision is from ten to fifteen centimetres long. This exposes the globe of the gall-bladder. The colon and small intestines are pushed downward behind the abdominal wall by means of a large flat speculum. An incision exposes the right lobe of the liver, exposing the hepato-duodenal ligament. This is caught by the fingers of the left hand. In this duplicature run the large gall ducts, and toward the median line run the portal vessels. In order to isolate the ductus-cysticus, which lies farthest to the right, expose the gall-bladder up to it by separation of such peritoneal ligaments as are present with a few strokes of the knife. A silk ligature is applied, and firmly tied about the cystic-duct one or two centimetres from the neck of the bladder. The desire being to cause permanent closure of the duct, catgut is avoided.
The bladder may now be aspirated if desired. (This was done in case reported.) The gall-bladder is easily separated by cutting through the loose areolar tissue which holds it down in its fissure, the peritoneal coat being slit up on a line of the circumference of the gall-bladder. The separation is accomplished partly by traction on the stone held fixed by a forceps and the cystic duct is now cut on the side of the ligature nearest the bladder, care being taken not to permit any escape of its contents into the peritoneal cavity. Care must be taken not to injure the liver-tissue, which is so vascular. As a rule, vessels requiring ligature are encountered. The abdominal wound is closed by sutures in the usual way.

Upon opening the gall-bladder in this case only two cholesterine stones of the size of mill grain were found, and it was considered that repeated purging had contributed to a thorough discharge of stones.

The walls of the bladder were markedly thickened, showing that there had been previous inflammation. He considers that the trouble is kept up by the constant painful, though normal, passage of the concretions, which are constantly being reproduced. He justifies the operation by the fact that the gall-bladder is not an absolutely essential organ in the economy. That in certain animals it is found wanting (horse, elephant, etc.). That in man it is often found at autopsy filled with stones and pus, or in a cystic condition, not performing its functions for a long time and being the seat of disease or not showing the singularity of their early history and onset, and with the striking resemblance which some of them bear to cases related by Thudichum and others.

Notwithstanding this fact, which would tend to assist in the diagnosis, we find that this is rarely made, in the twenty-seven cases not having been established more than once or at least twice. The average age of these cases we find to be fifty-one and one-half years; the oldest eighty-three years, the youngest eighteen years. The ages of three cases are not given, one is stated to have been advanced. These would have brought up the average, for we find only three cases below the age of thirty-five years. Fiedler gives two hundred and seventy cases of gall-stone, with three only under twenty years of age.

As regards sex, twenty were females, six males, and one not given. The reason for the frequent occurrence in the female is simply because gall-stones are observed more frequently in this sex, and this probably by reason of their more sedentary lives, although some authors deny this. Hein, from an analysis of six hundred and twenty cases, gives the proportion as two to three, Fiedler as one to two and two-fifths. Of the cases resulting in spontaneous fistula seven recovered, two died—one only after three years, and one from surgical interference.

In the eight cases where the abscess was opened by the surgeon seven recovered, and the result of one is not given. There are eight cholecystotomies with five recoveries and three deaths. The one extirpation recovered. It is therefore seen that the condition does not have so bad a prognosis, no matter whether nature or the surgeon has the case in charge; but we must not lose sight of the fact that many of the operated cases would have done badly if left to nature, and that surgical interference might have resulted in harm to others. We meet with two classes of cases—the first where there is distended bladder with symptoms of occlusion of the duct from impacted stone, the second where the impacted stone is in the bladder. If the stone is not found or bladder wall, or the contents of the bladder have escaped into the peritoneal cavity. In either case we will have a recent or remote history of colicky pains, preceded probably by rigors and shivering, and attended with local pain and tenderness. There will probably also be a history of digestive derangement. During an attack of the pain, the pulse will be slow, showing it not to be of gastric origin. The colic ceases after a time, and is replaced by a stinging, burning, or pressing pain, or feeling of fulness. If the colic has ceased suddenly the stone has probably fallen back from the neck of the bladder, and may not have caused another attack for some time, or the pain may have been subdued for a time after the stone had become fixed in the cystic duct. Having the history and other signs of biliary colic to guide us, we bring to our aid palpation, percussion, and the exploring needle.

In the first class of cases we find that where the patient is in good condition and of a suitable age, operation does well, and is, in many cases, the patient's only chance. We have now a number of successes in cholecystectomy, to put it on a firm basis, and expect much from it in the future. That this statement can be so positively made I believe to be due, in a very great measure, to the work in this field of the late Dr. Sims. His was not the first case operated upon, nor did recovery take place, still he had with characteristic boldness and ingenuity applied sound surgical principles to the problem, which, as far as he knew, was being solved for the first time. He then 'brought it before the profession in his peculiarly impressive manner, and caused it to be recognized as a scientific and proper operation.

In the second class of cases we have an entirely different condition. Here the bladder contents have wholly or in part escaped, and the tumor which they have left has become of such size that it is not to be mistaken for thickening and suppuration attending the formation of the fistula. The opening may have been effected by a process of ulceration, or the bladder may have ruptured without previous ulceration. In the former case the process has excited adhesive peritonitis, and when the opening occurs the general peritoneal cavity is shut off by adhesions of success. In the latter case there is inflammation of the viscera is the usual cause, but Dr. Ciccone related a case in L'Indépendante, in 1876, in which it occurred without this factor.

"Patient, aged fifty-one years, was seized with pain in abdomen two hours after a meal. Diagnosis: Rupture of liver. Autopsy: Gall-bladder detached from its fossa, except by a thread of peritoneum. A recent laceration, without any sign of ulceration, was plainly made out in the bladder-walls."

It is difficult to conceive of a case of sudden rupture in which death would not take place suddenly from shock, or where a general peritonitis would not prove rapidly fatal. The opening may occur at the point where the bladder is in contact with the diaphragm, and become hypertrophied from the continued efforts at expulsion. Catarrhal inflammation may be induced, and adhesive peritonitis set up between the fundus and abdominal parietes, where they are in relation just below the tenth costal cartilage, or a long and circumferential tract may be formed, opening at a distance from the bladder.

In some of the cases the opening in the bladder or duct appears to have completely closed before the opening in the abdominal wall is accomplished. In others the opening appears to act in a valve-like manner, permitting an intermittent escape of the bladder contents.

In many of these cases the only surgical assistance necessary will be the opening of the abscess and establishment of the external opening of the fistula. When all the stones have passed, we expect the fistula to heal or to discharge very slightly. In other cases operation becomes necessary, when the sinus formation is doing damage and does not quickly reach the surface.

If adhesions have formed, they should be carefully protected in operation, the incision being made where they point their base through the external opening of the fistula. When the patient's condition is still good, and before extensive damage has been done by the sinus formation and burrowing of pus. Cholecystotomy ought to be done in suitable cases, where the bladder still contains concretions and the patient's age and condition and the urgency of the symptoms warrant the attempt.

101 E. FIFTIETH STREET.
SOME OBSERVATIONS UPON THE FEEDING OF INFANTS.

By CLEMENT CLEVELAND, M.D.,
NEW YORK.

In this paper I present merely the result of personal experience, not as anything new, but with the hope of starting a discussion which will bring out some points worthy of record.

The best food for the infant is unquestionably woman's milk.

If a mother cannot nurse her child, the milk of another woman, other things being equal, comes next in order.

The selection of a wet-nurse involves a great many moral as well as physical questions, and they must be all conscientiously considered. The responsibility usually and naturally rests with the physician. For him the task is certainly a difficult and often a thankless one. I say a difficult one, because it is to be supposed he undertakes the duty in the same spirit in which he would seek a nurse for his own child, and that the choice rests upon him, the requirements he would make under such circumstances. It is a serious duty, and I believe every man before accepting a wet-nurse should ask himself this question, "Would I have this woman nurse my own child?" If this were always done, I believe fewer wet-nurses would be employed.

The wet-nurse must be young—under thirty—healthy, neat, and well-tempered; must have good breasts and nipples, and the quality and quantity of her milk must be up to the standard. There must be no great difference between the age of the milk and the age of the child to be nursed. On this point authorities seem to be at variance, making it all the way from six weeks to six months. Most writers of to-day, however, agree upon six weeks as the time beyond which it is not wise to go.

The child of the wet-nurse must be seen, and found healthy and well nourished.

The possibility of some constitutional taint must be kept constantly in mind.

A primipara, whose child has died, I believe should be preferred. She has learned no tricks, has no preconceived notions, and the more readily falls into the ways of the family to which she goes. She is not constantly worrying about and yearning for her own child, and will the more tenderly care for her foster-child.

Most of the women who present themselves as wet-nurses are poorly fitted to perform the duty. I believe, however, that mother's milk is not so readily obtained by wet-nurse as may be supposed; but then she may not, and it is rare that she does, possess the other qualifications which are next in importance. These do not appear on the surface, and are not learned except by trial. The agony of that trial is very likely to induce a mother never to make a second.

The woman who drinks or quarrels with the other servants, is a mischief-maker, or exhibits some other fiendish qualities. If the baby is thriving, she has the family in her power and soon finds it out. She knows a great deal of allowance will be made for baby's sake.

When allowed to go out she will stay far beyond the time for nursing.

If the child cries she gives it the breast at any and all times, in spite of strict commands to do so only after stated intervals.

More than likely she comes from a life of hardship and toil to one of luxury and idleness. She naturally eats anything and everything that tastes good, never having learned what an indigestion is. She takes little or no exercise. Frequently all this is the fault of the child's mother, who, forgetting the changed life of the woman, gives her the richest food. She grows ill, her milk fails, and a change has to be made. This adds to the experience of the young mother, but to her burden also, and is hard on the baby.

If the woman is married the husband must not be overlooked. He is a very important factor in the question. His home is possibly broken up and he demoralized. If she is fond of him, all this does not add to her peace of mind. To retain his affection or to keep him from bad company and drink she will often give up her place. For the sake of baby the husband must be taken good care of. Notwithstanding the moral objections usually raised, I am inclined to think the young unmarried woman makes the best wet-nurse. She can be more easily controlled. She is often "more sinned against than sinning."

If the nurse is allowed to visit her husband or friends, it is impossible to watch her movements. She may go to any infected tenement and bring home disease. I believe she should never be allowed to visit friends. Under careful restrictions they might be allowed to come to her occasionally: the husband, for instance, once a week. For baby's sake, however, some indulgence may have to be given.

It is seldom that the first nurse suits. Often a large number have to be tried. I know of an instance where a change had to be made thirteen times in two weeks. This is not particularly good for the baby.

If she hears that her child is seriously ill, though she maybe with a family in the country, following her motherly instincts she leaves at once. You cannot blame her. All the same it is hard on the baby.

If she was a nurse to a man she would care for her own child as well. As it is, the mother, or some one engaged for the purpose, must keep constant watch upon her. It is a slave's life for the mother. This catalogue of woes might be extended indefinitely. I do not think I have overstated the matter. It is the sum of the experience of the majority of people who have employed wet-nurses.

Mother's milk is the most, next to woman's milk, really the best food for the infant. That can be laid down as an axiom. Good milk it is now not difficult to procure. It does not pay to adulterate as formerly. People are too keenly alive to the necessity of having it pure. In consequence, within a few years a large number of establishments have sprung up in this city which can be depended upon to supply a reliable article. Their milk is uniformly up to the standard.

The milk of many cows is to be preferred to that of one. It is more likely to continue uniform. Undiluted cow's milk is not readily digested by the infant. It is too rich in fat and casein. During the early months the power of digesting fat is very deficient. The caseine of cow's milk, when made into curds, is kept in check by the fat of milk into much larger. Fortunately these are difficulties that can be overcome to some extent.

A milk should be selected, if possible, that is not rich in cream. The morning's milk contains less than evening's. On boiling, much of the cream comes to the surface in the form of scum, and is to be removed by straining.

Water added to the milk helps the digestion of both fat and caseine. It can be helped also by gelatine, barley, or oatmeal water; or by some alkali, as lime-water, bicarbonate of soda, or potash.

The standard proportion of one part of milk to two of water is found to suit well the majority of children. I prefer, however, for greater caution, to begin with one part to three, and work rapidly up to one part to two if digestion continues good. I have found it an advantage to gradually increase the strength from month to month, and have been in the habit of following a formula of the late Dr. Buckingham, of Boston, modifying it as each case might require. He takes eight parts as a constant proportion for milk, and beginning with twenty-four parts for water gradually decreases as follows: First two weeks, 8 parts of milk to 24 of water; second two weeks, 8 to 20; second month, 8 to 16; third month, 8 to 12, etc.
to 14; fourth month, 8 to 12; fifth month, 8 to 10; sixth month, 8 to 8; seventh month, 8 to 6; eighth month, 8 to 5; ninth month, 8 to 4; tenth month, 8 to 2.

Some children do better with a little water with the milk, even after the twelfth month. This formula makes a very convenient guide, and is meant to be considered such, rather than as a rule to be followed in all cases. I have found it so admirable a guide, however, that it has become almost a rule with me. Both the milk and the water should be boiled. The dilution should be slightly sweetened with pure brown sugar or milk-sugar, and a little salt added.

It is a good plan to prepare with morning's milk the whole amount to be used in twenty-four hours; pour it into a large bottle—a preserve jar answers the purpose—and set it away in the refrigerator, where it will keep perfectly. Where it is possible, a small nursery refrigerator should be used for this purpose alone. In travelling it is indispensable.

Cow's milk is slightly acid or neutral. To render it perfectly digestible it is sometimes necessary to make it slightly alkaline. This helps the digestion of the casein by causing its distribution into finer flakes. Whenever under these circumstances the passages I add to the dilution—half or one grain of bicarbonate of soda for the amount to be given at each feeding. This, in most cases, will correct the difficulty. Should it not, I try barley-water, made by boiling the pearl barley for hours, using a heaping teaspoonful of the barley and a saltspoonful of salt to each ten ounces of water, and passed immediately, as in the formula above. Where there is constipation, milk or less obstinate, I have found Melinn's and Horlick's food very satisfactory in removing the difficulty. It is very rare that the milk is not made perfectly digestible by one or the other of these agents.

The amount of food to be given varies from month to month and from day to day. On this and at birth the child takes about four ounces. After the second month it will hold six. The capacity gradually increases. By the fifth or sixth month eight to ten ounces will be required. The amount should be a little increased from time to time, and the quantity the child takes is a fairly good guide as to the amount it needs. Unless it is urged, it rarely takes more than it has room for.

For the first month the child should be fed every two hours; never oftener than that. It takes fully two hours for milk to digest. This rule, therefore, should be rigidly followed.

During the early months the child may cry a great deal, apparently from hunger. It is more likely to be due to indigestion of food, with a consequent over-correction, though the passages be normal. The monthly nurse, who knows all about it, insists that it is due to hunger, and gives the bottle every hour and a half, or oftener. The child is quieted for the time possibly, and the nurse is confirmed in her opinion, which no argument can change. It is, however, only stowing up trouble in the shape of fixed indigestion. Moreover, these little creatures form habits very quickly, and if the exact routine to which they are accustomed is not punctually carried out, they notify us at once, in their own peculiar way. From habit their little stomachs demand something, but not necessarily food. A little water, which fills the "aching void," but does excite the secretion of gastric juice, will often quiet them at once, and tide them over to the next time for feeding. It is rarely necessary to give medicine, and I avoid doing so just as much as possible.

After the second month, every two and a half, or even three months, may be ofte enough. I have never seen any ill effect, nor do I believe there can, from giving the milk every two hours and a half during the day, whatever be the age of the child.

The more food the child takes within these limits during the day, the less it is likely to demand at night. After the third month the child should sleep most of the night. To become a sound sleeper it should early find the habit of a full and undisturbed rest. I believe it is mainly a matter of discipline, and that every healthy infant will readily form the habit of sleeping seven and eight hours, or longer, at night. The last bottle should be given at about ten, and the first in the morning at about six or seven. At first it will probably cry for hours, till it soaks itself to sleep, and this it will possibly do for three or four nights. After that time there will be no more trouble. It will sleep through the night from ten to six or seven without waking. This plan is often objected to as cruel and heartless, and because the child must surely hurt itself. I have seen it tried many times with the happiest results, and have never known any harm come from it. Children early disciplined in this way become good sound sleepers.

Bottle-feeding should be made as simple as possible. I believe it better to discard every form of patent nursing-bottle. They cause an unnecessary expense, and, moreover, are positively harmful in the hands of ignorant or careless people. A bottle should be used which requires little or no effort to keep clean. The simple long-necked white bottle, with the passages I give in the formula above, is the best. It is only necessary to thoroughly cleanse it after each feeding, and set it aside filled with water.

The nipple I have found uniformly the best is the one made by the Davidson Rubber Company, of Charlestown, Mass., and is known by its name. It is warranted not to contain any harmful or injurious ingredients.

Formerly all the nipples that could be found in the shops contained large holes in the end. It was impossible to find any with very small ones.

It is one of the most important points in bottle-feeding that the child take the milk slowly into the stomach. When the nipple with large openings is used, the milk is taken in far too rapidly for it to be well digested and absorbed. Once an hour at least, I believe, is necessary and sufficient, and large indigestible curds are the result.

Eight years ago, through Caswell, Hazard & Co., I got the Davidson Rubber Company to make me some nipples without holes. I believe they were the first ever made; I know they were the first they had ever made. In these, at the apex, I made one small hole with the finest cambric needle heated to redness in an alcohol flame.

Through an opening of this size the infant can draw the same amount of milk as from the breast. It requires some effort, which develops the buccal muscles, as nature intends. The milk flows slowly and keeps pace with the formation of gastric juice.

This system has been tried, under a number of children then under my care, and has given me confidence in advising the bottle for the children of my patients ever since.

If a child is ill from any cause the digestion is likely to suffer. If undigested casein appears in the passages it is advisable to weaken the dilution a little. For instance, if a proportion of eight parts of milk to twelve of water is being used it is well to make it eight parts to fourteen or sixteen, or even weaker, till the signs of imperfect digestion have disappeared.

Can condensed milk I do not think it safe to use; it is too rich in sugar. Of course when it is very much diluted it does not appear too sweet, and, having commenced with it, and if the child is doing well, we are likely to go on with it. From month to month we dilute it less and less; when at half the consistency of crude milk it is excessively sweet. It is true, children have apparently done well on it, but there are children who will thrive on any food. I believe such an amount of sugar is positively harmful. The condensed milk made fresh every day without sugar is not, of course, open to the same objections.

I have seen so much trouble caused by wet-nurses, directly and indirectly, that I invariably advise the bottle
where the infant is healthy, and the mother cannot or will not nurse her child. I believe it safer to run the slight risk of the bottle’s not suit ing than to introduce such an element as a wet-nurse into a family.

The physical defects of the bottle we understand pretty well, and can, to a great extent, guard against them. Its moral qualifications, compared with those of the wet-nurse, are simply sublime.

Reports of Hospitals.

ST. FRANCIS HOSPITAL, NEW YORK.

SERVICE OF DR. GEO. F. SHRADY.

(Reported by J. H. Browning, M.D., House Surgeon.)

ANÆSTHESIA BY RECTAL Etherization.

The following cases are reported for the purpose of illustrating some points of practical interest bearing upon etherization by the rectal method:

J. S., aged fifty-four years, cigar-maker, was the subject of Dupuytren’s contraction of ulnar aspect of right palm, involving the little finger. The usual operation by multiple subcutaneous incisions was performed April 18th, by Mr. Shady, complete anæsthesia having been induced by the administration of ether by the rectum. The simple apparatus made by Mr. Ford was used, consisting of a cylindrically shaped glass vessel containing sulphuric ether (vide p. 504), provided with a perforated cork, a rubber tube, to the extremity of which was attached the vaginal nozzle of a Davidson’s syringe. The vessel was immersed in a pitcher of hot water, 120° F., and the nozzle introduced to its full length into the rectum. The following phenomena were noted by Dr. Spence, a member of the house staff: Three minutes after the introduction of the nozzle into the rectum the patient experienced a sense of moderate distention of the colon, accompanied with a fullness in the head and a taste of ether in the mouth. The odor of the ether was at the same time detected in his breath. Four minutes after the commencement of etherization, the patient talked incoherently, the respirations increasing to twenty-eight per minute. Pulse increased in frequency and force. No other evidence of excitement; no vomiting. In six minutes patient appeared completely anæsthetic. The operation was then performed, lasting eighteen minutes; at the end of that period, twenty-four minutes in all, the tube was withdrawn from the rectum. Amount of ether used was two and a half ounces. Recovery was rapid and complete. No nausea. The only thing noted by patient was fulness of abdomen. This latter condition continued to a considerable degree during the night, and the passing quantities of gas having the odor of ether were discharged. No diarrhea or other evidence of intestinal irritation.

On the same day a woman, aged thirty-five years, was etherized by the same method for the purpose of redressing a severe compound dislocation of the ankle. Three and one-fourth minutes after the introduction of the rectal tube the patient tasted the ether and exhaled the characteristic odor. She then complained of bearing down sensations as if threatened with evacuation of the bowels. None, however, occurred, but instead she vomited a meal eaten an hour before. No other vomiting, nor intestinal trouble. In seven minutes muttering began, followed by a short period of excitement and crying. Face flushed and eyes staring. Twenty minutes elapsed before anæsthesia was effected. Although muttering and apparently slightly cognizant of what was going on, she suffered no pain. The limb was dressed and plaster-of-Paris splint applied. Patient under the influence of ether fifty minutes. Amount used two and one-fourth ounces. Patient recovered rapidly without vomiting, bowels moderately distended. No diarrhea. Patient, who had taken ether by the cone four times before, expressed decided preference for the rectal method, as it saved her from feelings of suffocation and subsequent vomiting.

PRESBYTERIAN HOSPITAL, NEW YORK.

SERVICE OF DR. GEO. F. SHRADY.

(Reported by Alphred Freeman, M.D., House Surgeon.)

ADMINISTRATION OF ETHER BY THE RECTUM.

A male, aged twenty-two, was etherized by the rectal method, April 29th, for the purpose of opening a bursal sinus over trochanter. (The same apparatus was used as previously described.) One minute after introduction of tube patient noticed a fullness in head, distention of the bowels, tasted the ether and exhaled the same in the breath. At the end of three minutes there was a short period of marked exhilaration. At seven minutes he became unconscious, and had involuntary evacuations of bladder and rectum. At ten minutes he was completely relaxed and anæsthetized, when the operation was performed; Drs. Briddon, Castle, A. H. Smith, Wendt, and members of the house staff being present. Immediately before the operation patient became slightly cyanosed by the slipping backward of the tongue. Two ounces of ether used. Vomited a slight amount of mucus on recovering. Complained of no uneasiness of the bowels. Was conscious within twenty minutes after the operation, and was so entirely free from nausea that he ate a supper two hours subsequently.

C. M., male, aged twenty-five, was etherized same day by the rectal method for the purpose of cauterization for carious disease of os calcis. On introduction of tube complained of burning sensation in rectum. This was possibly due to condensation of ether vapor in the nozzle. In one minute symptoms of intoxication manifested themselves and ether odor in breath was perceptible. A minute after became emotional. This condition finally culminated in violent resistance, displacing the tube. The latter promptly reintroduced. Ten minutes elapsed before anaesthesia was induced. Relaxation not marked. Pacquelin’s cautery applied at end of thirteen minutes. Patient under ether fifteen minutes, less than two ounces used. No undue distention of bowels. Patient of united once for discharging before taken to the ward. No subsequent nausea. During the succeeding twenty-four hours there were three liquid evacuations attended with the discharge of gas. Recovery from ether took place within an hour, without excitement.

A female, aged fifty-six, was next etherized by the same method, for the purpose of examining rectum, and operating upon hemorrhoids. Immediately after introduction of tube she complained of distention and tenesmus. At four minutes she became dizzy, flushed, and tasted the ether. At seven minutes was so completely anæsthetized that there was for a short time stertorous breathing. There was more or less constant escape of ether vapor from the side of the tube in the examination, to constriction caused by an epithelioma high up in the rectum. Sufficient ether passed through the stricture to produce the anaesthesia. Amount of ether used, two and one-fourth ounces. No vomiting or subsequent diarrhea. Recovery from ether in one hour.

The accounts of the above phenomena in these cases were furnished by Dr. Garner, senior surgical assistant, who took careful notes during the progress of the etherization.

CHLOROFORM AND OIL OF CLOVES.—Prof. Nussbaum recommends a few drops of oil of cloves to be dropped in the towel or apparatus used for the administration of chloroform in cases where the chloroform is disagreeable.
ANÆSTHESIA BY THE RECTAL METHOD.

The method of administering ether by the rectum has, as might have been anticipated, attracted a great deal of attention. Since our notice of it in last week's issue we have heard of its being employed by several surgeons of this city, and it is fair to suppose that operators in other localities have not neglected their opportunities for testing Molière's theories. Elsewhere will be found reports which on one hand tend to show the possibility of inducing complete anesthesia by vapor introduced into the rectum, while on the other hand they are offset by a case terminating fatally after such etherization. While it is proper to note the timely warning sounded in the latter instance, it cannot be denied that rectal etherization has a range of adaptability which can only be measured by more extended experience. It has proved, as far as a few cases can do so, that it is at least a valuable addition to the ordinary means of etherization. Our first care, of course, must be to eliminate the possible dangers which may attend such administration. Although these can only be practically indicated by extended trial, it is proper that we should discuss in this connection one or two possibilities. Distention of the intestines, although not endangering rupture, may in prolonged operations embarrass the respiration.

Again it would seem that the degree of etherization may not be always under control. There may be at times, after complete anesthesia is induced, an amount of vapor in the intestines which may tend to deepen the anesthesia beyond safe limits. This extra quantity of vapor is practically beyond our reach, as there does not appear to be any means by which we can secure its ready escape.

In ordinary anesthesia the cone may be quickly removed in case of danger, the lungs can be allowed to empty themselves, and fresh air can be freely admitted. How an equal degree of safety can be secured for the rectal method under like conditions remains to be proven.

The number of patients who have subsequently suffered from intestinal irritation is another item to take into account in estimating the relative advantages of the two methods. It is quite possible that these results may be explained by the introduction of condensed vapor, and that improved methods of administration may effectually guard against them.

It is quite remarkable to note how quickly the vapor is absorbed, some of the patients tasting the ether within two minutes after the introduction of the rectal tube. The general anesthetic effect is not so rapidly obtained, as a rule, as that by the cone, yet the former administration is less distressing to the patient, and the usual accomplishment of the cone method, the fear of suffocation, is absent. Subsequent vomiting is also less frequent by the rectal than by the old method. Patients recover more quickly from the effects of rectal than from ordinary etherization, and manifest less subsequent excitement. The comparative merits of the two methods are illustrated by the testimony of the patient in St. Francis Hospital, who had tried both. These are matters which deserve important consideration from many points of view.

The new method is neither applicable nor necessary in prolonged operations. Even in those upon the face and throat, anesthesia by the rectal tube need only be alternated with that by the cone, in a large range of cases which will readily suggest itself to the operator. Indeed, in all severe and prolonged operations upon the face a hypodermic injection of eight or ten minims of Magendie's solution of morphine, given a few minutes before cone etherization is commenced, is sufficient, in a large majority of cases, not only to tide over the intervals when the mouth must be free, but to enable the operator to dispense with the ether altogether for varying periods.

In most nervous persons it may be found advantageous to commence etherization by the rectum until unconsciousness is produced, when the anesthetic effect can be maintained by the cone with the usual surety and safety. But, as we have already remarked, the range of applicability of the rectal method must be determined by time and experience, and we must be prepared to labor and to wait accordingly.

THE STATE BOARDS OF HEALTH AND THE AMERICAN PUBLIC HEALTH ASSOCIATION.

At the last meeting of the American Public Health Association, held in Detroit, an informal meeting of members of the State Boards of Health was held for the purpose of considering the question of perfecting an organization of these bodies, either within or without the Public Health Association. After an interchange of opinions a committee was appointed to prepare a plan of organization to be presented at a future meeting. This committee is to meet at Washington during the first week in May.

There has been for several years a growing desire, on the part of the members of the State Boards of Health, to have larger opportunities for annual discussions of the topics which pertain to their special kinds of work, than they have at the annual meetings of the Association. When the Association was organized in 1872, there were but five State Boards of Health in existence, and they were very feeble bodies. The members of these boards heartily joined in the organization for the purpose of gaining thereby better grounds of support and maintenance. Now there are thirty State Boards engaged in active and vigorous work, and many of them have become powerful factors in shaping and controlling public health administration in their respective States. Meantime the
sociation has grown to be a large and powerful body, whose annual sessions are so crowded with business and papers that but little time can be given to discussions. It follows that to meet the new and increasing interests which centre in the annual meetings of the Association, either the original plan of organization must be changed or other associations must be formed.

In our opinion the reorganization of the Association is in every respect the preferable course to pursue. While the multiplication of associations may have some special advantages by giving greater prominence in the discussions of individual topics, yet there is a great and necessary loss to members of that larger contact with co-workers in allied fields of the public service, and of thinkers and writers on sanitary subjects, which follows a meeting of the Association, and which tends to liberalize and stimulate every mind. It is evident, also, that the present elements which make up the Association can readily be harmonized in one body, and yet each separate interest have all the latitude required for healthy development. Every national organization which has attained the importance and dimensions of the Public Health Association ought to create sections in which the first reading of papers is required, and preliminary discussions allowed, while the meetings of the Association should be reserved for discussions only, and of well-defined and formulated subjects of interest to all members. By this change in the method of its meetings every paper should be fully considered and discussed by those most interested in the subject; every member would have opportunity of bringing forward in the appropriate section such questions as he was desirous of submitting for consideration; while the sessions of the Association would be made tenfold interesting and profitable by well-organized and conducted discussions. We trust the Committee having this matter in charge will decide positively against the organization of a new association, but will meet the growing wants of the various interests represented in the Association by proposing the formation of a suitable number of sections.

THE SEVENTH CHOLERA REPORT OF DR. KOCH.

Dr. Koch has sent a seventh report of his work to the German Minister of the Interior, dated Calcutta, April 4th.

He says that, since his previous report, twenty more autopsies have been made upon victims of cholera, and that the dejections of eleven cholera patients have been examined. This makes the total number examined in India, of cadavers forty-two, of cholera patients twenty-eight. The last cases do not furnish anything new, but confirm the results of previous examinations.

Experiments are now going on with reference to the power of certain agents, such as sublimate, phenol, etc., to destroy the (alleged) cholera-bacilli. These investigations are not yet completed. Only it seems to have been established that dry heat kills the bacilli, and that they remain active a long time in moist media.

The most important feature of Koch's last report is his account of the discovery of the bacillus in certain water-tanks. He states that throughout India there are numerous tanks of water which the inhabitants use for washing, drinking, and bathing. These tanks are not kept very clean, and latrines are often placed near them, so that they often become infected with excrementitious fluids. Now, it has often been noticed, says Koch, that small epidemics of cholera are apt to surround these tanks, the disease affecting those who have been using the water. A circular epidemic of this kind was investigated by the Commission. It was limited exclusively to a ring of huts about the tank, and affected about one hundred persons. The water of the tank was examined, and the same bacilli were found that were seen in the cholera dejections. After the subsidence of the epidemic, none of these organisms could be found in the tank. These facts are looked upon as strong arguments in favor of the specific character of the organism which Koch has discovered.

THE CODE QUESTION AT THE AMERICAN MEDICAL ASSOCIATION.

We can hardly add anything to the following able presentation of the code question by the editor of the Cincinnati Law and Clinic. We believe it expresses the general feeling of the profession:

"The code question, like Banquo's ghost, will not down, and will cause discussion. In fact, it will bear discussion, and we hope that a large committee of representative men will be appointed to report on the desirability of a revision of that document. We would further suggest that such committee be constituted most largely of the younger members of the Association. As a class, they are much more interested in the enactment of laws that are to govern professional intercourse than those who have already served their day and generation, and who have obtained all the honors the profession have seen fit to bestow upon them. It is in the interest of the whole medical profession that it should not be divided into factions, and yet that is bound to be the result of a retention of a code in its present form. We have the utmost respect for the code, and believe it has been a mighty factor in the elevation of the standing and education of the medical profession; but as a time did come when it became necessary, for the salvation and unity of the nation, that the Constitution should be amended, so it has come about that, in order to preserve the harmony and unity of the American medical profession, it becomes necessary to remand that document to a large and representative committee for amendments, and such amendments should be sent back to the societies now entitled to send delegates to the Association for affirmation or rejection.

"Unless the Association takes some such action the quicksands of disaffection and consequent disintegration are absolutely certain to take place, and, instead of a united, influential and grand body, the American Medical Association will become a skeleton faction, eminently respectable and honored for the good it has done."

THE BEST FORM IN WHICH TO USE IODOFORM.—Hoefman is of the opinion that the evil influence from iodoform is due to the form in which it is used, the crystals being less objectionable than the powder. Czerny thinks it depends more on the extent of the wound and the presence of fat. Koenig thinks it dependent rather on the age of the patient—the older the patient the greater the susceptibility.
News of the Week.

THE NEW YORK CANCER HOSPITAL.—The trustees of the New York Cancer Hospital have purchased a site on Eighth Avenue, between One Hundred and Fifth and One Hundred and Sixth Streets, 200 feet by 180, on which they intend to erect buildings without delay. The funds on hand amount to $275,000.

THE GARFIELD MEMORIAL HOSPITAL.—The Board of Directors hope to open this hospital in May. The medical and surgical staff has been formed as follows: Drs. Fred. May and N. S. Lincoln, Consulting Surgeons; Drs. W. W. Johnston, J. Taber Johnson, and A. Y. P. Garnett, Consulting Physicians; Drs. C. E. Hagner and J. H. W. Lovejoy, Attending Surgeons, and Dr. Swan M. Burnett, Ophthalmologist and Otologist.

DEATH OF DR. SANDFORD B. HUNT.—Sandford B. Hunt, M.D., editor of the New York Advertiser, died on April 27th, at his home in Irvington, near Newark, N. J., aged fifty-eight years. He was a native of Ithaca, N. Y. About 1855 he became Professor of Anatomy in the Buffalo Medical College, and editor of the Buffalo Medical Journal. Afterward he was the editor of the Buffalo Commercial Advertiser. He was the surgeon of the One Hundred and Ninth New York Volunteers, and became surgeon-in-chief and medical director at New Orleans. He was mustered out of service with the rank of brevet lieutenant-colonel. During the first year of peace he wrote the history of the Sanitary Commission.

GOVERNMENT QUARANTINES.—The Ship Island (Miss.) quarantine station, Surgeon Robt. D. Murray, U. S. Marine Hospital Service, in charge, is now open for the reception of infected ships, as is also the Sapelo station, under charge of Acting Assistant Surgeon Geo. H. Stone, with Dr. Brunner as an assistant, and stationed on the island. Cape Charles quarantine station (Fisherman's Island, Chesapeake Bay) will be open for work on the 15th inst., under charge of Passed Assistant Surgeon Fairfax Irwin, U. S. Marine Hospital Service.

MEDICAL BERLIN.—At the meeting of the Society of Therapeutics, Dr. P. Mendel read an elaborate paper upon the "Pathology and Treatment of Epilepsy." Most of the paper was devoted to a discussion of the pathology. Mendel was inclined to accept Nothnagel's view that epilepsy is a disease in which the convulsions are produced by anemia of the medulla, rather than the view that the disease is cortical. Cortical epilepsies, he thought, were always partial. In the treatment he recommended the usual course of bromides given in valerian tea. Atropia he thought of some value also.

MEDICAL PARIS.—At the meeting of the Société de Biologie, March 29th, M. Rabuteau made a communication upon "Anaesthetics," in which he stated that all monatomic ethers were bad anaesthetics, and all diatomic ethers were good anaesthetics. M. Ch. Richet, in a paper upon the "Influence of Cerebral Lesions upon the Bodily Temperature," made the generalization that cerebral lesions, as a rule, cause a considerable rise of temperature. M. Burke made some remarks upon "Metallotherapy," in which he replied to criticisms against it.

At the meeting of the Society, April 5th, MM. Megnin, Rochefontaine, and Laborde presented facts showing that "copper has no power against cholera." M. Blanchard announced that the "tetrachloride of carbon" was not an anesthetic, as asserted by Rabuteau. M. Quinquaud presented a note in behalf of M. Philippeaux, to the effect that cadavers could be preserved for five months by packing them in bran and charcoal. M. Quinquaud also presented a report relating to the action of "paraldehyde upon the blood." By injecting the drug into the circulation, a great decrease in the excretion of carbon took place and the animals died in twenty-four hours.

TO MAKE ALL QUALIFIED PHYSICIANS EQUAL BEFORE THE LAW.—Senator Colquitt, of Georgia, presented on April 23d the petition of Dr. F. H. Orme and others, citizens of Atlanta, Ga., praying for the passage of Senate bill 1223, making all qualified physicians equal before the law in the Government service. Referred to the Committee on Civil Service and Retrenchment. Similar petitions were presented by Senator Sawyer, of Wisconsin, from H. L. Palmer and forty-five other citizens of Milwaukee and Appleton, Wis., and by Senator Blair, of New Hampshire, from Dr. J. Lance and forty-nine other citizens of Campton Village, N. H., which were also referred to the same committee. The following is the text of the bill referred to: "A bill to secure to the medical profession equal rights in the service of the United States.—Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled, That all appointments to medical service under the Government shall be made from graduates of legally chartered medical institutions, without discrimination in favor or against any school or theory of medical practice. Section 2. That any violation of the foregoing section shall be punished in the same manner as prescribed for like offenses by the act entitled 'An act to regulate and improve the civil service of the United States,' approved January 16, 1883." Read twice and referred to the Committee on Civil Service and Retrenchment.

On April 23d Senator Pendleton, of Ohio, presented a similar petition to above, signed, as he said, by "a great many citizens of Covington, O."

CONGRESSIONAL ITEMS.—Mr. Collins, of Massachusetts, introduced a joint resolution on April 28th, providing for the continued reports of the Columbia Hospital and Lying-in Asylum; read a first and second time, and referred to the Committee on the District of Columbia, and ordered printed.

The Dingley shipping bill was passed by the House on Saturday last. It was amended so that the expenses of the Marine Hospital Service shall be paid out of the tonnage tax instead of by a tax on seamen. This will relieve the service of much clerical labor, and as the tonnage tax is mostly paid by foreign vessels, everybody should be happy.

DR. RALPH D. MARSH, of this city, died April 28th. Dr. Marsh entered upon the practice of his profession in the Ninety-ninth Street Hospital, where he was in charge. In 1881 he retired from the hospital, and soon took rank as one of the leading physicians of Harlem.
THE MEDICAL ASSOCIATION OF THE STATE OF ALABAMA met at Selma on April 8th, and had an ethical rather than scientific session. It "resolved" to congratulate the Old Code New York State Association on having separated from the "demoralizing movement" of the State Society. A resolution condemning the Louisville Medical College for unethical advertisements was also passed. In fact, the Society seems to have done everything except scientific work—this latter being represented by an omnibus discussion and a "Plea for an Unborn Child."

THE TENNESSEE STATE MEDICAL SOCIETY, at its annual session, April 8th and 9th, appropriated $50 for the Sims Memorial Fund. The meeting of the Society was largely devoted to the subject of securing better medical organization, and, if possible, a medical registration law. A committee was appointed to memorialize the Legislature for this purpose.

ANOTHER FORTUNATE MEDICAL COLLEGE.—We congratulate the Bellevue Hospital Medical College upon being the recipient of a gift of $50,000 from Andrew Carnegie, one of the trustees of the college. This sum is to be expended in the erection of a building and in apparatus to be devoted to laboratories for practical work and teaching in the different departments of the science of medicine.

THE BILL TO DEFINE THE TITLE AND DUTIES OF CERTAIN OFFICERS OF THE MEDICAL DEPARTMENT OF THE ARMY, introduced by Senator Logan in February last, has been up for consideration several times during the last week. The following is the bill as amended:

"That from and after the passage of this act the six officers of the rank of colonel now authorized by law, designated as chief medical purveyor, surgeons with the rank of colonel, and assistant surgeon-general, shall be styled assistant surgeons-general, continuing to have the rank, pay, and emoluments of colonels, to be placed on the Army Register in the order of seniority of dates of present commissions as colonels. That the senior assistant surgeon-general shall be charged with the duties of chief medical purveyor, who shall be located in Washington City, and that the other assistant surgeons-general shall be assigned to such duties in the Medical Department as the interests of the service may demand. Sec. 2. That the officers of the rank of lieutenant-colonel now authorized by law, designated as surgeons with the rank of lieutenant-colonel, and as assistant medical purveyors, shall be styled deputy surgeons-general, with the rank, pay, and emoluments of lieutenant-colonels, to be placed on the Army Register in the order of seniority of dates of present commissions as lieutenant-colonels. That the deputy surgeons-general shall be assigned to such duties in the Medical Department as the interests of the service may demand. That the duties of assistant medical purveyors shall be performed by officers detailed. Sec. 3. That all acts or parts of acts inconsistent with the provisions of this act are hereby repealed."

CORRECTION.—In Dr. Jackson's article on Danduff, page 430, the quantity of colonel used should be 40 instead of 11 grains.

THE TER-CENTENNIAL AT EDINBURGH.—The Edin-urgh papers give glowing accounts of the centennial ceremonies. The degree of LL.D. was conferred upon about twenty-five medical men of Europe, and upon Drs. Fordyce Barker, John S. Billings, and (in absentia) S. D. Gross, of this country.

THE SIMS MEMORIAL FUND.

To the Medical Profession and Others throughout the World:

The great achievements of Dr. J. Marion Sims call for some more lasting testimonial than obituaries and eulogies. To him medical science is indebted for much brilliant and original work, especially in gynecological surgery. Those who have been benefited by his teachings and new operations, and such as have had the direct advantage of his personal skill are among the first to recognize and acknowledge this debt.

To him is due the honor of giving the first strong impulse to the study of gynecological surgery in America. It is believed that the medical profession everywhere, the vast number of women who owe their relief from suffering directly to him, and those who realize the benefits he first made possible, will gladly unite to honor the man through whose original and inventive genius such blessings have been conferred upon humanity.

At the suggestion of many friends, therefore, the subjoined committee has been organized, and it is proposed that a suitable monument be erected to his memory in the city of New York.

To this end the active co-operation of the medical profession and the many other friends of Dr. Sims throughout the world is respectfully solicited. Contributions of one dollar and upward may be forwarded to the journal which has been constituted the treasury of this fund—The Medical Record, New York.

Note.—The Faculty of Physic of the University of Maryland should have been credited with the $100.00 contribution to the Sims Memorial Fund, instead of the Faculty of Physicians of the University of Baltimore, as stated in our issue of March 20th. This seems all the more just, as the University of Maryland was the first medical school in the country to move in the matter.

Obituary.

WILLARD PARKER, M.D., LL.D.

NEW YORK.

Though not unexpected, news of the death of Dr. Willard Parker, on April 25th, was a shock to his many friends in the profession. For over a year and a half he had been suffering from pellagra, and for some months past he had been at times critically ill. About a week before his death he was attacked with paralysis and all hope of his recovery was abandoned.

Dr. Willard Parker was born in Lyndeborough, N. H., September 2, 1800. He came of hearty and hardy Puritan stock on both his father’s and mother’s side. His father was a farmer, and when the doctor was but five years old
age his parents removed from New Hampshire to the old homestead in Massachusetts, which was owned by the doctor up to within a short time of his decease. Willard Parker was a sturdy, ambitious youth, who assisted his parents on the farm in summer and attended the village school in the winter. His great ambition was to secure a college education. To provide money for this purpose, his father being unable to furnish him with the funds, he began teaching school when eighteen years of age. He taught for four years, and having accumulated what seemed a sufficient amount he entered Harvard University in 1822 and was graduated in 1826. He had intended to study for the ministry, but during his college career circumstances led him to change his plan.

In the spring of 1827 he received an appointment as an interne at the Chelsea United States Marine Hospital. He remained there but two years, receiving $13 a month for his services. Afterward he was appointed Professor of Anatomy in the Berkshire County Medical College at Pittsfield, Mass., then one of the leading institutions of its class in the country. In 1832 he was also made Professor of Surgery, and for four years filled both chairs, delivering two lectures daily. In 1836 he accepted the chair of Surgery in the College of Physicians and Surgeons, remaining there for three years. During his occupancy of this position he made a trip to Europe to study the methods in the French and English medical colleges. In 1839, after his return from Europe, he settled in this city, having been appointed lecturer on surgery in the College of Physicians and Surgeons.

His practice soon became considerable, and he rapidly rose to the position of one of the foremost surgeons and general practitioners of the city and country, his fame extending even across the waters to the European continent. Dr. Parker was both successful and popular as a lecturer. This was due to his wonderful aptness in elucidating the most abstract and difficult possible, technicalities, seeking his subjects among common-place and readily understood objects and incidents.

Among the public works in which Dr. Parker took an active part was the reorganization of the city hospital system in 1845. This resulted in converting Bellevue Hospital from an alms-house into a charity hospital, under a board of Governors. Dr. Parker and the late Dr. James R. Wood were appointed visiting surgeons. Though not, perhaps, so prominently identified with the growth of that institution as Dr. Wood, he was more or less actively and intimately connected with the steps which led to its growth. He took a deep interest in its success and contributed much to this end. Dr. Parker was also prominently identified with the reorganization of the Health Department of the city. In 1865 Dr. Parker succeeded Dr. Valentine Mott as President of the State Inebriate Asylum at Binghamton, entering upon the work somewhat as a matter of duty. He saw, too, a possibility of carrying out well-digested views as to the treatment and cure of dipsonania. He believed that alcohol was a poison, never a food, and that drunkenness was a disease, often hereditary in character. He counselled all his patients to abandon the use of spirits at all times, except on the advice of a physician. Dr. Parker resigned his active duties as Professor in 1870, in which year he received the degree of L.L.D. from Princeton College. Since that time he had been consulting surgeon to the New York, Bellevue, St. Luke's, Roosevelt, and Mount Sinai Hospitals, and Professor Emeritus of Surgery in the College of Physicians and Surgeons. He was an active or honorary member of many societies, medical and surgical, in this and several other States. With his retirement from teaching came a partial retirement from his labors as a general practitioner. He continued to practice, however, in many families whose physician he had been through a long series of years, and he was frequently called in consultation in difficult surgical and medical cases. Dr. Parker insisted upon having the full confidence of his patients, and in return he confided to them his full diagnosis of the case, its causes, possible results and mode of treatment, and materials used to assure a cure. To this method he ascribed much of his success. His methods of treatment were of the simplest possible character as a rule, and he had no faith in, or fondness for, medication, save where he deemed it absolutely necessary. Homely remedies, such as are sometimes called "old women's remedies," and which called simply for an obedience to the rules of health, a simple diet, and abstinence from medicament, were often his sole prescriptions. Since retiring from teaching, in 1870, Dr. Parker had passed the greater portion of his time at his farm in New Canaan, Conn. There he indulged his fondness for agriculture, and found health, rest, and strength. His first city residence was at the southeast corner of Bleeker Street and Broadway. There during his first year's practice his income from his professional business amounted to but $300. During the height of his professional career, however, this sum would not begin to equal his weekly income from the same source. It was as a surgeon that Dr. Parker achieved his most brilliant successes. He was ambidextrous, using either hand equally well in operating. He frequently performed two operations at once during the past year he performed delicate operations without the use of glasses, using either hand, as came the most convenient. Among his contributions to the art of surgery were cystotomy, for the relief of chronic cystitis; an operation for the cure of abscess of the appendix vermiformis, and the laceration of the perineum, cured by the division of the coccygeal attachment of the sphincter and subsequent closure of the perineum by sutures. He was also the first to point out the condition known as concussion of the nerves as distinguished from concussion of the nerve-centres, and which had previously been mistaken for a condition of inflammation. Dr. Parker was not a writer, and even his reports of remarkable cases or delicate operations have been made for him by other members of his profession. Though a close student, he disliked to write, this aversion being in part due to the fact that the pen was not rapid enough to follow his thoughts. A large number of reports of his cases appear in medical and surgical journals. It was due in great part to Dr. Parker's simple mode of life that he displayed so much vigor in his advanced years. He had an erect carriage, an elastic step, and eyes and features that sparkled with life and animation.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from April 20, 1884, to April 26, 1884.

HOFF, JOHN VAN R., Captain and Assistant Surgeon. To be relieved from duty at Alcatraz Island, Cal., and to report to the commanding officer at Fort Mason, Cal., for duty as Post Surgeon. S. O. 45, par. 3, Headquarters Department of California, April 16, 1884.

PORTER, JOSEPH Y., Captain and Assistant Surgeon. Granted leave of absence for two months, to take effect about May 5, 1884. S. O. 38, Headquarters Division of the Missouri, April 19, 1884.

J. BRAINT, VICTOR, Captain and Assistant Surgeon. Granted leave of absence for two months, to take effect about May 5, 1884. S. O. 91, par. 2, A. G. O., April 19, 1884.

LA GARDE, LOUIS A., Captain and Assistant Surgeon. Granted leave of absence for one month, with permission to apply for two months' extension. S. O. 91, par. 1, A. G. O., April 19, 1884.
Official List of Changes in the Stations of Medical Officers United States Navy, for the week ending April 26, 1884.

AULICK, H., Passed Assistant Surgeon. Detached from iron-clads and ordered to New Hampshire.

DIXON, W. S., Passed Assistant Surgeon. Detached from Hartford, and ordered to Coast Survey steamer Hassler.

TERRILL, F. H., Passed Assistant Surgeon. Detached from Hassler and ordered to Hartford.

WISE, J. C., Surgeon. Detached from New Hampshire and placed on waiting orders.

SCHOFIELD, W. K., Medical Inspector. Appointed Medical Inspector on Active List.

NASH, F. S., Passed Assistant Surgeon. Detached from Laboratory and ordered to Alert (Greely Relief Expedition).

HALL, J. H., Passed Assistant Surgeon. Ordered before Retiring Board.

NELSON, H. C., Medical Inspector. Placed on Retired List.

BATTLE, S. W., Passed Assistant Surgeon. Placed on Retired List.

TERRILL, F. H., Passed Assistant Surgeon. Resigned.

Reports of Societies.

ARKANSAS STATE MEDICAL SOCIETY.

Ninth Annual Session, held at Little Rock, Ark., April 30, May 1 and 2, 1884.

(By Telegraph to THE MEDICAL RECORD.)

FIRST DAY, WEDNESDAY, APRIL 30TH.

The Society met in the Capitol Building, Little Rock, Ark., Wednesday, April 30, at 10 A.M., and was called to order by the President, J. M. KELLER, M.D.

Ninety-one delegates were present, and many invited guests.

DR. L. R. STARK gave the ADDRESS OF WELCOME

to the members, extending the hospitalities of the city and congratulating them upon the promise of a profitable and successful meeting.

ADDRESS OF PRESIDENT.

DR. J. M. KELLER then delivered his annual address. After a few appropriate introductory remarks he proceeded to glance at some points connected with the progress of medicine and surgery. Among these antisepsis in surgery claimed paramount attention. He reviewed the benefits which have accrued from its adoption, principally in the direction of guaranteeing results which were impossible without it. Other topics of interest touched upon were the advisability of excision of the primary sore in syphilis, the value of cremation as a sanitary measure, the employment of whiskey for anesthetic purposes, and the necessity of concerted action in obtaining medical legislation in favor of legitimate medicine, and the influence for good which medical men, associated in scientific bodies, could exert to that end.

CONCLUSION OF THE SPINE.

DR. E. BENTLY, U.S.A., read a paper on concussion of the spine caused by blows, falls, and railroad collisions, in which he defined the kinds and degrees of shock in each, also their symptoms and pathology. The treatment in all was mainly in the direction of rest, with toics and careful attention to local and general hygiene.

DR. W. P. HART presented an able argument against the generally accepted doctrine of the germ theory in syphilis, exposing its lack of demonstration and inconsistency, principally in connection with the assumption that said germs exist in the primary and secondary, but not in the tertiary forms of the disease.

SOME IDEAS ON ANTISEPTICS AND ANTISEPSIS was the title of a paper by DR. R. B. CHRISTIAN, in which it was very justly claimed that the main points in the treatment of wounds, cleanliness, free drainage, and rest, did not, as a rule, receive their proper recognition.

DR. D. C. EWING read a paper on PROCIDENTIA UTERI ATTENDED WITH RUPTURE.

The procidentia occurred during labor; the child was delivered by the forceps, and there was rupture of the os uteri and five inches of the body of the organ. The parts were sewed up without delay and without antiseptic precautions, recovery taking place in three weeks.

SECOND DAY, THURSDAY, MAY 1ST.

MISCELLANEOUS BUSINESS.

The meeting was called to order at 11 A.M. by the President, and the morning session was occupied in the transaction of routine business and the reception of the reports of the Standing Committees on Medical Education, Medicine, Surgery, Gynecology, Medical Legislation, Necrology, State Medicine, and County and Municipal Societies.

At the commencement of the afternoon session DR. W. P. HART presented an exhaustive argument AGAINST THE GERM THEORY OF MALARIA, founding the same principally upon the facts of the occurrence and non-occurrence of the fever independent of the conditions claimed to be required.

USE OF OPium IN CONGESTIVE FORMS OF FEVER.

DR. J. J. M'ALMONT read a paper on the above subject, advocating small and repeated doses of opium in the congestive forms of fever, with a view of counteracting the depressing influence of malaria on the nervous system, and of increasing the blood-pressure. In following out such indications he believed that the drug was as much a specific as quinine.

THE MANAGEMENT OF DYSPERSIA.

DR. T. E. MURRILL read a paper on this much hackneyed subject, but brought out some practical points which are worthy of note, viz., that the disease in this country is mostly due to an excess of amylaceous and saccharine foods, and could be in a measure relieved by a more varied diet, in which fresh meats largely entered. He was greatly in favor of hot water drank an hour before each meal in cases where there was much pain or discomfort in the digestive processes.

At the evening session DR. G. W. HUDSON presented a case of congenital extravasation of the bladder, complicated with uterine and hernia, relieved temporarily by a suprapubic plate and receptacle. He proposed a radical operation when the patient was old enough for the same.

A case of gunshot wound of the bladder was related by DR. W. F. BLACKBUR. It was treated by drainage, opiates, and nourishment. Recovery took place without peritonitis.

A case of laceration of cervix, complicating epithelioma of same, cured by Emmett's operation, was related by DR. J. T. JELKS.
THE MEDICAL RECORD. 495

Third Day, Friday, May 2d.

The morning session was occupied by the transaction of
miscellaneous business,
comprising reports from Judicial Council, special committees, and the election of officers; the afternoon by a report on the correlation of pharmaceutical and medical professions, the close relations between pharmacists and physicians, concluding with a denunciation of counter-prescribing and the use of patent medicines. The usual resolutions of thanks were then passed, when the Society adjourned to meet the Wednesday before next meeting of the American Medical Association in 1885.

In the evening a complimentary banquet will be tendered by physicians of Little Rock at the Capitol Theatre. The meeting was a very interesting and successful one, and was in no small degree due to efforts made to that end by the Secretary, Dr. J. P. Gisson, of Little Rock, Ark.

AMERICAN SURGICAL ASSOCIATION.

Fifth Annual Session, held at Washington, D. C., April 30, May 1, 2, and 3, 1884.

(By Telegram to The Medical Record.)

The Fifth annual meeting of the American Surgical Association began its four days' session in the city of Washington, D. C., on April 30th, at the National Museum. Its officers are: Edward M. Moore, M. D., LL. D., President; Wm. W. Dawson, M. D., First Vice-President; Claudius H. Mastin, M. D., LL. D., Second Vice-President; J. R. Weist, A. M., M. D., Secretary; John H. Packard, M. D., Treasurer; J. Ewing Mears, A. M., M. D., Recorder.

The Council is composed of Geo. W. Gay, M. D. (1884); Henry F. Campbell, A. M., M. D. (1885); Hunter McGuire, M. D. (1886); F. S. Connor, M. D. (1887).

The Association numbers 93 Fellows, and 3 Honorary Fellows.

After the reading and approval of the minutes of the last annual meeting of the Association, held in Cincinnati, Dr. Edward M. Moore, the President of the Association, delivered

The Annual Address

in which he reviewed the progress of surgery, from the cruelties practised in the days of Hippocrates down to the present time.

Members Who Signed a Document Criticizing the Code of Ethics.

The Secretary stated that he had received two letters of resignation from Fellows who had taken grounds against the Code of Ethics adopted by the American Medical Association. Other members who have been called upon to define their position have not yet replied.

After some routine business was disposed of, papers were read as follows:

An Experimental Study of Anesthesia, by B. A. Watson, A. M., M. D., of Jersey City. His deductions were based upon experiments on 82 rabbits and 25 dogs, and bore out his opinion that ether is by far the safest anesthetic now known.

Discussion was participated in by Drs. Dawson, of Cincinnati, and Tiffany, of Baltimore, who supported the deductions of Dr. Watson, and by Dr. Maclean, of Detroit, who maintained the safety of chloroform if exhibited with proper precaution, and by Dr. Byrd, of Quincy, Ill., who defended bromide of ethyl and alcohol mixture.

The next paper read was

Some of the Dangers and Disadvantages of Anesthesia, by David W. Cheever, M. D., of Boston, who favored the use of sulphuric ether, and illustrated the dangers of suffocation, and its symptoms by a plaster cast of the head and neck. He explained the cause of death in many cases to be from debility, etc., and said great caution should be used in the administration to apoplexies, drunkards, and persons of debilitated constitutions.

Dr. Prewitt, of St. Louis, spoke in favor of ether in all cases, and Dr. Gay, of Boston, exhibited an apparatus for giving anesthetics; he also read a letter giving an account of three cases where anesthesia had been produced by administering per rectum.

Professor Gross being absent, on account of sickness, his paper on

Wounds of the Intestines

was read and commented upon most favorably, as he spoke of the advantages of enlarging the openings, etc.

A resolution was adopted by a rising vote, thanking Professor Gross by telegram for his valuable paper and hoping for his early recovery.

Ligation of Common Femoral Artery, by L. McLane Tiffany, M. D., B. A. Cantab., of Baltimore, was the next paper, in which he condemned this operation, and was supported in the discussion of the paper by Dr. Campbell, of Augusta, Ga.

The next paper read was upon

Traumatic Cephalhydrocele, by P. S. Connor, M. D., of Cincinnati, who gave three interesting cases of this affection.

He was followed by Dr. Charles B. Nancrede, of Philadelphia, on

Surgical Interference in Cerebral Abscess, favoring this method of relieving the brain, on the same principle you should use any other organ or part of the body when practical. He gave the history of a remarkable case in which such interference was successful after the patient had apparently died under the operation.

The first day's session closed at 4 P.M., to meet at 11 A.M. on Thursday, May 1st.

(To be continued.)

EIGHTY-SIXTH ANNUAL SESSION OF THE MEDICAL AND CHIRURGICAL FACULTY OF MARYLAND.

Held at Baltimore, Tuesday, Wednesday, Thursday, and Friday, April 23, 24, 25, 1884.

(Specially reported for The Medical Record.)

(Continued from page 468.)

Third Day, Thursday, April 24th.

The gentlemen whose names were previously mentioned again recommended for membership by the Examining Board, were elected members.

Drs. I. Bermann and J. D. Arnold presented their resignations of membership.
THE MEDICAL RECORD.

[May 3, 1884.

PROF. WM. PEPPER, of Philadelphia, was elected to honorary membership.

SECTION ON ANATOMY, PHYSIOLOGY, AND PATHOLOGY.

Dr. J. W. CHAMBERS, Chairman, presented a report which consisted of a report of

FOUR CASES OF ABSCESS OF THE BRAIN.

CASE I.—German, aged thirty-five, struck on left frontal eminence with dish. Lacerated wound two inches long. No apparent injury of skull. No symptoms except insomnia till tenth day, then epileptic convulsion especially marked in left arm, followed by paroxysm of same. Convulsions recurred involving right leg, with chilly sensations and rigors. Admitted to City Hospital five weeks after injury with granulating wound at site of injury, paroxysm and anaesthesia of right arm and leg. Patient in state of hebephrenia. On fourth day after admission aphasic symptoms noted. On seventh day symptoms of inflammation of brain. He grew worse and died in coma on the forty-sixth day after the injury. On post-mortem examination a necrotic segment of an oval shape, and measuring 2.5 cm. by 1.5 cm. by 0.5 cm., was found in leathery bone at site of injury, an abscess found in left lobe of brain containing three ounces of pus. Immediate cause of death probably oedema of brain due to pressure of abscess.

CASE II.—Similar injury to first case, on right side. On thirteenth day epileptic convulsion, with paroxysm of left side, occurred in coma on thirty-first day. Post-mortem examination revealed similar sequela to first case, due to necrotic periosis. Discoloration of membranes and slight gangrene of brain-substance at site of injury. Pus-cavity in frontal lobe the size of small orange, which had ruptured into the lateral ventricle, causing death by compression. The skulls of cases I. and II. were exhibited.

CASE III.—Admitted with double croupous pneumonia with symptoms of collapse. On the tenth day pneumonia had disappeared, but a typhoid condition remained with mental aberration, and paralysis of left arm. Two days before death chronic convulsions set in. Temperature, 106° in axilla. Death in coma twenty-six days after admission. Post-mortem examination, no pneumonia, but recent signs of it. No disease of bone or ear. Arteries on right side of circle of Willis plugged with fibrous clots. Entire white substance of posterior portion of frontal, parietal, and temporal lobes replaced by pus which had ruptured into the lateral ventricle, causing death.

CASE IV.—An adult female, admitted into hospital December 6, 1883, having been attacked, two weeks previously, with severe chills followed by fever and sweats, believed to be malarial. She also had violent headache. At the time of entrance she had some headache, nausea, and constipation, but intelligence was good and there was no paralysis or anaesthesia observed. Transient unconsciousness supervened, which became, on the second day, permanent. Death ensued December 8th, the temperature having risen to 103°. The autopsy revealed an abscess in the posterior portion of the frontal and entire parietal lobes of the right hemisphere, which had ruptured into the lateral ventricle and produced death.

The above four cases present wide differences in causation and symptoms. Cases I. and II. were clearly due to the localized contusion of the brain following the injuries. Case III. was evidently embolic, while Case IV. was probably idiopathic, or it may have been due to pigmented emboli which sometimes occur in intermittent fever. Case II. is especially interesting from the absence of all symptoms pointing to cerebral abscess until twenty-four hours before death, which occurred thirty-one days after the injury, and which was the ultimate cause of the abscess. The skulls shown illustrate a form of injury which has either not been observed by others, or, if observed, has been mistaken for fracture. There are no evidences of depression or of fissuring in the external or internal tables. One could hardly conceive of a button of bone being punched out in this manner, and not driven into the substance of the brain. It seems to me that the lesion is the result of a necrotic periostitis following contusion of the bone at the point against which the missile impinged. I have searched all the literature accessible to me, including the "Medical and Surgical History of the War," without finding a similar injury of the bone recorded. I venture to present these specimens, therefore, to the faculty as not hitherto described in surgical works.

A supplementary report from the same Section was presented by Dr. JOSEPH T. SMITH, on

THE PROGRESS OF BACTERIAL PATHOLOGY.

He reviewed the work of the German and French Cholera Commissions in Egypt, and instituted the following comparison.

The Germans made 20 autopsies, the French 24; in both the subjects were examined immediately after death. The Germans found the blood free from microorganisms, and seem to have attached but little importance to its condition, while the French obtained from this fluid their most important results, finding it of a dark color, and free from coagulation. In the clear spaces between the blood-globules small elongated bodies were found, and these the Commission look upon as the causative micro-organisms of the disease, though they failed to cultivate them. The Germans found in the intestinal walls the bacilli of cholera; the French a large number of micro-organisms, but could not find in them anything specific.

He also discussed the bacillus tuberculosis question, and concluded that the subject was still in doubt.

SECTION ON OPHTHALMOLOGY, OTOLARYNGOLOGY, AND LARYNGOLOGY.

The report was presented by DR. SAMUEL THROBDOLI, chairman, who took for his subject

PREVENTABLE BLINDNESS.

There are 996 blind persons in Maryland. It was estimated that one-half of these cases were preventable, although exact data on this point were not obtainable. They fail to see a physician at the critical period. Ophthalmia neonatorum causes the largest number of cases. A period of 24 hours to 9 days after birth is the best period to strike at, as no cases should be lost after the beginning of the affection; if severe, gr. xviii. to the ounce, or nitrate of silver, gr. j.–iii. to the ounce, may be added. Atropia solution may be applied simultaneously. Scrofulous ophthalmia is also very common among the poor. Treatment should be iron and bark, with sulph. atropize, gr. j.–iv. to the ounce, and yellow oxide of mercury, gr. j. to the ounce, applied once daily. Iritis is another cause which should never be ignored. It is usually treated domestically, often by atropine, collyria, under the impression that it is a simple conjunctivitis, until adhesions have occurred when atropine solution is the most important measure in treatment.

Granular ophthalmia destroys ten times as many eyes as it should, and purely because of neglect. It is common in institutions where children are crowded together. Syphilitic ophthalmia is common because of neglect to have a bad eye taken out. Glaucoma also because often overlooked. Acute glaucoma is most often confounded with neuralgia of the fifth nerve, chronic glaucoma with cataract, and free from coagulation among workers in stone, etc., because of a neglect of the simple precaution of wearing glasses. In this class, the cornea is often found dotted over with opacities from injury from particles of stone, etc.
THE MEDICAL RECORD.

The remedy for the above state of things is for doctors to fit themselves for the treatment of eye diseases, and to instruct patients in regard to the same.

Dr. Chisolm presented a supplementary report on the
REMOVAL OF FRAGMENTS OF IRON FROM THE EYE BY THE MAGNET.

This method was first employed in 1874. Dr. Chisolm employed Gruening's instrument, which has a powerful battery, extracting particles when brought within one-fourth of an inch of them.

Case.—A mechanic, aged twenty-four, was struck in the right eye, March 6th, by a piece of metal, which destroyed his sight. Two hours after the accident he was brought to Dr. Chisolm. There was a small wound in the lower part of the cornea. There was a sense of fullness in the eyeball and stiffness in the lids. The patient was sure there was no iron in the eye. The needle of the magnet was introduced into the wound, and when withdrawn, a stout scale of iron, one-half of an inch long and one-eighth of an inch wide, came away with it. One end of the scale was narrower than the other, and fortunately the former had adhered to the needle. Cold water and atropia constituted the after-treatment. An artificial cataract was left, but in two weeks the patient was well enough allowed to leave the hospital.

In another case, a blow was received on the eye by a mechanic while striking iron, with obliteration of sight. Vitreous humor came from the wound in the ball. Atropine was instilled into the eye, but pain, congestion, and blood extravasation continued. The needle was introduced tentatively into the vitreous chamber through the wound, the patient being placed under the influence of bromide of ethyl, but without result. The symptoms continuing, the ball was enucleated two weeks after the accident. Its contents were found to be disorganized, and a small fragment of steel was found imbedded in a fibrous clot in the vitreous chamber. The explanation of the failure of the magnet in this case, was that the needle did not approach the fragment sufficiently for its magnetic power to take effect.

There was no report from the Section on Psychology and Medical Jurisprudence, Chairman, Dr. R. Gundry.

SECTION ON MICROSCOPY, MICRO-CHEMISTRY, AND SPECTRAL ANALYSIS.

The report of this Section was presented by Dr. A. G. Horn, of Waverley. His subject was PHOTO-MICROGRAPHY.

He began by remarking that hitherto photographing with the microscope has been shrouded in a mystery of difficult chemical and technical manipulation. The necessity of having at hand very expensive apparatus, such as hellostat, condensers, various mediums for filtering the sun's heat rays from the actinic, etc., have all been obstacles with the microscopist, who has not all the advantages of apparatus offered by a large university or some government institution, such as we have at Washington, heretofore under charge of Col. Dr. Woodward.

The method I am about to describe is so simple and involves so little expense that it lies within the scope of every physician who possesses a microscope, which can be inclined horizontally and which is supplied with a medium one-half and one-fourth inch objective, to take good and accurate photo-micrographs of all interesting pathological and histological specimens as they come to his hands.

It is, of course, understood that the photo-micrographer possesses the necessary knowledge and technic to properly prepare his specimens for microscopic examination, and I find that tissues, as ordinarily cut and stained with carmine or picro-carmine, are admirably adapted for photography with the low and medium powers.

All writers, as far as I can ascertain, advise the use of the objective alone to project the image of the specimen, to be photographed on the ground glass for focussing; this necessitates a camera with a long bellows in order that the proper amplification may be obtained by placing the sensitive plate at a distance of two, three, or four feet from the objective. I find that by using the eye-piece in conjunction with the objective, as good if not better results are obtained, and with a much more compact apparatus.

As a means of recording microscopic observation, nothing is so absolutely true as a good photo-micrograph. Objects drawn with the camera lucida are very beautiful in many instances, but suffer under the delusion of the draughtsman, whose imagination is almost certain to enter and mar his picture.

Those who have worked with the microscope, and compared their observation with the cuts found in the various works on microscopy will readily appreciate this.

For perishable preparations, such as scrapings from tumors, vomits, urinary deposits, etc., it is admirably suited, giving a record, which if preserved with care, will last forever.

Pathological histology, which in the past few years has taken so prominent a position, receives another impetus in photo-micrography, and I will venture to say, that in all our medical schools where this important branch of medical science is taught, the production of micrographs on a screen by means of a lantern or speciopicon, will be the means, in the near future, of conveying to the student the idea and appearance of the microscopic object and field.

The various manipulations of the wet process were shown as far as it was possible to do so.

The character of the negatives exhibited, as also that of the prints from these, proved conclusively that good work could be done without the use of expensive apparatus; the illumination of the object in this case being effected by an ordinary mirror, mounted on a movable pivot and fixed to a window-sill having a southern outlook. The use of the blue-glass cell, so strenuously insisted on by most authors, was found unnecessary; a ground glass, however, situated on the side of the aperture in the stage of the microscope was found indispensable, both to insure an even illumination and to render the rays of light parallel.

The preparation of the plates, such as collodionizing and sensitizing, is so simple that any one who has once seen the process could easily follow. After a proper field has been secured in the microscope ocularly, the instrument placed in connection with the camera, and the illumination properly adjusted, the image is sharply focussed on the ground glass of the camera. The exposure is now made by withdrawing the dark slide from the plate-holder, and according to the lenses used a longer or shorter time is given. The development conducted in the dark room is secured by a solution of iron and acetic acid.

On the whole, the process commends itself for its extreme cheapness, $25 being sufficient to supply the camera, bath, dishes, etc., with all the necessary chemicals. Another great advantage which the wet plate possesses over the dry is, that in the former a few seconds over or under exposure does not affect it harmfully, whereas in the latter either one way or the other is sure to be ruinous, unless in the hands of a very skilful developer.

VOLUNTARY PAPERS.

Dr. F. Donaldson presented a paper on
THE INFLUENCE OF LUNG RETRACTILITY IN PLURISURY AND PNEUMOTHORAX.

The application of the knowledge acquired by physiological research of the retractile force of the lungs to the
investigation of the pathological conditions of the chest has been strangely overlooked, and this has retarded, in no small degree, our thorough study of diseases of the chest. Marcy, Hutchinson, Saltzer, Powell, and Le Gros Clarke considered this knowledge of the subject.

It was not, however, until 1877, that the amount of lung retractor force was ascertained or even more than guessed at. Stone, of London, then reported his experiments on sheep, from which he concluded that the retractor power was equal to four or five inches of water; he also showed that even when the effusion was considerable in the pleural cavity the lung still possessed contractile force sufficient to support two inches of water, so that to evacuate the fluid it was necessary to use external suction sufficient to overcome this lung fraction.

Garland, of Boston, shortly after published his work on "Pneumo-Dynamics," which gave an immense impetus to the study of dynamics of the chest, and explained satisfactorily some conditions, especially found in pleurisy.

Previous to 1843 it was taught that effused pleural fluid obeyed the law of gravity as in open vessels or a vacuum, and hence assumed a horizontal level. M. Da
doiseau, in 1843, first showed the fallacy of this, and that the line was irregular, with more or less the form of a parabola. With few exceptions it has since been acknowledged that the line is horizontal when the patient is sitting or standing, unless the fluid fill the cavity up nearly to the clavicle.

In 1874 and 1876 Dr. Calvin Ellis described the line as beginning low down on the back near the vertebrae, passing outward and upward obliquely to the axilla, where it reaches its highest point; then in a straight line with a slight descent to the sternum. This has been confirmed by the author and others, and has been designated the letter S curve. As the fluid increases the curve flattens out and no longer presents its S shape after the fluid reaches the second rib, but is then nearly horizontal. Garland explained the reason of the above facts and demonstrated that the physical cause of the condition of the pleura in estimating the quantity of fluid in the pleural cavity, and the indications they afford us as to the advisability of resorting to thoracentesis.

The author next considered the influence of the retractor lung-power in the production of displacements of the heart, lungs, diaphragm, intercostal spaces, and liver and spleen on the pneumothorax.

The paper terminates: "We conclude that lung retraction is not only a powerful physiological force in respiration, but that it also produces modifications of a decided character in the movement of the chest. The facts of this relation of the diaphragm and pneumothorax, the time and extent of the action of the latter and the effect of the former on the latter indicate the advisability of resorting to thoracentesis."

PROFESSOR C. STANLEY HALL, of the Johns Hopkins University, read a paper on BRAIN LOCALIZATION.

The methods for localization of function in the cells and fibres of the cerebro-spinal nervous system are now many. Among these are new methods of preparing microscopic sections, the method of secondary degeneration, and researches respecting the order in which various bundles of fibres acquire their medullary sheath two or three months before and after birth. Among the results made probable by these methods are the continuity of the pyramidal fibres of the cord to the cortex through the inner capsule without the interruption formerly supposed in the cells of the large basal ganglia. These tracts decussate only in part, and are the tracts, at least from the limbs, of volitional motor innervation. Another reason for the presence of irritation of the lenticular nucleus and striate body from the cortex, and of the thalamus from the optic tracts. The cerebellum, whatever other functions it may have, appears to be very largely a commissure between the hemispheres, particularly between the "latent" sylvian and occipital regions, the projection system and the "psychic zones" lying between these. Its very intimate connection with the red nucleus, the olivary bodies and the lateral column of spinal fibres is now very probable.

The results of these experiments were illustrated by maps and by Aebly's brain-phantom made of colored cork and wire.

At the conclusion of the address of Professor Hall, a vote of thanks was passed to him.

FOURTH DAY, FRIDAY, APRIL 20th.

DR. J. S. CONRAD, Superintendent of Malley Hill Sanitarium, read a paper on SUICIDE WITH PRESENTATION OF MECHANICAL MEANS OF RESTRAINT.

There are but two methods of restraint: 1st. Cont. Continued eating by day and night. Few can stand the expense of this, the attendant costing not less than $20 per week, making the patient's expenses altogether $35 to $40 per week. 2d. The use of restraints. Dr. Conrad has much more confidence in the latter than the former. He had known a patient attempt to choke herself with fragments of a night-gown, and a man to cut his throat with a pocket-knife under the sheet while the attendant sat near by. He uses the gloves only at night. He then exhibited the gloves he uses, which are a sort of mitten, fastened securely around the wrists, and tied to the extremity of which are attached rings by means of which the hands are securely fastened to a brace going around the waist and over the shoulders. The gloves are perforated in order to obviate unpleasant sweating of the hands.

A paper by W. HOWELL, Fellow of the Johns Hopkins University, and F. DONALDSON, Jr., M.D., some time Graduate scholar in Biology in the same, was read, entitled, THE MAXIMUM VOLUME OF BLOOD SENT OUT BY THE LEFT VENTRICLE IN A SINGLE BEAT, AND THE INFLUENCE OF VARIATIONS IN VENOUS PRESSURE, ARTERIAL PRESSURE, AND PULSE-RATE UPON THE WORK DONE BY THE HEART.

The authors undertook to determine this question, hitherto unsettled, and according to Foster not to be accurately determined by directly measuring the blood ejected from the left ventricle of a dog's heart isolated by Professor Martin's method.

The results fall under four heads:

1. The maximum quantity of blood which can be thrown out from the left ventricle at a single systole. The method of working in determining this quantity was to increase the amount of blood flowing into the right side of the heart by raising the supply flask connected with the inferior vena cava, until the force of pressure and quantity of blood flowing into the right side of the heart caused no increase in the quantity of the blood sent out from the left ventricle. The main result of these experiments may be stated as follows: With a mean pulse-rate of 180 per minute in the dog, the mean ratio of the maximum weight of blood pumped out from the left ventricle at each systole to the body weight is $\frac{1}{12}$ or .0083. The maximum outflow from the left heart was obtained in all cases at or below a venous pressure on the right side of 60 cm. of debrinated cat's blood (46 mm. of mercury). From one experiment taken at the normal pulse-rate of the dog (120 per minute), the ratio under these circumstances is $\frac{1}{24}$ or .0041. Reasoning from these facts, the belief that the left ventricle during life is destined to about its maximum capacity. Owing to differences in pulse-rate between the dog and
man no inference can be safely made from these results to the case of man.

2. Arterial pressure was varied by raising or lowering the end of the outflow-tube leading from the aorta. Such variations from 58 to 147 mm. of mercury have practically no effect upon the quantity of blood sent from the left ventricle, and it seems probable that within these limits at least the force of the ventricular contraction is not influenced by variation in arterial pressure, but remains maximal throughout.

3. Variations of venous pressure showed a marked influence of the latter, the outflow from the left ventricle increasing with it, but not proportionately up to the point of maximum work.

4. The rate of beat of the heart was varied in these experiments by heating or cooling the blood supplied to it. In this way the pulse-rate was changed in one case from 228 to 77 beats in a minute, and back again to 140 in a minute, and in another case the variation was equally great. The general result may be stated as follows: A diminution of pulse-rate, brought about by lowering the temperature of the blood flowing into the heart, causes an increase in the quantity of blood thrown out from the ventricle, and vice versa. The changes in the outflow from the ventricle at each systole are not, however, inversely proportional to the changes in the pulse-rate. The pulse-rate is not the only term to which during any given period of time decreases with a diminution of pulse-rate, and increases with an increased pulse-rate.

Dr. L. McLane Tiffany, Professor of Surgery, University of Maryland, read a paper on

THE RESULT OF OPERATIVE MEASURES FOR RECTAL CANCER—REPORT OF CASES.

The author has operated five times, three times by left lumbar colotomy for the relief of suffering and to aver impending death from obstruction; once in the same situation for relief of pain without complete obstruction, the passage of fecal matters causing unutterable agony; and once the lower rectum with anus was excised for epithelioma.

The results of four of these cases (those of the fifth being given in the American Journal of the Medical Sciences, October, 1877) are as follows:

CASE I., reported in the American Journal of the Medical Sciences, October, 1877.—Patient lived fifteen months after the operation, twelve of which were rendered tolerable by the operation. The patient was found to be in a state of comparative rest afforded the rectum. Post-mortem examination showed the rectum for seven inches in entire circumference to be the seat of an epithelioma and adherent to neighboring parts.

CASE III. (Trans. Med. and Chir. Fac., 1882), left lumbar colotomy.—Patient survived seventeen months. At time of operation obstruction was complete and terrific pain accompanied. Immense and immediate relief was secured which continued until death by asphyxia.

CASE IV., left lumbar colotomy (Maryland Med. Jour., August, 1883).—Patient died of pelvic cellulitis after abortion, the fetus being supposed to have reached the fourth month. Complete obstruction with great suffering preceded operation. The presence of the fetus in no wise complicated the colotomy.

CASE V. (Trans. Med. and Chir. Fac., 1882), excision of lower rectum and anus.—February 27, 1882, patient still living. Has been examined several times; at last examination, November, 1883, no sign of recurrence; rectum seemed in all respects healthy, and there was no inconvenience of faces. The last named result seemed to be due to partial prolapse of the mucous membrane of the anterior rectal wall forming a fold and so closing the anal aperture. There was no untimely escape of gas. The failure to recur justifies the hope that an absolute cure may be obtained. Microscopic examination of the excised rectum showed that it was clearly malignant.

Dr. Charles G. Hill read a paper entitled,

THE COMMON SASSAFRAS A POTENT DRUG AND A DANGEROUS NARCOTIC.

Dr. Hill's attention was called to the narcotic properties of this supposed harmless agent by a case in which a boy took "two large swallows" from a bottle of the oil of sassafras, under the impression that it was good for an eruption from which he suffered. Coma supervened, resembling that in poisoning by opium, except that the pupils were rapidly and steadily dilated. Prompt emesis removed the remaining oil from his stomach, and consciousness soon returned.

Acting on this suggestion the author had made experiments with the oil of sassafras upon mice, cats, and dogs. Injected hypodermically, or given per os, in the mouse increased stiffness of the convulsions, and death. In the cat and dog insensibility and paralysis were noted.

Dr. Hill also ascribed strong antiseptic properties to the oil of sassafras, which he estimated to be half as great as those of carbolic acid.

Dr. John N. Mackenzie, Surgeon to the Baltimore Eye, Ear, and Throat Charity Hospital, reported

CASES OF REFLEX COUGH DUE TO NASAL POLYPY WITH REMARKS.

The author referred to a paper on "Naso-aural Catarrh," read by him before the Faculty at the last annual meeting, in which he had called attention to the frequency of reflex cough as a symptom of a number of pathological conditions affecting the turbinate bodies of the nose, especially the erectile tissue overlying the posterior extremity of the inferior turbinate bone, and had insisted upon the importance of local treatment in such cases.

The author then detailed several cases in which reflex cough was occasioned by polypl in the nostrils, and was dissipated by their ablation.

He then continued: "The dependence of asthmatic attacks upon the presence of polypl in the nasal chambers is sufficiently common, but the important rôle of the latter in the production of cough has been apparently overlooked. At the time of publication of my thesis but one such case had been recorded. Within the past year four similar ones have come under my notice. So far as my experience goes, it would appear that the cough is only present when the growths spring from or are brought in contact with a portion of the erectile area, and generally its posterior portion, or in other words it is only when the polypus acts as a mechanical irritant by causing engorgement of the mucous membrane and erectile cells, and thereby exciting reflex action that the explosive cough is produced. The probability, therefore, of cough excitation will depend, other things being equal, upon the position of the growth. Thus, a polypus high up in the nostril may fail to give rise to the reflex act, which its presence low down in the nasal fossa would excite. Or a movable growth in the more anterior portion of the nasal chambers may awaken no reflex when the head is in the vertical position, whilst when the vertical diameter of the nostril becomes horizontal, as in the recumbent position, the latter may be brought in contact with the posterior portion of the nostril, or, what is the same thing, with the most excitable spot in the sensitive area.

In the same way the asthmatic attacks which have been observed in connection with nasal polypl may be explained. At all events such an explanation is more plausible than the assumption which may be urged of direct nervous irritation starting from the polypus itself, since the ordinary mucous polypus is destitute of nerves, and can, therefore, only awaken reflex phenomena in an indirect or mechanical manner. Moreover, I have tried to obtain the reflex by direct stimulation of the growth, but so far without success.

Finally, I wish to observe that the change in position
of the polypos does not depend altogether upon the law of gravitation, but in some instances may be due to an increase in volume, either from local irritation of various kinds or from the hydroscopic character of the gelatinoid outgrowth. The augmentation in bulk thus brought about would obviously bring it into contact with parts which in its original position would not be encroached upon, and therefore not subjected to the pressure and irritation which it might occasion.

In regard to the mechanism of the reflex two explanations suggest themselves: either the assumption of the correlation of the nasal erectile area and the interarytenoid space (laryngeal cough centre) by virtue of which irritation and vascular engorgement of the former may lead to hyperemia of the latter through the medium of the vaso dilator nerves through the superior cervical ganglion and the consequent production of a laryngeal cough, or the direct transmission of the irritation through the phreno-palatine nerves to the medulla and its immediate reflexion outward to the muscles concerned in the expiratory act.

"Some Remarks on a Recent Epidemic of Typhus at Bay View Hospital," was the title of a paper by Dr. Elect. R. Reynolds, which, in the absence of the author, was read by title and referred to the Publication Committee. Dr. Eugene F. Cordell, Professor of Materia Medica and Therapeutics, Woman's Medical College of Baltimore, read a paper entitled

CONGENITAL ANOMALY OF THE FETAL HEART, CONSISTING OF THE ABSENCE OF ONE OF THE SEGMENTS OF THE MITRAL VALVE IN WHICH A SYSTOLIC MURMUR WAS HEARD BEFORE BIRTH.

The anomaly in question was found in the autopsy of a new-born child which died cyanotic one hour after birth, respiration having never been thoroughly established. The mitral insufficiency was the only abnormality present. The anterior segment was largely developed and was attached by its sides to several chordae tendineae, which sprung from two fleshy columns; the latter were connected with the outer surface of the ventricle. The condition seemed to be due to defect in development and not to pathological causes. For some hours before birth there had been heard, in this case, in the upper and left side of the abdomen a distinct systolic fetal heart murmur, which was presumed to be located at the mitral orifice. The rarity, if not uniqueness of such an abnormality, and the ignorance and obscurity of such sounds, were shown by references to authorities. The diagnosis will probably always be problematical.

In a paper

ON CERTAIN PRACTICAL POINTS IN THE PATHOLOGY, CLINICAL HISTORY, AND TREATMENT OF CANCER,

by Dr. George Roche, M.D., Professor of Hygiene and Clinical Dermatology, College of Physicians and Surgeons, Baltimore, the author spoke of the loose way in which the term cancer is used, being applied to both innocent and malignant growths. The invariable anatomical condition is epithelium out of place. This is due to an indefinable constitutional predisposition more marked in the white than black race. Where the constitutional predisposition exists, local irritation is alone needed to produce the disease.

The author illustrated from his practice the conversion of innocent epithelial growths into malignant growths. Pain and ulceration may be entirely absent in cancer, and induration is not characteristic taken alone. Induration of glands is not constant, and it is also to be remembered that it may be due to simple inflammation and irritation as well as infection. The author strongly urged extirpation as the rule, repeated in case of recurrence. He strongly recommended the use of arsenic, pushed to physiological limitation, to prevent the tendency to epithelial degeneration.

RESULTS FROM THE INVESTIGATION AND STUDY OF COW-POX,

was the title of a paper by Dr. St. George W. Teackle, State vaccine agent. The author referred to a paper read at the last annual meeting of the Faculty, entitled "A Case of Spontaneous Cow-pox," etc., and the exhibition at the time of a healthy cow successfully inoculated with crusts therefrom. He reported that he had obtained only negative results from crusts from this heifer. This had led him to investigate the subject and he had thus arrived at the conclusion that there is no such thing as spontaneous cow-pox, but that cases mistaken for it are constantly occurring especially during visitations of small-pox. That consequently Jenner was laboring under a delusion and that a fresh and reliable virus can always be obtained by direct inoculation of the heifer with small-pox virus whenever that disease exists, and that this is a much more perfect and convenient method. This completed the voluntary papers.

Dr. L. R. Coates offered his resignation and Drs. A. M. Belt and R. M. Hall, of Baltimore, were elected members.

The rest of the business was routine and much of it is not of sufficient interest to report in The Record.

Dr. TIFFANY reported from the Committee on Legalizing Dissection that the present law in Maryland is ampler, but that the law officers of the city are not disposed to enforce its execution. Consequently recourses had been had to the courts, where an early decision, favorable to the profession, is expected.

Dr. MORRIS, from the committee appointed to watch the progress of the supposed case of spontaneous cow-pox, presented to the Faculty a year ago by Dr. St. George W. Teackle, State vaccine agent, reported that it was not a true vaccinia but a spurious form, well-known since the days of Jenner.

Drs. Rohe, Morris, and Stewart were appointed a committee to carry out the sanitary suggestions contained in the President's address.

Dr. T. Barton Brune reported in behalf of the Directory for Nurses, that the Directory had met with lack of support and even hostility at the hands of the Faculty. Forty nurses, only one of whom was a wet-nurse, had registered: thirty-three were white and seven colored; thirty-three females and seven males. The committee was authorized to use surplus funds on hand to advertise the Directory.

Committee to Draught Law in Regard to the Rights of the Injured was continued; Drs. also Committee on Sale of Poisons, and Committee on Legislation in Regard to the Care of Feeble-minded and Imbecile Children.

Upon recommendation of the Publication Committee, Dr. Quinan was given authority to publish, at his own expense, a second edition of his "Medical Annals of Baltimore."

Dr. Michael gave notice of his intention to move an amendment to the constitution, substituting the word "persons" for "gentlemen" in the clause relating to membership, the object being, as stated by him, to render women eligible to membership.

ELECTION OF OFFICERS.

The election of officers for the ensuing year was then proceeded with and resulted as follows: Dr. Thomas S. Latimer, President; Drs. John R. Quinan and J. E. Atkinson, Vice-Presidents; Dr. G. Lane Taneyhill, Recording Secretary; Dr. Robert T. Wilson, Assistant Secretary; T. B. Brune, Corresponding Secretary; Dr. W. F. A. Kemp, Treasurer; Dr. Richard Thomas, Reporting Secretary; Dr. Williams, Michael, Stewart, Tiffany, and Lynch, Executive Committee.

The President then announced the members of the various standing committees and sections, delegates to various societies, curator, etc., after which the Faculty adjourned sine die.
NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, April 9, 1884.

GEORGE F. SHAPID, M.D., PRESIDENT, in the CHAIR.

PEDUNCULATED MYXOFIBROMA OF THE LABIUM MAJUS.

Dr. H. J. Garrigues presented a specimen accompanied by the following remarks and history.

Pedunculated tumors hanging from the labia are probably rather rare, since neither Thomas, nor Emmet, nor Barnes mention them in their treatises on gynecology. In the large German work edited by Billroth is found a figure representing a case observed in the policlinic of Koenigswarz, which is called a fibroma.

The present specimen comes from a virgin thirty-four years of age, pale and dyspeptic, and affected with eczema of the scalp and the hypogastric region. She noticed it first nine years ago. The tumor was attached to the middle of the outer surface of the left labium majus by a pedicle, which, when stretched by the weight of the tumor had the length and thickness of an index finger. The tumor itself measured eight by seven by four centimetres and had the shape of a flattened pear. It had the color of the surrounding skin, was somewhat elastic, and had an even surface covered with large peeling-off epithemeris scales. At the lower end was found a slough of the size of a large pin's head, surrounded by a suppurating line of demarcation, libelled a very offensive odor.

In the pedicle was felt a pulsating artery of the size of the umbilical arteries. In it, and near it, on the labium were seen enlarged and varicose veins. The tumor was not the seat of spontaneous pain nor sensitive on pressure. I removed the growth by putting a clamp on the pedicle near its upper end, forming two small skin flaps, cutting the delicate tissues off at the level of the clamp, tying the artery and uniting the flaps by two catgut sutures. It healed easily, and the linear cicatrix was found on a level with the surrounding tissues. Supposing it to be a fibrous tumor, I was much surprised to see how much blood could be pressed out of it, and oozed out from an incision made into its interior. But the microscopic examination accounted for this. It was covered with a very thick epidermal layer covering normal papillae. Nowhere hair-follicles or sweat-glands were found. The underlying tissue was formed of fibrous connective tissue, with many interspersed round and oval cells. In some places the reticulum of connective tissue became obliterated by the number of cells which increased so much as to form myxomatous tissue. Everywhere were found arteries and veins and in some places a few fat-cells.

CYST OF THE PAROVARIUM SIMULATING PREGNANCY.

Dr. E. M. Cushing presented a cyst of the broad ligament with the following history: E. S., aged six

Dr. Cushing had said it was suggested that the hemorrhage might be due to abortion. In such cases there were two possibilities: (1) that the decidua would be present, or (2) that it would have been cast off. If the abortion had been complete, he thought there would not have been any considerable hemorrhage. The case in which severe hemorrhage occurred were those in which there was incomplete abortion, usually the ovum was thrown off and the decidua remained. So far as Dr. Garrigues could determine there was no decidua remaining upon the specimen. The specimen was very interesting in one respect, and that was the development of a cyst of the broad ligament which had become sufficiently pedunculated to allow the pedicle to become twisted.

Dr. Cushing said that the mucous membrane of the vagina and vulva did not present the violet tint, but had the most palpit color. She was unable to say positively whether or not there was any change in the areola of the breast.

Dr. Garrigues remarked, with reference to the cause of the hemorrhage being taken as the purpose of dilating and exploring uterus, hoping by this means to ascertain and remove cause of hemorrhage. The result of exploration, however, was negative, absolutely nothing being found to account for hemorrhage. The patient, who had begun to have an elevation of temperature previous to any operative procedure, began to vomit and diarrhea as soon as the operation was introduced, and on the night of the day of exploration diarrhea was added to the vomiting. The fever became more pronounced, and the vomiting and diarrhea resisted all efforts to check them. On the third day following exploration the patient died.

Aurispy, fourteen hours after death, the opening abdomen the tumor which was taken for the uterus was found to be a parovarian cyst of right side, with unusually thick and firm walls. The broad ligament was stretched and twisted upon itself in such a manner as to throw the tumor on the top of the uterus, which it closely capped, seeming a part of the organ itself. The uterus was large, measuring three and one-half inches, and the body rounded. The membrane was thickened and congested, but there was no trace of a decidua, nor were there any fungosities upon its surface which could account for the hemorrhage.

With the exception of an old pleuritis, and moderate stenosis of mitral valves, there were no remaining pathological conditions of importance. In view of the above facts, it is believed that the hemorrhage arose from a ruptured cyst of the broad ligament, which included the Fallopian tube and numerous large vessels belonging to the pampiniform plexus, thus interrupting the return current from uterus, and that death occurred as a result of an acute anemia supervening upon a condition, already existing, of most profound denutrition, the result of previous prolonged anæmic state, manifesting itself in symptoms on the part of the stomach and the intestinal canal.

Dr. Garrigues thought there was one point of particular interest in the case, and that was to determine whether or not pregnancy existed. As to the clinical condition he would ask, first, what was the color of the mucous membrane of the vagina, and second, what was the condition of the manœvre, especially whether or not there was any increase in the depth of the dark color and enlargement of the areola. According to his experience, the earliest sign of pregnancy was to be found in the areola, together with somewhat doubtful gastric symptoms. He had diagnosed pregnancy as early as the sixth month in a patient in which the operator was not aware of the pregnancy. The limiting line loses its sharpness early, and always upward and outward, becomes indistinct, and the dark color begins to shade out into the color of the surrounding part, and at the same time there is some increase in the volume of Montgomery's glands. The violet color of the mucous membrane of the vagina he had also found to be a very reliable symptom of pregnancy.
of death, that it was most likely of septic origin. He had seen several cases where death had followed rather quickly the introduction of tents, and he thought that, as a means of diagnosis, their use should be limited as much as possible. It had been claimed that larnamaria tents, prepared antiseptically, could be used with comparative safety, but with their use he had not had any experience.

Dr. CUSHIER said that larnamaria tents were used in this case, prepared antiseptically, as they had been in the hospital for two years, where they had been used as occasion required and without any unfavorable results. The tents, moreover, were not introduced for purposes of diagnosis, but to ascertain, if possible, the cause of the hemorrhage, supposing it to be due to some product of conception remaining within the uterus, or, pregnancy not existing, the presence of fungoid degeneration perhaps, or possibly a polypus. She thought all the precautions were recognized in the introduction of the tents, and believed that in this case their use could not have been avoided.

Dr. Garrigues remarked that what he had said concerning the use of tents was not in any way intended as a criticism upon the treatment of the case.

Dr. CUSHIER asked Dr. Garrigues what he would do to control the hemorrhage in such cases.

Dr. Garrigues replied that he would first use the tamponade. He would also try to find out, with reference to the presence of a tumor, the existence of pregnancy, that he had reached the conclusion that there was no pregnancy, he thought that by means of the sound he could determine whether or not there was anything within the uterus. Perhaps it would be necessary if a polypus was found to introduce a tent for the purpose of dilating the cervix preparatory to its removal. If a polypus was removed, it could be removed by means of Thomas's curette without the use of tents. He did not wish, however, in any way to criticise the treatment instituted in Dr. CUSHIER's particular case.

Dr. ROBERT NEWMAN referred to a case which he had already reported to the Society. In this instance there was a distinct cyst of the fallopian tube, and there was also constant hemorrhage, as in Dr. CUSHIER's case.

Dr. PUTNAM-JACOBI said the patient began to have fever before the introduction of the tents, and that, with the intense anemia of the uterine walls, served to explain the irritability of uterine fibers. But the appearance of the heart did not seem to give evidence of a reaction likely to be helpful. Rather, a small, almost a dense colorless clot. Unless this clot was formed in consequence of septic poisoning, the question could arise whether it was not due to intense anemia producing exhaustion. Acute exhaustion from hemorrhage for two days preceding death, occurring in a heart in which there previously existed endocarditis, rendered it probable that the patient died of cardiac failure which facilitated the formation of a thrombus, and that there was no evidence of septic disease at all.

Dr. Garrigues offered another suggestion with reference to the possible cause of the hemorrhage, namely, that it may have, perhaps, been due to the simple endometritis which existed, at least the endometritis evidently present should be taken into consideration in studying the etiology of the case.

Dr. CUSHIER asked if hemorrhagic endometritis occurred without fungus degeneration.

Dr. Garrigues replied that while the most common cause of hemorrhagic endometritis was the presence of the fungoid excrences, that condition was entirely different, while here we had to do with a febrile disease.

Dr. CUSHIER remarked that there was hemorrhage for a long time, and whether elevation of temperature was present during that time or not they were unable to ascertain; but at the time the patient was first seen there was no elevation of temperature, and the hemorrhage still persisted.

CARCINOMA OF THE BONES.

Dr. F. Ferguson presented microscopical slides illustrating carcinoma of the sternum, ilium, and clavicle. The disease primarily began in the breast and involved the ribs and also the vertebrae.

Dr. Ferguson also presented fresh specimens of general tuberculosis, with tuberculosis of the mucous membrane of the uterus.

They were removed from the body of a woman twenty-seven years of age, a native of England, who gave a good family history, and who, up to the first week of March, 1884, had been always healthy. At that time she complained of nausea, sharp aching pains about the body and limbs, loss of appetite, and general weakness. On admission the patient was languid, did not want to talk, and laid perfectly quiet with eyes half closed. Physical examination was negative except the presence of numerous small moist rales at the base of each lung. Her bowels were constipated and she vomited occasionally. Her tongue was dry, cracked, and bleeding. Her quiet condition gradually merged into stupor, which deepened until death, which occurred one month after the inauguration of her first symptoms.

Her temperature ranged from 99° F. to 102° F., generally a degree higher in the afternoons. Her urine, two folded, having reached a negative both chemically and microscopically. She coughed but very little, and that shortly after admission.

MYOCARDITIS.

Dr. Ferguson also presented five hearts, illustrating myocardia or fibroid induration of the heart. In some the lesion was associated with endocarditis and also with pericarditis, while in others it occurred alone. In one specimen it was seen in the left ventricle near its apex. In none of the cases in which he had had an opportunity to make an examination had he been able to find the lesion in the right side of the heart. It occurs most frequently in the left side of the heart near the apex, and as a rule is associated with endocarditis and pericarditis.

Two of the specimens were accompanied by the following histories.

1. Heart from an unknown woman, about sixty years of age, who died comatose on February 20, 1884. There was extensive hemorrhage into the lateral third and fourth ventricles, and entirely detached right side of the brain. The vessels at the base presented the lesions of atheroma and endarteritis obliterans. The kidneys were in the condition of chronic diffuse nephritis. The heart is hypertrophied, the left ventricular wall being especially thickened. The endocardium is thickened and there are extensive areas of fibrous tissue in the left ventricular wall. These areas of myocardia are more plainly seen near the apex of the heart. The cusps of the aorta are thickened and slightly retracted with a deposition of calcareous matter. The aorta presents all stages of atheroma.

2. Heart from a man seventy-five years of age, a native of Germany, who died in New York Hospital on March 28, 1884. His heart-sounds on admission were inaudible, pulse at the wrist was imperceptible. He had pulmonary edema and dyspnea. He had edema of legs, scrotum, and prepuce, and fluid in both pleural cavities to the eighth rib. His cerebration was apparently unimpaired; he spoke broken English; his utterances were unintelligible, and no previous history could be obtained from him. His urine fell off to twenty-four ounces per day, with specific gravity of 1.00, and contained albumen, hyaline and granular casts. He died eleven days after admission into the hospital. His heart action was irregular and continued extremely weak until his death. The coronary arteries are extensively calcifi-
reous, and also present the lesion of endarteritis obliterans.

Dr. Ferguson said, with reference to the clot in the heart presented by Dr. Cushier, that, whatever might be its cause, such clots were very frequently found at autopsy. One physician in a large hospital had withdrawn a certain quantity of blood from the right ventricle during life, and then introduced an alkaline solution to prevent the formation of clot, and yet at the autopsy a well-formed clot was found. From his experience in making autopsies and from experiments performed he had come to regard clots of like appearance as post-mortem in character.

Dr. Putnam-Jacobi had seen tuberculosis over the peritoneum of the uterus, but thought it much more rare for tubercle to develop upon the mucous surface. She would ask whether or not fibroid induration of the heart was not often due to syphilis?

Dr. J. Lewis Smith asked if the absence of cough was not due to the semi-comatose condition of the patient?

Dr. van Santvoord remarked that it was not very uncommon to find marked changes in the apex of one lung without any clinical history of either cough or expectoration.

Dr. Ferguson said that fibroid induration was frequently described as occurring in syphilitic patients. Exactly the percentage he did not know. In most of the cases in which he had seen it the patients denied syphilitic history, and almost without exception they were sufferers more or less from rheumatism, and all were the subject of chronic diffuse nephritis. He did not regard them as to syphilis, although it is generally attributed to that disease.

ACUTE DIFFUSE PERITONITIS—THROMBOSIS OF THE UMBILICAL VEIN.

Dr. J. Lewis Smith presented specimens removed from the body of an infant fourteen days old, who died of peritonitis in the New York Infant Asylum. The child was born natural, and there was no evidence of septic poisoning in the mother. The nurse stated that for about a week prior to his visit the baby had been unusually fretful, and there was a slight febrile movement, although its bowels were regular. The resident physician had diagnosed peritonitis before Dr. Smith’s arrival.

When he saw the patient there was great distention of the abdomen, which was difficult to compress. Examination of all other parts of the body seemed to be negative. The umbilical cord separated on the seventh day. The rectal temperature on the day of his first visit was 102.4° F., and the day before, 100.6° F. The resident physician stated that the surface of the umbilicus, when the stump dropped, looked somewhat raw, and that there had been a slight oozing of purulent liquid. The child died on the morning of the fifteenth day of its age.

Dr. W. H. Welch made the autopsy, twenty-six hours after death, and in his report diagnosed acute diffuse peritonitis with thrombosis of the umbilical vein. The abdomen was greatly distended. Six ounces of turbid serum were removed from the cavity, containing yellowish flakes of fibrin. There was a fibrous deposit along the transverse fissure of the liver, and on the under surface of the liver, and along the course of the umbilical vein. There was no marked congestion of the peritoneum. A number of lymphatic vessels filled with pus could be seen underneath the peritoneal surface of the diaphragm, showing a pleuritis could occur in such cases if the patient lived long enough.

The umbilical vein was filled from the navel to the transverse fissure of the liver with a grayish material. In places there was broken-down purulent thrombus, which could be traced the entire length of the umbilical vein. It did not extend into the vena cava or portal vein, but was closely adherent to the walls of the vessel. The umbilical vein itself was thickened from the disease. The heart exhibited hemorrhage into the substance of the valve. The pericardial cavity contained more than the normal quantity of serum, with a few flakes of fibrin. The lungs showed hemorrhagic spots on the posterior surface, and the bronchi contained brownish mucus. There was no evidence of pneumonia in the lungs. The kidneys were hard and showed a yellowish turbid fluid in the bladder. The ovaries and uterus were normal. The pancreas and the suprarenal capsules were normal.

Dr. Smith remarked that puerperal fever had occurred in the maternity wards of this institution within the last two years, and that he had not heard of any case for a time. Two infants had died of peritonitis, and associated with it was erysipelas. Whether the existence of erysipelas had any connection with the recent occurrence of puerperal fever he did not know. The mothers presented in these cases no abnormal symptoms whatever. Heretofore it had been a puzzle to him as to how peritonitis could occur from thrombosis of the umbilical vein; but Dr. Welch thought it could be explained by micrococci passing through the walls of the umbilical vein and causing peritonitis.

Dr. W. P. Northrup had met with four cases of peritonitis occurring in children. In one case the child was nine days old, in one eleven days, in one twenty days, and in one two months old. In all of the cases the umbilical vein was examined, and in none was there any thrombus found. In one case there was an abscess of the shoulder, and that was the only thing which could at all attract attention. All the viscera were apparently perfectly healthy, nothing existing except tubercular peritonitis, so far as could be discovered, and in all, both the vescicul and the parietal peritonitis presented all the lesions of acute diffuse peritonitis.

Nothing was discovered concerning the condition of the umbilicus, as necessarily their attention was directed to this part. There was no relation between the cases and erysipelas and puerperal fever.

Dr. Smith remarked that it was a well-known fact that new-born children are especially liable to peritonitis, and in a considerable proportion of cases there is cause for it in the umbilical vein. He believed, however, that in other cases, as in the one to which he had alluded in which erysipelas occurred, there is nothing wrong with regard to the umbilical vein.

Dr. Putnam-Jacobi held that Henoch held that all cases of peritonitis occurring in the new-born were due to puerperal infection, and that it must be from the umbilicus, as usually the affection was accompanied by thrombus of the umbilical vein. It seemed to her that there could be no question with regard to the association of these conditions, but she was unable to understand why sepsis was transmitted by micrococci going through the umbilical vein to the peritoneal veins. She had supposed there was a marked lymphangitis, and that septic micrococci were found in the lymphatic vessels, and that it was, strictly speaking, a lymphangitis, such as was commonly seen in puerperal women. As peritonitis may occur by simple absorption of poison which does not leave any trace, she supposed that with a more careful search one might find septic micrococci, and was unable to see why, in Dr. Northrup’s cases, the absence of thrombus of the umbilical vein excluded septic infection any more than it would from the mother who dies with painless septic infection without phlebitis and inflammatory peritonitis. In the case in which there was peritonitis, and also an abscess in the shoulder, she was unable to see how the conclusion could be avoided that there was septic absorption. Shulzted had pointed out that there was a greater liability to septic infection in children who had been born asphyxiated, as under such circumstances aspiration is imperfectly performed, the veins collapse imperfectly, and thrombi are formed and furnish material for septic poisoning. She would ask Dr. Smith
if there was any evidence that the child was asphyxiated when it was born?

Dr. Smith replied that there was no history of asphyxia. He further remarked that the greatest amount of fibrinous exudation was along the course of the umbilical vein and the peritoneal covering.

Dr. Northrup remarked that his four cases were distributed over a period of six or eight months; that all of the children were brought in as foundlings, and as a matter of necessity had been subjected to more or less of exposure.

The Society then went into executive session.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, April 4, 1884.

Beverley Robinson, M.D., President, pro tem, in the Chair.

CAPILLARY PULSATION.

Dr. G. L. Peabody exhibited a patient in whom could be seen the capillary pulsation which sometimes accompanies aortic regurgitation. The patient was an Irishman, aged thirty-six, who was admitted to Bellevue Hospital on January 23d, and is still under treatment in that institution. Two months before his admission he began to notice that he was short of breath on making any severe exertion, and even on going up stairs or lifting any heavy weight. He also suffered from cardiac palpitation, etc., and in short gave a good clinical history of serious valvular disease.

Examination showed that he had consolidation at the apex of each lung, and that his aortic valve was both obstructive and insufficient. Both murmurs significant of this condition were loud and distinct, but from the fulness and force of the pulse it is presumed that but little obstacle to the egress of blood existed. It was to the feel a distinct Corrigan pulse. Besides this there was hypertrophy of the left ventricle, and there were the usual physical and rational signs of visceral-congestion, both thoracic and abdominal. The chief interest in the case was in the fact of the capillary pulsation.

When the patient first came under observation, synchronously with the radial pulse the vessels of the skin, as seen through the nails, were filled with blood, immediately after becoming quite anemic. The alternating pink and white colors accompanying respectively the systole and diastole were very evident, and the same phenomenon could be produced anywhere on the surface of the body at will, by merely causing an artificial hyperemia by friction. At this time pulsation of the retinal vessels was also visible with the ophthalmoscope.

During the past two months he has depreciated perceptibly. He has had an attack of dry pleurisy, his phthisis has advanced; cough and dyspnea have given him wakeful nights, and his pulse has become much weaker and more frequent. At present he labors under considerable excitement and his heart is beating quite feebly, 120 times in the minute. During the past two months evidences of failure of the hypertrophy to compensate for the valvular lesion have become more and more pronounced, and with the supervision of this condition the capillary pulsation has become less distinctly visible. At present it can usually be demonstrated by making him walk rapidly once or twice the length of the ward.

A few minutes after allowing him to drink a glass of whiskey, the capillary pulse under the nail was demonstrated to those present at the meeting.

The President asked if the phenomenon did not depend upon some individual peculiarity, such as special elasticity of the capillaries. He had seen cases of aortic regurgitation frequently, but thought this condition occurred very rarely.

Dr. Peabody thought there was no reason to suppose that the patient's capillaries differed from those of other people, except in the presentation of this phenomenon during the performance of their function.

Dr. Kinnicut suggested that a certain delicacy of the skin might possibly be a factor in the production of the peculiar appearance.

Dr. Dana asked if this form of cardiac disease was the only condition in which capillary pulsation was seen.

Dr. Peabody said that, so far as he knew, it had been observed only in connection with aortic regurgitation.

Dr. Dana asked why it was necessary to produce a certain kind of paries of the capillaries of the skin by rubbing in order to develop the phenomenon, if that was the true explanation.

Dr. Peabody thought the appearance of the pulsation in the skin after slight rubbing was not due so much to pariesis of the capillaries as to other causes, for the reason that in parts where the capillaries are substantially normal, the pulsation also could be seen. The conditions which seemed to be most essential to its appearance were fulness of the capillaries and thinness of the epidermis, which would enable the observer to see the circulation in the smallest vessels.

Dr. Clement Cleveland read a paper (see p. 483) on the feeding of infants.

Dr. H. F. Walker said that he had always had great reluctance in putting a child on bottle-feeding. He did not have the feeling that had been expressed by the author of the paper. He always advocated the use of a wet-nurse, and endeavored to make her as small a dragon as possible. This he had been having for some time, but he had not found it easy. The child had having understood it at the very beginning that she could and would be discharged as summarily as the cook or the chambermaid would be if the necessity arose.

With reference to the age of the child and the milk of the wet-nurse, he thought that both the author of the paper and the books had laid too great stress on the statement that they should be about equal. He would never refuse a good wet-nurse, even though she had been nursing six or seven months, if it was probable she would be able to take the child through the period of teething. He thought it was more important to have a nurse who could furnish milk as long as the child required it, than merely to have one whose milk corresponded with the age of the child. He had frequently seen two children nursed successively by one wet-nurse, and the second child did perfectly well.

With reference to bottle-feeding, the suggestion that the child should not be allowed to take milk too freely, Dr. Walker regarded as a very important one, and he also thought that Dr. Cleveland's idea concerning the closed rubber nipple was very valuable.

Dr. Kinnicut referred to those fortunately rare cases of inability in young infants to digest milk (breast or cow's) in any form. Two such cases had come within his personal observation during the past two years. One of the patients was seen by him in consultation with Dr. Richard Wiener. During a period of nine months the baby was unable to digest milk. Several wet-nurses were tried, and also cow's milk prepared in every conceivable way, but with no success. A second patient was under his personal observation for nine months, and with an exactly similar experience. In the latter case recourse was finally had to koumyss, which the patient finally took to the amount of nearly three pints daily, and with good result.

Dr. Polk thought the cases must be exceedingly rare where discrimination and persistence in selecting a wet-nurse were practised.

Dr. Kinnicut referred to one case in which the child had three wet-nurses, the mother being one of the three,...
but all failed, and the mother would not make any further trials. The child was being brought up on a bottle and was thriving very well.

Dr. A. B. Ball was pleased to hear Dr. Walker take such high a view of the nursing of wet-nurses, as his opinions coincided upon that point as to the great majority of cases. He thought that one reason why physicians were troubled in getting good wet-nurses was because they were unwilling to take the pains necessary in selecting one. He believed that in a city like New York, it was perfectly possible to get a wet-nurse who would give satisfaction both physically and morally, if the physician was willing to take the trouble to do so. As to the period of nursing as compared with the age of the child, he had not been able to satisfy himself that it was necessary to select a woman whose milk was so near the age of the child as had been mentioned by the author of the paper. He had seen a good number of cases in which milk several months older than the child had given entire satisfaction.

With regard to bottle-nursing, he thought there was less danger connected with that than had formerly been supposed, especially where the best resources were at the command of the physician, such as taking the child out of the city for a considerable portion of the year, etc. In his experience he did not hesitate to recommend to bottle-nursing, but should not recommend it if the family was to remain in the city for a considerable portion of the summer. He supposed all agreed that the right kind of wet-nurse was superior to bottle-nursing, and with proper care and patience he thought it would be found to be extremely rare that a thoroughly good wet-nurse could not be obtained.

Dr. W. M. Polk was in full accord with Dr. Walker and also Dr. Ball, and had had far less trouble in getting good wet-nurses than in keeping the digestive organs of the baby all right when bottle-nursed. The matter of raising a child on the bottle was a piece of fine art, if attended to properly. The question of discharging wet-nurses the same as any other servants, for good cause, was an important one, and he had been accustomed to tell the people to discharge them quicker, and for less offence, than they would a cook. Probably a child, until July and August, would do as well on the bottle as on the breast; but then, especially if the child was teething, it was well to have a wet-nurse. As between a bottle-fed child and one that had been brought up on a good breast of milk, there was no choice.

As all wet-nurses had a constitutional tendency and ability to prevaricate, he made it a rule to have the parents weigh the child occasionally to determine whether or not it was gaining flesh. Very frequently the failure on the part of the nurse did not show itself in the _quantity_ of the milk furnished, but alone in the _quality_, and of the quality a good estimate could be made by occasionally weighing the child.

When forced to feed a child with the bottle, he had nothing but thanks to Dr. Cleveland for the rules which he had given, every one of which should be followed strictly.

Dr. Peabody asked if, when properly carried out, bottle-feeding was attended by any greater mortality than occurred with wet-nursing.

Dr. Ball thought it was generally conceded that bottle-feeding, as practised in large cities among the ignorant classes, was attended with a very great mortality, but that did not apply to bottle-feeding when it was properly done. He was not aware, however, that any statistics had been made up based upon cases in which bottle-feeding had been done with care.

Dr. Polk had a general impression that the rate of mortality was greater among bottle-fed children than among those fed from the breast, even when the bottle-feeding had been done properly.

Dr. C. L. Dana thought it was an important advance if bottle-feeding could be made as safe as wet-nursing, for in the country it was difficult to obtain wet-nurses, and in the city there were very many who could not afford to employ one. It seemed to him that it should be possible to bring up a child on the bottle as well as with a wet-nurse. The digestive powers of children were rather elastic, and the quality of milk was not so very variable as to render it impossible.

He regarded the consideration of age in a wet-nurse as a very strong point, for a change occurred in woman’s milk almost from week to week, and the general rule was a steady deterioration, until finally, as the child became more intimate with artificial food, the breast milk was unfit for use as a nutritive.

Dr. Cleveland remarked that during the last eight years he had regretted bottle-feeding in only one case.

Dr. Peabody asked if there was any method of determining the quality of a woman’s milk, aside from the experiment of putting the child to the breast.

Dr. Dana did not believe that the microscope could answer the question.

Dr. Kinnicut said it had been stated by those who had studied the question that there was no way to test the quality of the milk, except by watching its effect upon the child. It could not be tested by the specific gravity, or the quantity of cream, or by the size of the oil-globules.

Dr. Polk said he had a general impression that the milk which contained a large number of colostrum corpuscles was less nutritious than the milk which did not exhibit them.

Dr. Dana said the latest theory was, that milk was formed from the white blood-corpuscles rather than from the epithelial cells of the gland. If that was true he would suppose that the presence of a great number of such large corpuscles showed that the proper change had not taken place, and that a condition existed which verged upon suppuration.

Dr. Gibney asked, in case the child had been fed by a wet-nurse perhaps for a long time, and it became desirable to discharge the nurse at once, what would the child subsist on until another one could be obtained.

Dr. Polk thought an adroit physician would prepare for the emergency by securing a new nurse in advance of the discharges of the old one.

Dr. Cleveland said that certainly he believed woman’s milk was better for a child than any other food, but there were so many cases in which it was so exceedingly difficult to get it, that he had been led to turn his attention to the study of bottle-feeding. The point of economy he regarded as an important one, and one not to be overlooked.

Dr. Polk thought the actual difference in expense was not very great, inasmuch as a good nurse was very essential while rearing children on the bottle.

Dr. Polk further remarked that a child that was very sick, from any disease, did better when fed from the breast than from the bottle. Again, children who were being fed from the breast did better than bottle-fed children, if they contracted any disease.

The Society then adjourned.

The Great Mortality in Russia.—The death-rate of Russia is the highest in Europe. This is attributed to the paucity of medical men and the habits of the rural population. According to late returns the average duration of life is only twenty-six years, and the mortality among infants is frightful. More than sixty per cent. of infants die before they reach their fifth year, and nearly 2,000,000 children perish every year. Of 8,000,000 boys, only 3,770,000 attain the age of military service—that is to say, their twenty-fifth year; and of these at least 1,000,000 are found, by reason of shortness of stature and weakness of body, to be unfit for military duties.
THE MEDICAL RECORD.

SIXTEENTH ANNUAL SESSION, HELD AT BELTON, TEX., APRIL 22, 23, 24, AND 25, 1884.

(Specially reported for THE MEDICAL RECORD.)

THE President, Dr. A. P. Brown, occupied the Chair.

Two hundred and eighty members were present during the session and eighty-eight new members were admitted. Dr. W. B. Park, Essayist, delivered an address on "Evolution."

Dr. A. P. Brown, President, delivered the annual address giving an historical résumé of medicine.

Dr. J. Larendon, Treasurer, reported the amount on hand as $20.25.

ONE HUNDRED DOLLARS WERE DONATED THE SIMS MEMORIAL FUND.

with suitable resolutions.

The Association passed resolutions endorsing the Code of the American Medical Association.

The Committee on Necrology reported thirty-six deaths among Texas physicians during the year, seven of whom were members of the Association.

Thirty-four articles on various medical subjects were presented, discussed, and referred to the Committee on Publication.

Dr. A. M. Falle, of Belton, presented a paper on "Bimurate of Quinia with Urea used Hypodermically," contending it was easily soluble and not irritating to the tissues.

Dr. S. H. Stout, of Cisco, presented a paper on "Continued Fever," which provoked quite an animated discussion.

Dr. J. M. Willis, next read a paper on "Mineral Waters of Texas, notably Wooten Wells, Lampasas and Palo Finto Springs, Sulphur and Luling Springs, and Sour Wells."

Dr. C. M. Ramsdell gave a brief résumé of "Intestinal Paralysies in Texas."

Dr. C. R. Johnson discussed on "Hot Water in Heart-Failure from Hydrate of Chloral."

Dr. D. C. Milner, of Gainesville, remarked on "Alcohol as a Poison," and Dr. H. W. Dudley on "Animal Liquigates from the Texas Mule-eared Rabbit," showing specimens.

Dr. J. D. Osborn, of Cleburne, reported a case of mulberry calculus one inch by one-fourth inch in diameter removed from a child four years old.

Dr. T. H. Nott reported a case of mulberry calculus much larger, weighing 526 grains.

Dr. W. H. Brown, of Waco, referred to one still larger weighing 12 ounces, and measuring in circumference 12½ by 7½ inches.

Dr. C. W. Trueheart, of Galveston, reported "A Case of Periosteum Grafting," in which the periosteum was removed from a dog and transferred to a man, resulting in a reproduction of two and three-fourths inches of the clavicle, also one of "Fibroid Tumor of Middle Ear," successfully removed.

Dr. Edward Goldman, of Monterey, presented some clinical observations on the "Antagonism between Syphilis and Carcinoma."

Dr. G. P. Hall, of Galveston, remarked on "Near-sightedness caused by a Carious Molar."

The following papers were read by title: "Fibro-Cystic Tumor;" "Typho-malarial Fever;" "Blood-letting Traits;" "Operation Cyclone;" "Surgery of the Lying-in Chamber;" "Prolonged Vomiting;" "Meningeal Phases and Cholagogue," and referred to the Committee on Publication. Dr. W. J. Burt, Chairman, Dr. J. E. Daniels, and Dr. J. S. Broils.

The following officers were elected for the ensuing year: Dr. H. C. Ghent, of Belton; President; Dr. E. P. Becton, of Sulphur Springs, Dr. H. H. Carr, of Caldwell, and Dr. M. Martin Hearne, Vice-Presidents; Dr. W. J. Burt, of Austin, Secretary, and Dr. J. Larendon, of Houston, Treasurer.

The next meeting will be held at Houston, Texas, in April, 1885.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, April 28, 1884.

S. Oakley Vander Pol, M.D., LL.D., President, in the Chair.

Willard Parker, M.D., LL.D.

The President announced the death of Dr. Parker, and paid a fitting tribute to the sterling integrity, the manly worth, zeal, and acquirements of his personal friend and professional brother. A memorialist will be appointed.

Dr. Garkish moved that a committee of three be appointed to draft resolutions. Carried.

TRACHOMA AND THE ETIOLOGY OF JEQUITIVITY OPHTHALMIA.

Dr. Joseph A. Andrews read a paper on the above subject, in which he devoted considerable space to the study of the histology of the conjunctiva, followed by a consideration of the etiology of the condition based upon the results of experiments performed on animals, and the microscopic investigations in cases developed in the human eye. The special point of interest in his etiological remarks was the fact that he had reached conclusions exactly opposite to those announced by Professor Sattler, of Erlangen, who regarded the disease as due to a particular micro-organism.

Dr. Andrews then gave the method by which his investigations were carried on. He had found micrococcii in blenorrhoeic trachomic pus, but had not succeeded in establishing by cultivation a physiological condition, namely, an isolated micrococcus which was capable of producing trachoma. Nevertheless it might exist.

The author of the paper then referred to the influence of the general condition of the system on the development of micro-organisms, and all these conditions of the eye; also the influence of race and geographical causes in the etiology of trachoma. In Southern Russia a much larger percentage of cases occurred belonging to this class of eye affections than in New York and Brooklyn, where the ordinary rules of cleanliness were more generally observed.

Probably micrococcii were the real promoters of the contagion, although there might be no special micro-organism of the disease.

Dr. Andrews then spoke at some length on the histology of the conjunctiva, with special reference to the existence of adenoid tissue, and gave the conflicting views of a large number of observers. He had come to believe that if the follicles were a pathological product in man, the proof was exceedingly slight that they existed physiologically in animals; that the presence of this condition was due to the manner in which animals were cared for, and that it was pathological, due to spreading of the disease by direct transfer of the contagion.

The writer then directed attention to the definition of trachoma, the nature and structure of the trachoma follicles. His own views were based upon observations made in fifty-six cases. He had never been able to find tubular glands in the conjunctiva, but only the deep furrows which had been regarded by some as tubular structures glandular in character. The tendency to the formation of cysts was exceedingly common, but not peculiar to the trachomatous process.

With reference to treatment, the presence of granulations did not furnish immunity against other forms of conjunctivitis. The fact that actual trachomic bodies sometimes disappeared spontaneously confused the study of therapeutic measures. Solutions of the bichloride of...
mercury were of special service for cleaning the mucous membrane. Caustics might destroy tissues which we wished to leave unaffected, as well as the granulations; they might have given good results in a few cases, but in the great majority they had caused suffering, and generally substituted another condition which was much more mischievous than the original trouble. The author of the paper then spoke of the use of astrin gente, such as copper, etc., and referred to three cases which he had treated successfully by excision of the conjunctiva.

With regard to jequirity ophtalmia, he thought it important to bear in mind the fact that it had a period of incubation, and hence the applications were to be repeated with caution. The cornea was exposed to risks in the two weeks after the action of the infusion could be controlled by limiting the number of applications and bearing in mind the period of incubation. Neither purulence nor the formation of a pseudo-membrane was an essential feature of jequirity ophtalmia. In thirty-seven of his fifty-six cases the cure was complete, that is, the granulations and pannus disappeared. In the best cure vision was restored to 20/20.

Reference was then made to complications due to the use of jequirity. One important danger was removed by its use, namely, liability to inoculate the opposite eye. He had inoculated the opposite eye in several cases of jequirity ophtalmia, but always with negative results. So far, chemical attempts had failed to isolate the active principle. The actual cause, however, of the ophtalmia produced by it was probably a ferment developed after application to the eye.

Dr. T. R. Pooley said his use of jequirity had been confined to chronic cases, such as frequent dispensaries, as he wished to determine whether or not it was applicable to the form of trachoma usually treated by copper. The effect in all those cases was almost nil. In scarcely any cases did he succeed in forming the characteristic pseudo-membrane. He had the conviction that the remedy was applicable only to those cases which at one time were treated by inoculation with binocular pus, an extremely dangerous method, but one occasionally followed by good results. He was still of the opinion that its use should be confined to that class of cases, those in which it was necessary to do something even at the hazard of the patient’s vision, but he did not believe that its universal use in cases of chronic trachoma would be adopted.

Dr. Knapp said that certainly trachoma was not limited to the poorer classes, and he did not think bad hygienic conditions were responsible for its production. He believed that the most important etiological factor was climate, as its greatest prevalence was in low countries, along rivers, as in the valley of the Nile, etc.

With regard to the agent which produces the ophtalmia when jequirity was used, he only knew that recent writers were in accord with Dr. Andrews in the belief that it was a chemical poison and not a bacillus. With reference to jequirity as a therapeutic agent, he had used it in all kinds of trachoma, and, while he had obtained good, even brilliant results, he had come to regard its action as not uniform, not controllable, and dangerous. He cited cases in which the jequirity developed diphtheritic inflammation as genuine and dangerous as he had ever seen.

Dr. Gruening thought that if de Weccker had not written anything concerning jequirity except his first article, it would have been sufficient; for he recommended that a three-tenths per cent. infusion be used in the treatment of cases of total pannus which could not be treated by any other means, and treated formerly by the extreme measure of inoculating the eye with gonorrheal pus, and when so used it did not produce diphtheria. But the strength of the infusion had been increased to one, two, three, and even to five per cent, and also granulations with slight pannus had been treated with it as well as those for which it was first recommended. Dr. Gruening’s first cases were entirely satisfactory, and he still believed that if a three-tenths per cent. infusion, prepared from fresh beans, was used, an effect would be produced which would not be dangerous to the cornea, and that it would be serviceable in chronic hospital cases as well as elsewhere. For total vascular pannus no remedy excelled jequirity. He cited a case in which diphtheria followed a single application of a three per cent. solution.

Dr. R. C. Brandéis reported a case of atrophic pharyngitis in which he made a single application of a three per cent. solution, with the result of producing an intense irritation, congestion, and oedema of the pharyngeal and larvalgeal mucous membrane that nearly destroyed the life of his patient.

Dr. Andrews, in closing the discussion, said he thought it well to limit the use of the remedy to chronic cases with well-marked pannus; that it should not be resorted to until all ordinary means had been used unsuccessfully; that we should begin with the weakest solution and take advantage of the fact that there is a period of incubation; and also that the fact that all eyes are not affected in the same way by the remedy should be constantly kept in view.

REPORT OF THE COMMITTEE ON HYGIENE IN PUBLIC SCHOOLS.

Dr. A. Jacobi, Chairman, said that, owing to the lateness of the hour, he would ask the Secretary of the Committee to read a bill now before the Legislature, and if the object sought in the measure needed further explanation before the Society took any action, the report could be continued.

Dr. Van Santvoord then read the bill entitled “An Act to Provide Additional Accommodations for the Common Schools in the City of New York.” The Act provides for issuing bonds by the city of New York for two million of dollars, to be expended under the direction of the Board of Education, which had recommended by a vote of fifteen affirmatives to two negatives that it become a law.

Dr. Jacobi moved that the Medical Society of the County of New York hereby records its approval of the Act to provide additional accommodations for the schools of the city of New York, believing that this provision is sound and expedient and will be of great advantage to the city of New York by providing the necessary school accommodations to meet the rapid growth of the population. Carried.

The Society then adjourned.

Correspondence.

THE RECTAL ADMINISTRATION OF ETHER.

To the Editor of The Medical Record.

SIR: On the 21st inst. my attention was directed by Dr. W. T. Bull to an article by Dr. Moillière in the Lyon Medicale of March 30th, on the administration of the vapor of ether by the rectum. I tried this method for the first time on the 21st inst. My apparatus consisted of a citrate-of-magnesia bottle, a piece of rubber tubing, and the vaginal tube of a Davidson syringe. The patent was placed on the side, the tube inserted into the rectum, and the bottle half full of ether placed in a pitcher of water of about 150°. In four minutes the patient was decidedly affected by the ether, and in eight minutes and a half was profoundly under its influence. The tube was retained in place while the operation of curettage was performed and while a thorough examination for suspected ovarian disease was made. The anaesthesia was maintained for twenty-five minutes. The quantity of ether consumed was an ounce and a quarter.
There was no struggling during its administration, and there was no subsequent vomiting or diarrhoea. The bowels did not move afterward until a cathartic was given.

My second case was on the 24th inst. The patient became nearly unconscious in four minutes, when a movement from the bowels took place, and as time was pressing the inhaler was resorted to.

My third case was on the 24th inst. The patient was thoroughly anaesthetized in six minutes and a half, and anaesthesia was maintained for twenty-three minutes. The quantity of ether consumed was two ounces. There was no vomiting and no diarrhoea afterward.

The fourth case was one of ovariotomy. The patient was rendered perfectly unconscious in six minutes and a half by the use of an ounce and a half of ether. It was then deemed expedient to resort to the inhaler, as it was feared that distention of the bowels might interfere with the operation. This patient had no subsequent diarrhoea or vomiting.

My fifth case was on the 28th inst. In seven minutes the patient was ready for operation (on the cervix), which was then begun. The anaesthesia was maintained twenty-seven minutes. The quantity of ether consumed was two ounces.

My sixth case was on the 28th inst., in a patient on whom I performed an operation on the perineum. The rectal method was employed to place the patient under the influence of ether, when the inhaler was substituted. A defect in the apparatus occasioned a loss of time in the rectal administration, but the patient was unconscious in less than ten minutes. No diarrhoea.

The method in question promises, in my opinion, to effect a radical improvement in the method of administering ether. A striking feature is the small quantity of ether required, showing how large a quantity is commonly wasted. The absence of any unpleasant sensation on the part of the patient is a matter of no small importance. The rapidity with which anaesthesia can be induced and the general absence of struggling and opposition by the patient give the rectal method a decided value, even if it should be used only as a preliminary to the usual method. It is evidently desirable that the bowels should be freely moved by an enema beforehand.

Mr. Ford, of Caswell, Hazard & Co., has made for me a very simple apparatus for the use of ether in this way. It consists of a graduated glass vessel, a curved hard rubber rectal tube, and tubing to connect the two. This apparatus enables the operator to observe accurately the quantity of ether consumed. One danger to be guarded against is the condensation of ether by the use of a connecting tube too long and of too small a calibre.

Yours respectfully,

JAMES B. HUNTER, M.D.

2 EAST THIRTY-THIRD STREET.

ON THE DANGER OF INDUCING ANÆSTHESIA BY THE RECTUM.

TO THE EDITOR OF THE MEDICAL RECORD.

Six: In your issue of to-day you call attention editorially to an article by Mollière, of Lyons, upon the interesting subject of the induction of anaesthesia by the rectum. The great advantage of such a method in connection with operations upon the face, aside from the other claims advanced for it by Mollière, will widely attract the attention of surgeons, and will undoubtedly lead to its being tested on every side. A very brief experience, however, has induced me at once to place before the profession a risk not alluded to by Mollière—which belongs to the mode of administering an anesthetic—namely, much death has occurred in one of my trials with the method. Rectal anaesthesia is, so far as I know, was first used in this city by Dr. W. T. Bull, in the New York Hospital. In his cases the anaesthesia was not complete, and required the use of the usual cone to permit the operation to be begun. The next day, at my clinic at the College of Physicians and Surgeons, I gave ether by the rectum to a boy aged fourteen, for the removal of a sarcoma of the hand, but although he was rendered sleepy and his breathing became stertorous, yet at the end of fifteen minutes, insensibility not having been produced, etherization by the ordinary way was employed and the operation completed. The next case in which the rectal etherization was tried was for the operation of hare-lip in a robust child aged eight months. The patient came fully under its influence in three minutes without any struggling, and the operation was completed in the usual manner, though it was somewhat prolonged by a reaplication of sutures at the lip to secure a more satisfactory line of union. During the latter part of the anaesthesia, by the use of fresh hot water a too free evaporation of ether vapor took place, and the child's intestines became somewhat distended thereby, but this was readily relieved by releasing the nates, which had been slightly pinched to keep in the vapor and faces. Less than two ounces of ether was used and the amount of hemorrhage from the wound was but trifling. The child was at the close of the operation somewhat depressed, but rallied under stimulants and heat, and one of the climax of efforts remained with it for several hours until reaction was fairly established. During the night it, however, had several large and bloody passages and died the following morning. This intestinal hemorrhage might have been considered as either accidental or due to the over-distention from the ether vapor, but in some seven cases that have occurred in Dr. Bull's service I learn that in nearly all of these diarrhoea, simple or bloody, has taken place, and that in one case, at the Chambers Street Hospital, the patient was much collapsed afterward. It is obvious, therefore, that considerable risk is entailed by anaesthesia carried on in this manner, and it is my anxiety that this note of warning should appear as closely as possible to your article calling attention to the novelty which leads me to this hasty communication.

Yours very truly,

ROBERT F. WEIR, M.D.

37 WEST THIRTY-THIRD STREET,
April 26, 1884.

TREATMENT OF LUPUS.—In an item upon this subject on page 330 of THE RECORD, it is stated that Lemoyet uses hypodermic injections of ether for the cure of lupus. This is a mistake, as it should have been understood as came from the similarity of the French words for lupus and wen.
MEETING OF THE AMERICAN MEDICAL ASSOCIATION.

The meeting of the American Medical Association, held during the present week at Washington, was quite largely attended, and was as representative in character as could be expected under the circumstances of its present organization and its peculiar system of pledges. It cannot be denied that the present restrictions of membership and delegate system have told in many ways against the extended usefulness and the wide-spread influence of what a national scientific association should be. Certain it is that many who would have gladly added interest to the discussions, and would have contributed to the scientific merit of the meeting, have been denied a hearing on account of opinion’s sake regarding the performance of conscientious professional duties. And even in that regard, where the line has heretofore been so rigidly drawn, there would appear to be merely a technical difference without a tangible distinction. This seems quite evident from the rather remarkable standpoint of the president of the Association, who in his annual address makes concessions which are not entirely in keeping with his former utterances on the Code question.

He now advises an interpretation being put upon the Code which will allow of a wider range of consultation than is now supposed to be permitted. It virtually makes the old and new Code agree, and is a distinct admission of the fact that some change is needed. He is, however, just in the position that the New York Code Committee was. It did not think that the old Code could be made sufficiently elastic without practically emasculating it. This method will certainly obtain if the propositions made are consistently carried out. He admits that under certain circumstances, to be judged by the individual physician, the higher law of philanthropy must prevail over every code. Beyond this no one cares to, or can conscientiously, go. The State Society took the same ground two years ago, and the members who declared in favor of it are denied representation. It is quite evident, however, that the Association is inclined to look upon the question in a calmer light than heretofore, to allow the force of argument, and to admit that individual differences of opinion have some claim for general recognition. Whatever the ultimate issue may be, the Association can no longer afford to shut off discussion or deny the right of an individual member to think for himself, and to govern his actions toward his patient accordingly. There is, however, a vagueness in the suggestions of the distinguished president as to changes necessary to be made in the Code, which will be readily excused under the circumstances.

The portion of the address referring to medical education was hardly as successful in its aim as that just alluded to. Certain it was that the Association did not heed the injunction not to criticise the medical colleges in their laudable endeavors to elevate the standard of medical education. But the profession itself still needs much instruction as to its duties in the matter. Unfortunately, however, there is a general belief that the medical colleges themselves are too much interested in doing things in their own way to look at the subject in a perfectly impartial light. That this objection does not apply to the distinguished teacher, or to the school which he has so long honored, goes without the saying. But there are always two sides to a question, and that is the only reason why there was such an apparent difference of opinion as to whether the colleges shall rule the profession, or the profession rule the colleges.

It is hardly safe, in these days, to ignore the utility of State examinations for a degree, especially on such grounds as taken by the orator. The objections urged are not only utterly untenable, but add force to the advocacy of a measure in which every one not connected with a medical school has implicit faith.

In reviewing the general work of the session, it may be said that it barely came up to its usual average. Some of the sections did remarkably well, however, and reflected great credit upon their respective chairmen, who, for months beforehand, manifested a becoming zeal in securing papers, and, where it was safe to do so, in asking gentlemen to participate in the discussions.

The Journal of the Association received, as might have been anticipated, considerable criticism. Everyone who has read the Journal for the past year is hardly ready to second the opinion of the distinguished chairman of the Publication Committee, in believing that it has been conducted as well as could have been expected. Still it deserves considerable credit considering the material it had to work with, and the skill, energy, and enterprise of its management. It has proved itself a journal for the Association, nothing more and nothing less, and it is pleasant to know that the said Association declared its satisfaction by such a decisive vote.
The addresses delivered by the chairmen of various Sections were generally of a practical character, and were becomingly received by the Association.

Various measures relating to public health were advocated in the general sessions and duly passed. One of the most important was that referring to the sanitary regulations of transatlantic steamers. It was proper that the Association should call attention to this subject, and the action taken is an earnest of a reform which is much needed, and which we doubt not will be eventu-
ally carried out.

The suggestion that the next meeting of the International Congress be held in this country, will be cordially received by the profession of America, and the action regarding the same will doubtless be seconded by the medical men and medical societies of the chosen city. But it is not our purpose to review in detail the doings of the Association. This is unnecessary, in view of the full telegraphic report of the entire proceedings presented in this issue.

THE UTICA ASYLUM INVESTIGATION.

The Assembly committee appointed to investigate the recent homicide in the Utica Insane Asylum, and its management, have submitted the evidence taken, and their report thereon. The testimony lies before us, in the form of a portly volume of fourteen hundred closely printed pages, and so arranged that it is all but impossible to form any opinion of its merits as a whole, or to come to any proper and satisfactory conclusion on the subjects investigated. The whole investigation seems to have been loosely organized and prosecuted, and it is not surprising that out of such an amount of chaff as the committee gathered, so few grains of wheat have been winnowed. The committee was formed on the impulse of the first excitement caused by the announcement of the homicide, and some who were appointed had loudly expressed their hostility to the institution. The investigation, therefore, assumed from the first too much the character of a prosecution, and did not at any time have that deliberation and judicial fairness which should characterize the examination of a State institution by a legislative committee. This fact is seen in the kind of testimony taken, and the entire absence of rules governing the taking of evidence.

We cannot attempt to sift this immense accumulation of materials, but shall limit ourselves to noticing some of the more important features of the committee's report or "findings." The committee first allude to the homicide, and state the facts concerning it, but remit the question of guilt of the attendants to the court before which they are to appear. The evidence of the cruel treatment of inmates was given by patients and former attendants, and was conflicting. The testimony of both classes evidently requires the most careful sifting, for the insane, being so intolerant of every form of restraint, often regard their treatment, however mild, as cruel; while discharged attendants usually seek revenge by stories of abuse and mismanagement. We notice that attendants discharged from the asylum for cruelty and immoral conduct now appear as accusers, and even relate their own violation of the rules by maltreating pa-

patients, for the purpose of making out a case. Such evidence as this will weigh little with unprejudiced minds. The committee allude to the number of injuries recorded in the injury-book as proof of violence toward patients. They conclude that patients are often treated rudely, and with too little regard to their mental condition.

In seeking a remedy the committee very wisely conclude that it lies in the direction of a better class of attendants, training-schools, and higher wages. The charges of certain female patients, of improper liberties taken with them by the medical officers, are dismissed as not being sustained; but the committee urge the appointment of a woman physician, not only to prevent scandal, but for the better treatment of patients suffering from uterine diseases.

A large share of the report is taken up with the discussion of the business management of the institution, and the conclusion reached is, that greater economy would be secured if there were a central State agency, through which all of the purchases were made.

The committee recommend that the Attorney-General, the Comptroller, and the President of the State Board of Charities be appointed a commission to devise a plan for the better business management of the charitable institutions of the State, receiving the aid of the State, and report to the next Legislature.

This report will prove very disappointing to those who have believed that the Utica Asylum embodied all the cruelties ever practised upon the insane. It is evident that the committee left no stone unturned to discover abuses in every department of its management, for not only were witnesses invited by public proclamation to appear before the committee, but they were allowed to give their testimony in secret, without the presence of the asylum officers, or even of the counsel of the asylum. The evidence shows that the medical and business affairs of the institution were examined in a manner to expose not only all wrong methods and acts, but to ventilate the grievances of all who had ever had occasion to censure its management.

While it is probable that the public interests will in some particulars be served by such examinations as this, we do not believe that the greater and more important interests of the insane are thus subserved. There is no doubt that the whole system of lunacy administration in this State needs revision, and the methods of caring for the insane, acute and chronic, should be placed on a basis more in accord with the recent advances in our knowledge of insanity and the wants of the insane. But when the Legislature enters upon that inquiry, we trust that a commission will be formed embracing medical, legal, and lay talent, and thereby be fully qualified to solve the complex problem of the public care, treatment, and custody of the insane.

THE AMERICAN SURGICAL ASSOCIATION A CLOSE CORPORATION.

At the meeting of the American Surgical Association in Washington, last week, several applications (eleven we understand) were made for membership. Out of this number four were selected by the Council to be voted for by the Association, and all were rejected by the uni-
form number of ten black balls. When it is stated that
the applicants were all well-known and prominent sur-
geons, scattered from one end of the country to the other,
this action looks a little remarkable.

News of the Week.

Prof. S. D. Gross.—The body of Prof. S. D. Gross,
of Philadelphia, was cremated on the 8th.

Yellow Fever and Cholera.—Reports from Rio
Janeiro show an increase of yellow fever deaths at that
place; 28 deaths occurred during the week ending
March 15th, and 42 deaths during the following week.
At Calcutta the cholera is increasing, as shown by con-
sular reports, there having been 51 deaths from this di-
ease for the week ending March 8th, and 95 deaths dur-
ing the following week.

The Kirmess for the New York Skin and Can-
cer Hospital.—A "kirmness," or fancy-dress fair, was
held this week at the Metropolitan Opera House, for the
benefit of the New York Skin and Cancer Hospital, and
proved very successful.

Mr. John Jacob Astor lately gave $200,000 toward
the founding of the hospital, making a total of $289,-
000 already raised. A lady who hides her charity under a
bushel has given ground worth $35,000. These gifts,
with the proceeds of the Kirmess, make the Skin and
Cancer Hospital an assured fact.

The American Medical Association and the
Code.—Another correspondent, a physician in this city,
writes that he has had an experience with the American
Medical Association similar to that of Dr. Hamilton's.
He was invited by letter to take part in the discussion
on epilepsy, but on learning his "ethical" position the
chairman dropped him.

Medical Invasion of Austria.—Several Prussian
physicians, including two professors, have moved to Vi-
enna and other cities in Austria. This has greatly dis-
urbed the Vienna medical press, who speak of it indign-
antly as an ärzte-invasion.

The Discoverer of the Micro-organism of Hom-
cholera.—There seems to be some dispute yet as to
who first discovered the micro-organism of the "infect-
ious pneuomo-enteritis" of swine. We have received a
letter from a Western correspondent, who asserts that we
have done injustice to a worthy man in not acknowled-
ging the priority of Dr. Detmers as the original discoverer
and cultivator of this organism. A similar charge is
made by Dr. Gradle, of Chicago, in a letter to the Me-
dical News. If these correspondents had consulted some
of the issues of The Record, containing criticisms of the
reports published by Dr. Detmers several years ago,
they would understand why so little reference is made to
that gentleman now. These reports showed then, as they
do now, that Dr. Detmers furnished no scientific proof
whatever that he had really found a specific micro-
organism, while his methods of cultivating what he did
find were to the last degree imperfect and inconclusive.
In fact, Dr. Detmers went no farther in actual authorita-
tive discovery than Dr. Klein, who preceded him, and
whose work he was slow to acknowledge.

The Medical Society of the State of Pennsyl-
mania will hold its thirty-fifth annual session at Phila-
delphia, May 14th, 15th, and 16th.

Against Legalizing Social Vice.—Senator Mitchell,
of Philadelphia, on April 22d, presented to the U. S.
Senate a petition of the Moral Educational Society of
Philadelphia, officially signed, praying that the power
delegated by Congress to the National Board of Health
may be so clearly defined that it will not legalize social
vice. Referred to the Committee on Epidemic Dis-
cases.

Exempt from Jury Duty.—There are in this city
2,925 physicians and 357 dentists who are exempt from
jury duty. The number of lawyers is 4,900, that of cler-
gyman, 1,000; of druggists and clerks, 2,000; of physi-
cally disabled, 30,000.

A Violator of the Minnesota Medical Practice
Act met with a warm reception recently in Northern
Minnesota. He spent the night in jail, and in con-
sideration of suspension of proceedings, took the first
train out of the State.

The next Meeting of the Minnesota State Med-
cical Society will be at Stillwater, Thursday and Friday,
during the third week in June, instead of Tuesday and
Wednesday of the same week, as per adjournment. This
change has been made by the Executive Committee upon
the request of the President of the Society, Dr. W. L. Lin-
colin, in order to accommodate the members of the Society
who are members of the five Pension Boards of the State.
The change will inconvenience no one and be a great
accommodation to a large number of the Society.

Neurology in the West.—Dr. J. S. Jewell, of
Chicago, has issued a circular to those especially inter-
ested in the study of the nervous part of the human
organism in the West, in order to ascertain whether or not
it is desirable and feasible to form an association in
the West for the study of the nervous system.

Training-Schools for Nurses in Paris exist now in
several of the hospitals, viz., Salpêtrière, Bicêtre, and La
Pitié. This has been brought about largely through the
efforts of Dr. Bourneville, the able editor of Le Progrès
Médicale.

Chicago Medical College.—Dr. W. H. Casselbery
has been appointed Professor of Materia Medica and
Therapeutics, Dr. J. W. W. Jaggard Adjunct Professor
of Practical Obstetrics, and Dr. F. S. Johnson Lecturer
on Histology in this college.

The Alleged Cases of Foot and Mouth Disease in
Kansas are thought by Dr. D. E. Salmon to be cases of
gangrene from ergot in the hay. But how does ergot get in
hay? Secale cornutum is not generally thought to
flourish upon grass.

The German Government has under consideration
a law making it necessary for students who wish to get
degrees in German universities, to take all their courses
in these universities. This has much disturbed the Swiss
universities, where it is customary for a certain portion
of German students to spend part of their time. The
Correspondens-Blatt f. Schu. Arts gives a table showing
that the percentage of German medical students in the
three Swiss universities varies from 24 to 10.
American Medical Association.

Thirty-fifth Annual Meeting, held at Washington, D. C., May 6, 7, 8, and 9, 1884.

(By telegraph to THE MEDICAL RECORD.)

TUESDAY, MAY 6TH—FIRST DAY.

The Association met at the Congregational Church, Washington, D. C., and was called to order, at 10.30 A.M., by Dr. A. Y. P. Garnett, of Washington, Chairman of the Committee of Arrangements.

Prayer was offered by Rev. W. A. Leonard, D.D. Dr. Garnett then introduced the President, Dr. Austin Flint, of New York, after which he delivered the address of welcome.

Letters from A. Pearce Gould, F.R.C.S., London, Eng., were received and ordered entered upon the minutes.

The Secretary, Dr. W. B. Atkinson, then read the names (590) of those who had registered, and on motion the register as read was confirmed, except as to those against whom protests had been affirmed.

On motion by Dr. Brodie, of Detroit, the ex-Presidents were invited to seats upon the platform.

Dr. J. H. Trumbull, of Chili, Dr. Jonas A. Marshall, of Massachusetts, and Dr. Garlick, of Racine, Wis., were elected Members by invitation.

Also all the members of the Medical Association of the District of Columbia who were not delegates or permanent members.

A letter from Dr. John L. Atlee, ex-President, expressing regret at his inability to be present, was received and ordered entered upon the minutes.

THE PRESIDENT'S ADDRESS.

Dr. Austin Flint, President, then delivered his address, in which he first made reference to the origin of the Association, and to the objects for which it was founded. The plan of organization, with Constitution and By-laws and Code of Ethics, was adopted in 1847, and therefore it was in the thirty-eighth year of its existence.

The motives which led to the formation of the Association were first a desire to promote improvement of medical instruction and advance the standard of medical acquirement, as most satisfactorily set forth in resolutions drawn by Drs. Stillé and Hays. Little was to be expected from State Legislatures in those days, and in that respect no marked progress had been made, for, indeed, the terms regular and irregular were then, as now, not entitled to legal distinction. There seemed to be, therefore, need of unity of council of the members of the medical profession from all parts of the country for its own protection.

The development and growth of the Association were rapid, and now it has passed through a healthy adolescence into mature age. It had outlived and profited by the errors of its youth, and before him was the evidence that it was replete with vitality and vigor.

The text of the President's address was the preamble to the plan of organization adopted at the formation of the Association: "Whereas, the medical convention held in the city of New York, in May, 1846, have declared that it is expedient for the medical profession of the United States to establish a National Medical Association," etc., in which are set forth the special objects already mentioned, and to those his remarks had special reference.

The terms "cultural and advancement of medical knowledge" implied that medicine was progressive. Allusion was then made to the evidence in favor of the statement that progress had been made, and especially with reference to our knowledge concerning the causation of disease, particularly as to the influence of specific poisons in the form of micro-organisms.

A new era is about to be developed, and the time will come when means will be found to destroy morbid agents outside of the body, and thus secure prevention of disease; and means will be found to destroy the agent within the body, and thereby afford the power to arrest the course of disease.

"FOR ELEVATING THE STANDARD OF MEDICAL EDUCATION"

were words which expressed the second of the objects mentioned in the preamble of the original resolution, and included the requirements concerning the examinations for the degree of Doctor of Medicine. It had been said that the recommendations regarding medical education had been nugatory, but there was less room for reproach in that direction than some had supposed. It would be absurd to suppose that the recommendations then made were those which should be followed at the present time, for most of them had been surpassed by the medical colleges. The reformatory was room for further advancement, no one would deny, but it was not at all certain that it would continue to the satisfaction of those who regarded with disapprobation the progress in medical education manifested in this country.

The President then referred to the close relation which should exist between didactic and clinical teaching, the institution of recitations for didactic lecture, the extension of the period of time for medical teaching, and the advantages of a preliminary education. Concerning the latter, it might be fairly questioned whether the time spent in the study of Greek and Latin might not be expended with more profit in the study of physics and chemistry and the French and German languages.

The progress which had been made with regard to the preliminary education of the medical student had been less satisfactory than that made in medical instruction. The more progress had not been made was partly the fault of the medical schools and partly that of private presidents; more, however, with the latter than with the former.

WHAT CAN THE ASSOCIATION DO TO PROMOTE THE STANDARD OF MEDICAL EDUCATION?

First of all, the things desirable not to do. It was not desirable to decry medical instruction in this country as unworthy of any commendation and contemptible when contrasted with the education of other countries. Such disparagement was not warranted by facts, and we had no occasion to be ashamed, as the members of our profession in this country are not ignorant or in any respect unworthy. The profession was honorable and honored. In no country was its social status higher. The sweeping charges against the medical schools were unwarranted, untrue, and unbecoming. He did not wish, however, to appear as an apologist for abuses which exist, directly or indirectly, the standard of medical education. He suggested the appointment of a standing committee, whose function should be to communicate with State associations and medical colleges, with a view to securing uniform action concerning the requirements for matriculation and graduation, and to report to the Association what had been actually accomplished. Not all the improvement desired could be accomplished; but perhaps the question of preliminary education could be considered first and with decided advantage.

With regard to establishing Boards of Medical Examiners, Independent of the Teaching Body, the President, without stopping to discuss this point, said that, while there might be some seeming advantage in the plan, it would be impracticable to secure
On motion of Dr. Ferguson, of Troy, N. Y., the President's address was referred to a committee of seven, to be reported on as speedily as possible.
Dr. Albert Blumenberg, of Alleghany County, Pa., and Dr. B. F. Shreve, of Iowa, were named for
MEMBERS BY INVITATION.

Dr. Keller, of Arkansas, raised the point that none could be made members by invitation except those from regions not otherwise represented. The point was declared to be well taken.

Dr. Keller then moved that all those who had been named as members by invitation be invited to seats in the present meeting of the Association.
Dr. X. C. Scott offered a protest against the admission of Dr. A. G. Sherman, which was referred to the Judicial Council.

The Association then adjourned to meet at 10 a.m. May 7th.

WEDNESDAY, MAY 7TH—SECOND DAY.

The Association was called to order at 10 a.m., by the President, and prayer was offered by Rev. W. A. Bartlett, D.D.

COMMITTEE TO PREPARE RESOLUTIONS ON THE DEATH OF SAMUEL D. GROSS, M.D., LL.D., D.C.L., OXON., LL.D., CANTAB.

The President referred to the death of Dr. Gross, and appointed the following committee to prepare resolutions: Drs. T. G. Richardson, of La.; Lewis A. Sayre, of N. Y.; J. H. Packard, of Pa.; F. H. Hamilton, of N. Y.; Moses Gunn, of Chicago; W. T. Briggs, of Tenn., and I. Minis Hays, of Pa.

On motion by Dr. Jenks, of Texas, the President was added to the Committee, and on motion by Dr. Richardson, Dr. Flint was made Chairman of the Committee.

The Secretary read the following telegram, received from Dr. Samuel W. Gross, addressed to the Association: "Your resolutions and extract from the President's Address were received too late. Accept the warm thanks of the family with great tenderness and consideration."

The communication was accepted and ordered entered upon the minutes.

Drs. C. D. Altmann and D. Kellogg, of Iowa, were made invited guests.

The Secretary announced the following

COMMITTEE ON NOMINATIONS:

COMMITTEE ON THE PRESIDENT'S ADDRESS.
N. S. Davis, of Illinois; W. W. Dawson, of Ohio; W. T. Briggs, of Tennessee; T. F. Prewitt, of Missouri; J. L. Cabell, Virginia; H. B. Ransom, and D. W. Stormont.
COMMITTEE ON INTERNATIONAL MEDICAL CONGRESS.

J. S. Billings, D. C.; L. A. Sayre, New York; L. Minis
Hays, Pennsylvania; A. W. Foster, Massachusetts, and
H. F. Campbell, Georgia.

MEDICAL AND SANITARY SERVICE ON TRANSATLANTIC
PASSENGER VESSELS.

Dr. A. N. Bell, of New York, chairman of the commit-
tee appointed last year, reported progress, and read the bill
now before Congress. The report showed that the rate
of mortality for four years ending 1883 was much greater
than for four years ending 1879, and the causes were in-
cluded in two words, negligence and filth.

For instance, of Michigan, proved that the re-
port be accepted and the committee continued, to report
at the next meeting of the Association.

The subject was discussed by Dr. P. D. Keyser, of
Philadelphia, and Dr. J. A. Irwin, of New York, who
pointed out some of the defects of the bill, especially
those which make it inoperative by the fact that the med-
ical officers are not required to report to some independ-
ent body. Further remarks were made by Dr. Gibson,
U.S.N., and Dr. Jones.

The motion was adopted.

Dr. Pratt then offered the following, which was adopted:
Resolved, That the American Medical Association
urge upon Congress, through their respective Committees
on Commerce, the necessity of suitable and efficient legisla-
tion to promote the well-being of immigrants to this
country, and to protect our public health.

ADDRESS OF THE CHAIRMAN OF THE SECTION ON PRACTICE OF MEDICINE, ETC.,

by JOHN V. SHOEMAKER, M.D., of Philadelphia.

Mr. President, and Gentlemen of the American Medi-
cal Association: As Chairman of the Section in Prac-
tical Medicine, etc., it is made imperative upon me, by
our by-laws, to lay before you a resume of the progress
made and the new discoveries announced in these
branches of our science during the past year. The
responsibility of this duty, in view of the numerous in-
vestigations and important discoveries by the members
of the medical profession throughout the civilized world,
and the steadily increasing volume of medical literature,
etc., renders the task more and more difficult with each
succeeding year; for as new theories arise and supplant
older ones, they, in turn, will be superseded by others
yet unconsidered.

Medicine, at the present time, has a tendency to
elevate itself beyond the narrow sphere occupied by it
years ago. Empiricism is no longer recognized. The
ultimate investigation of the cause of disease, and the
remedial measures suited to it, seem the absorbing ob-
ject.

Sceptics hold that with all our efforts no advance has
been made upon the inroads of disease, and that man-
kind is as much subject to its influence as when medicine
blindly groped its way. This allegation I most certainly
deny. No longer are whole continents devastated by
disease; no longer are epidemics the terror of nations,
nor countries made uninhabitable to the human race;
for with an intimate knowledge of disease and its origin,
scientific medicine has adapted measures to its stay, its
relief, and its extermination.

The means for making medicine more thoroughly
understood and serviceable are, without doubt, the gen-
eral distribution of its principles and conditions by the
wide development of medical literature. With the uni-
versal spread of knowledge of disease and its origin,
scientific medicine has adapted measures to its stay, its
relief, and its extermination.

The means for making medicine more thoroughly
understood and serviceable are, without doubt, the gen-
eral distribution of its principles and conditions by the
wide development of medical literature. With the uni-
versal spread of knowledge of disease and its origin,
scientific medicine has adapted measures to its stay, its
relief, and its extermination.

It is the studious investigator, however, who, with un-
mitting zeal and devotion, has disinterestedly employed
his time to the study of health, disease, and its curative
measures, that medicine has to thank for its principal
advancement during the past year. While it is not our
privilege to enumerate or name them here, it becomes
certainly our duty to mention that noble hero, Dr. Thul-
lion, of Paris, who, with the French Cholera Commission,
penetrated into the very pest-houses of Egypt to serve
the cause of medicine, and gave up his life there.

I can say but little of the progress of physiology during
the past year. The observations that have been recently
put forth have not, as yet, stood the test of time.

In the field of pathology and pathological research
the study of the infinitesimal has attracted great atten-
tion. Humoral pathology of old has had its day. Ana-
tomic-pathology now seems fast to lose its hold upon
our workers, in view of the discovery of the constant
appearance of micro-organisms as concomitants of special
types of disease. They have been demonstrated, class-
ified, propagated, and shown to be constant with certain
features of tissue changes. Their causative influence is
as yet a matter of grave doubt, and one that in accord-
ance with close observation will probably not be soon
cleared up.

Of the subjects prominently brought to the attention
of the profession and exciting universal interest, more
than any other is that of the bacillus theory of tuber-
culosis and its contagious character. Only a few years
ago Koch stood almost alone in its advocacy. Now
there are numbers of unbiased observers who confirm
his famous discovery.

But, while the adherents to Koch's theory have in-
creasingly been met with, wonderfully, there are those not
wanting who are open in their criticism, and opposed to the ac-
ceptance of anything like a bacterial origin of tuberculous
or other diseases. Their opposition is not based merely
upon assertions or critical evidence, but the result of
years of observation and experiments conducted here,
and as well as at the very birth-place of the bacillus theory.
Thus it will be seen that this subject is by no means
disposed of yet; and it will undoubtedly form one of the
main and interesting points of our discussions at this
meeting, in which some of our most prominent path-
ologists, practitioners, and teachers have promised to
take part.

The bacterial origin of other diseases has also been
earnestly advocated. Thus, a micro-organism has been
found of pneumonia, of infective pleurisy, of syphilis,
of gonorrhea, of pertussis, of nephritis and purpura, of
impetigo contagiosa, and herpes labialis, in the blood
of patients ill with typhus, in the blood of the spleen of
typhoid fever patients, of leprosy, of scarlet fever, of
syphilis, of erysipelas, of cholera, and of yellow fever.

MEDICINE.

Medicine, in a word, comprises everything relating to
the healing art; necessarily we will have to give it here
a closer meaning in its relation to clinical observation
only.

The knowledge of nervous affections, though it has not
progressed with the giant strides of other branches of
disease, is steadily advancing and emerging from its
mysterious enfoldings. The treatment of the insane has so vastly
improved that it is to be regretted our knowledge of the etiological
factors of psychical disease does not keep pace with it,
and from this cause, no doubt, arises the difficulty experi-
enced by those who have no knowledge alone has medicine risen
from empiricism, until to-day it may be called a scient-
ific system indeed. It is a matter of congratulation
that this great, and the most prominent, Association of
practitioners of medicine of our country has launched a
journal, which has taken the place of the time-worn
"Transactions," in which the valuable investigations of
the members of our Association were quietly buried.
Typhoid fever has arrested the attention of the profession to some extent, with a view of learning the real danger hidden in it, which is now almost universally conceded to be the accompanying hyperpyrexia, giving rise to the tissues. The same hyperpyrexia, as a concomitant of the medical pyretics, is now thought to be the most serviceable, if we can trust to the statistics of recent investigators, as well as to the thorough researches of Sassetzky in the analyses of the excreta.

Of renal diseases, albuminuria has long been the subject of scientific inquiry, being considered more and more of nerve-poisoning. Its close relation to diabetes, with mutual interchange in certain affections, has brought forward the proposition that both albuminuria and glycosuria may be produced by irritation of certain parts of the floor of the fourth ventricle. And the proposition is well established.

The subject of myxodema has received new impetus with our countries abroad.

The disease known as actinomycesis, and described by Ponfick as peculiar to horses and cattle, has been exhibited by Treves in a man, whom he brought before the London Pathological Society.

Trichinosis is with us a very rare disease indeed, in comparison to its frequent occurrence in Continental Europe. In spite of the prohibitive edict against our pork in Germany, it has long been known that actinomycesis prevailed there of late. The mortality from trichinosis in this country, in comparison with Germany, would lead us most certainly to discriminate in favor of our product to that of the foreign.

With reference to small-pox, the questions if the disease be exhausted the material for its propagation, or if the vigorous vaccination insisted upon by the medical profession has successfully stayed its ravages, are points which are not yet settled. Again the subject of a common origin of vaccinia and variola has been brought forward, and Voight states that variola is inoculable into cows, and if used for protective inoculation with man it is effective, and even preferable, to vaccine, provided that the virus be far enough remote from its first source, else variola, with all its characteristics, may be developed.

In regard to scarlatina much interest has been attached to its prevalence among animals—as the horse, cat, and dog. It has been claimed that contagion was carried both from them to man, and vice versa. The pinkeye of horses is said to be in many cases nothing else than equine scarlation, and contagious while this is cited every now and then where the source of the disease unmistakably pointed to the domestic feline or canine pet. The speaker then referred to the occurrence of cholera in Egypt, and of yellow fever in some of our Southern ports. As regards yellow fever, that it is both infectious and contagious can be no longer denied, and if not accompanied by urinary suppression, it is a disease which otherwise shows a fair percentage of recoveries under proper treatment.

THERAPEUTICS.

It may be said of therapeutics, that while in past years they were ignored to a great extent by many physicians and scientists, they have undoubtedly assumed new features entitling them to a prominent position.

Among the permanent remedies which have found approval during the past year, there is probably none of greater interest than what promises to be one of the most powerful and reliable antipyretics, kainin. Although it has as yet found but little practical application in our own country, the reports concerning it from abroad are such as to make it desirable for us to give it a thorough, practical test.

Another very interesting remedial substance which has been presented to the medical profession as experimented with, is the paradelide, a substance isomeric with aldehida. It is asserted by Dr. Langreuter that it possesses powerful hypnotic properties, with no abnormal phenomenon excepting a slight and irregular pulse. It is claimed for it that it produces no cardiac depressant effect, but from its chemical source this seems doubtful.

By far the most useful, as well as the most interesting of the new therapeutic agents, given to us during the past year, is the Abrus precatorius, the jequirity bean of Brazil, in the treatment of pannus and other eye affections. The remarkable virtues of this drug have been due principally to the fact that in it we have pressed into our service the ubiquitous microbe, which is receiving at the present time so much attention.

Yet another matter of interest in therapeutics of the past year was the investigations of DaCosta in regard to the salts of nickel, and especially its bromide, which was found to possess the properties of the bromides generally, but in much smaller doses. It is claimed that it lowers the temperature, does not influence the pulse, nor affect the excretions; that it is a nerve sedative, without exercising a weakening or depressing influence, and of especial value in epilepsy.

The bismuth salicylate is also a new arrival among us, which has been used in the treatment of various forms of diarrhea and typhoid fever.

Nitroglycerine has again come to the surface, and new and striking results, as well as a larger sphere for its action, has been long foreseen by the medical profession, as a result of its physiological action. Its effect in albuminuria has been recently investigated by Bartholow, who states that it reduces the vascular tension more than any other remedy; lessens the work of the heart by removing the inhibition exercised by the pneumogastric nerve; and that by its action he has not alone seen remarkable instances of relief, but even permanent cures.

Recent investigations in the treatment of albuminuria, by Bartholow, also show the great utility of the chloride of gold and sodium in this disease, both in the subacute and chronic form. He states that "the earlier it is given the better, if structural changes are to be prevented or arrested, and its curative action will necessarily depend on the extent of the damage already inflicted on the kidneys."

The vast research in the field for micro-organisms as causative elements of disease, and the discoveries made therein, have given a new impetus to antiseptic treatment in every branch and affection. Antiseptic inhalations for pulmonary disease have proved of value, whereas the general practitioner has been sustained or cured.

A new feature of the greatest importance, which was first agitated by the British Medical Association, and brought before us at our last meeting, is that of collective investigation of disease. The reports already received from our English brethren have demonstrated their value, and prompt us to a similar mode of investigation.

The systematic collection of therapeutic results will alone be invaluable by showing statistically the worth of certain medicinal measures and their comparison in effects with others.

There appears, just at this time, and it is for this reason that I refer to the subject, a desire on the part of physicians and others to do their duty against their fellow-practitioners, settle to their own satisfaction momentous questions in this or any special department which they affect. Such organizations are generally composed of a few medical authors and teachers and some of their friends, who think themselves immeasurably superior to the profession at large, and would create an aristocracy as it were, in one of the most democratic of sciences and professions. Here lurks the danger to medicine as a science.

Medicine, to be beneficial to humanity, must be open to one and all, and if its practitioners are to be excluded from medical societies and their meetings—not from a lack of knowledge and good standing—such societies have outlived their usefulness. Special studies may be made by physicians in certain directions, but the ad-
vantages of their research and study must be verified by their practical demonstration through the general practitioner. Without a thorough knowledge specialization avails little. This powerful organization should represent every branch and specialty of medicine, and its knowledge should be open to all its members. We are all entitled to the benefits derived from associated investigations. The American Medical Association is the representative body of the medical profession of this country, and has been organized and conducted by gentlemen who have grown gray in its service, and whose brows are adorned with chaplets most worthily won, not only at home but abroad.

The address was referred to the Section in Medicine.

Dr. Brodie introduced Drs. Botsford and Steens, delegates from the Canadian Medical Association, and moved that they be made honorary members, and be invited to seats upon the platform. Carried.

The President welcomed the delegates in behalf of the Association.

ADDRESS OF THE CHAIRMAN OF THE SECTION IN OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN,

by Dr. T. A. Reamy, of Cincinnati, O.

Custom, as well as law, prescribed as one of the duties of the chairman of a section to present in his address a digest of the most prominent work which had been made in that special department during the past year. Compliance with the letter of the law was unnecessary, and therefore unprofitable. Medical journals, special and general, exhibited much energy and zeal in collecting and publishing promptly the latest advances, and moreover in placing before each reader editorial criticisms on new discoveries and operations, generally from the pens of those who had superior abilities for such work.

It was therefore deemed appropriate to refer the reader to these more fertile sources of instruction, and in lieu of a report, such as is indicated by the regulations, to give the

NOTES OF 231 CASES OF THE OPERATION FOR LACERATION OF THE CERVIX UTERI WITHOUT A SINGLE DEATH.

In 6 cases, peri- and para-metritis with general peritonitis occurred. In 3 of these 6 cases the symptoms were sufficiently severe to cause material delay in complete recovery. In one of the cases among the three, para- and peri-metritis and general peritonitis were so severe that the patient was confined to her bed for three months, but ultimately made a good recovery. In 170 cases the laceration was bilateral; in 30 cases unilateral. Of the latter, 23 were on the left side, and 15 on the right side. In 16 cases the laceration was stellate. In 5 cases, of the posterior lip only; in 2 of the anterior lip only. In 80 cases the laceration was extensive. In 15 of these it extended to the cervico-vaginal junction on both sides; and in 33 of the cases of bilateral laceration the injury extended to the cervical junction. In 167 cases there was perineal laceration sufficient to leave a deformity. In 15 cases the anal sphincter was damaged; and in 7 cases the recto-vaginal septum was opened. In 50 cases he operated on the perineum after recovery from the cervical operation.

Dr. Reamy did not hesitate to curette the uterus at the time of operating on the cervix, nor to resort to it, if necessary, immediately with perineorrhaphy. He caused a stream of hot water to flow over the parts continuously during the progress of the operation, and never used ligatures. He had not employed ligature or tourniquet for controlling hemorrhage, but allowed free bleeding from the denuded surfaces, because it softened and thus promoted absorption of the hardened tissues, and facilitated puncture with the needle carrying the sutures. To promote this absorption he regarded as an important factor in starting the process of involution.

The usefulness of trachelorrhaphy, if properly done, could not be overestimated.

Hot water had been so efficient in controlling hemorrhage that it had, in some cases, been necessary to withhold it, in order that sufficient bleeding might occur to soften the tissues before the sutures were introduced.

Among THE CAUSES OF LACERATION mention was made of early rupture of membranes and attempts at forcible dilatation, with either the fingers or the improper use of ergot, as far more fruitful sources of the injury than the use of the obstetric forceps.

Many cases occurred inevitably, and he thought the gynecologist should be the obstetrician, and that such protection should be voluntary.

Dr. Reamy then spoke of the influence of injuries inflicted during parturition in producing cancer, and said that cancer of the uterus was a disease of child-bearing women, and that the fretting of exposed tissues was a prolific source of malignant disease. In all cases of spontaneous healing of laceration of the cervix there was more or less of cicatricial tissue in the parts repaired. All cicatrical tissue, even if not producing reflex symptoms, should be removed thoroughly, so as to obtain union by first intention, in which cicatricial tissue has not been found, and thus removed a source of great danger of the development subsequently of serious disease.

Dr. Reamy then spoke of the

INFLUENCE OF THE OPERATION ON STERILITY.

He knew of thirteen cases in which conception occurred after the operation, and in six of these he attended the women in subsequent labors, and laceration did not again occur. He believed that if the operation was properly performed it favored fertility and often cured sterility.

Catgut sutures should not be used. In some cases reflex symptoms remained; in most cases they were benefited or entirely removed.

METHOD OF OPERATING.

1. He uses nothing with which to draw down the uterus except a single vulselsum, seizing one lip at a time.

2. He draws the uterus down as little as possible.

3. He outlines the denudation with a sharp knife, and then cuts the tissues included in the line with sharp scissors, which prevents rolling of the tissues at the borders of the line of denudation.

4. He allows the parts to bleed freely, but according to the condition of the tissues the absorption of which he wishes to promote.

5. He uses nearly a half-circle needle, Chinese silk, and a plain needle-holder.

Silk sutures may be left in for fifteen to thirty days without danger of cutting out. The perineum may be perfectly healed before the cervical sutures are removed.

6. Wash out the cervical canal with a recurrent stream. Wash the vagina with carbonized hot water within an hour after the operation, and then the vagina should not be syringed until the sixth day, when it should be again washed out, and the syringe used daily until the patient was discharged.

The address was referred to the Section on Obstetrics. Drs. J. W. Hanna and E. A. Burke were made invited guests.

A communication from the Section on Ophthalmology and relating to the death of Dr. Gross was received and ordered entered upon the minutes.

Dr. F. Horn, representative of the Virginia State Medical Society, offered a resolution with reference to

A PERMANENT FUND FOR THE FAMILIES OF DECEASED PHYSICIANS.

It was ruled out of order, as it was new business, which could not be entertained on the second day of the meeting.
DR. HENRY SMITH, of Philadelphia, offered the following resolution concerning

EXPERIMENTAL MEDICINE.

Resolved, That a Standing Committee of seven, with power to increase its number as may be deemed necessary, be appointed by the President, to be known as the Committee on Experimental Medicine of the American Medical Association, charged with the duty of opposing, by all legitimate means, any proposed legal interference with the progress of medical science, as unwise and ill-considered legislation.

The resolution was supported by Drs. P. D. Keyser, of Philadelphia, and John C. Dalton, of New York, and was adopted with only one dissenting voice, that of a woman in the gallery.

The President appointed Dr. Horatio C. Wood, Philadelphia, Chairman; Drs. Wm. Pepper, and James Tyson, Pennsylvania; Christopher Judson, Maryland; John C. Dalton and Austin Flint, Jr., New York, and J. S. Billings, U.S.A.

MEDICAL COLLEGE ADVERTISING.

DR. ATWOOD, of St. Louis, offered a memorial from the St. Louis Medical Society, on the above subject, which criticised severely the questionable methods of medical colleges and schools in that direction.

It was referred to the Judicial Council.

DR. BENJAMIN, of New Jersey, offered the following resolution, and supported it with a vigorous speech against medical colleges.

Resolved, That this Association earnestly urges upon all American medical colleges the necessity of elevating the standard of education, at least as far as to require preliminary examination and a three years' course, a registry of attendance, and practical demonstration of diagnostical skill.

The resolution gave rise to discussion, participated in by Dr. Brodie, of Michigan, who was willing to vote for the resolution if the end desired could be accomplished in that way, and Dr. Keller, of Arkansas, who thought that when preceptors furnished the medical schools good material, the schools, in turn, would give the profession educated medical men. A motion was made to lay the resolution upon the table, and amid considerable confusion was put and declared carried.

DR. M. H. HENRY, of New York, said that every time this question had been brought before the Association it had taken such an uninteresting and insignificant form. Dr. Quimby raised the point of order that the negative vote had not been taken when the motion to table was declared carried.

The vote was taken again: ayes, 76; nays, 150.

Dr. Henry then supported the resolution with a vigorous and caustic speech, and did not shrink though met by hisses, to whom he administered scolding reproof. The possession of a medical diploma obtained in this country he regarded as no evidence of qualification to either practise medicine or fill important and responsible medical positions.

Dr. Gibson supported the statement.

After some further random shots and calls of question, question, the resolution was adopted.

The President explained that the decision that the motion to lay upon the table was carried, the negative vote not having been taken, was an oversight, and further added that he was in sympathy with the spirit of the resolution.

DR. PACKARD, of Philadelphia, moved to take from the table certain amendments which had been put there at the meeting at St. Paul, pending the report of the Board of Trustees of the Journal of the American Medical Association, and that they be made the special order immediately after the delivery of the address of the Chairman of the Section in State Medicine on Thursday. Carried.

The Association then adjourned, after the reception of an invitation from Mr. Spencer W. Beard, Commissioner, to visit the place where artificial hatching of the shad was in progress.

THURSDAY, MAY 8TH—THIRD DAY.

The Association was called to order at 10 a.m. by the President, and prayer was offered by Rev. William Paret.

DR. KELLER, of Arkansas, rose to a question of privilege and asked that the Association change the report of the Secretary so that the Nominating Committee would designate a time for the annual meeting, in accordance with amendment to by-laws offered by him and adopted at the annual meeting at Cleveland. Request granted.

The President appointed a committee to nominate TRUSTEES FOR JOURNAL TO FILL VACANCIES caused by those who retire this year. It was composed as follows: Drs. E. D. Ferguson, New York; W. T. Briggs, Tennessee; J. E. Reeves, West Virginia; J. W. Prewitt, Missouri; George Peck, U.S.N.; Thomas Russell, Missouri; D. W. Stormount, Kansas.

REPORT OF COMMITTEE TO MEMORIALIZE CONGRESS CONCERNING A FIREPROOF BUILDING FOR THE ARMY MUSEUM AND LIBRARY.

The bill had been introduced in Congress, but no action had been taken. The House has increased the annual appropriation to ten thousand dollars. Report received—Committee continued: Drs. Austin Flint, T. G. Richardson, H. F. Campbell.

DR. G. M. STERNBERG offered the following resolution, which was adopted:

Resolved, That a committee of five be appointed by the President to petition Congress to make SPECIAL APPROPRIATION FOR PROSECUTION OF SCIENTIFIC RESEARCHES RELATING TO CAUSES AND PREVENTION OF INFECTIOUS DISEASES.

Money to be expended under the direction of the National Board of Health. The following gentlemen constituted the Committee: G. M. Sternberg, A. L. Gibson, I. Minis Hays, J. C. Dalton, and J. E. Reeves.

Dr. Keller offered resolutions relative to the CREMATION OF THE DEAD as a sanitary measure, which were, however, declared to belong to new business, and were referred accordingly.

REPORT OF THE COMMITTEE ON THE INTERNATIONAL MEDICAL CONGRESS.

The Committee unanimously favored carrying out the suggestion of the President, and recommended that a committee of seven be appointed, of which Dr. Austin Flint should be a member, whose duty should be to extend an invitation to the International Medical Congress at Copenhagen, to hold the next meeting in Washington, D. C., in 1887. It was also resolved that the committee shall have power to elect its own officers, and in case the invitation is accepted, to act as an executive committee, to make all necessary and special arrangements for meeting, solicit funds, and draw from the treasury of the Association a sum not exceeding five hundred dollars, to defray preliminary expenses.

Adopted.

J. M. Toner, the Chairman of the Board of Trustees of Journal, reported, giving an account of the FINANCIAL STANDING OF THE JOURNAL, in which was incorporated the report of the editor. It appeared that THE TOTAL INCOME FOR THE JOURNAL FOR THE FIRST YEAR was eighteen thousand five hundred and forty-seven dollar
and fifty cents. Deducing expenditures, there was left a balance in treasury of something over five hundred dollars. It appeared also that

THE EDITOR RESIGNED,

but withdrew his resignation, to be renewed finally and absolutely at end of next year.

The Journal had been conducted with economy, ability, and judgment, and the best interests of the Association been kept steadily in view.

Dr. J. H. Packard presented a minority report, signed by himself, saying that

THE JOURNAL HAD NOT APPROACHED ANYWHERE NEAR WHAT THE STANDARD AND ESTABLISHED ORGAN OF THE ASSOCIATION SHOULD BE,

and recommending that the resignation of the editor be accepted, and that the publication office be transferred to either Washington, Philadelphia, or New York.

It was moved to lay the minority report upon the table. Carried, ayes 191, nays 74. Majority report adopted.

REPORT OF THE COMMITTEE ON NOMINATIONS

was next presented:

President—Henry F. Campbell, Georgia.

Vice-Presidents—J. S. Lynch, Maryland; S. D. Mercer, Nebraska; J. W. Parsons, New Hampshire; H. C. Ghent, Texas; Treasurer—R. J. Dunglison, Pennsylvania.

Librarian—C. H. Kleinschmidt, District of Columbia.

Chairman of Committee of Arrangements—S. D. Logan, New Orleans.

Assistant Secretary—W. H. Watkins, New Orleans.

PLACE AND TIME OF MEETING, NEW ORLEANS—LAST TUESDAY IN APRIL, 1885.

Dr. N. S. Davis made a report for the Committee on Meteorology. The investigations included the reports of the Signal Service Bureau, daily observations on the amount of ozone and freed and albuminous ammonia in the air, and observations on the occurrence of acute diseases. The investigations regarding ozone and organic matter had been carried out systematically in the past year, and the results were published, in part, in the journal. Dr. Davis recommended that the work of the committee be continued.

He also reported that he had received communications from the British Medical Association regarding the subject of

THE COLLECTIVE INVESTIGATION OF DISEASE.

He had received cards and forms to be used, and had distributed a large number of them. The results were such as justified him in recommending that the American Medical Association co-operate with the British Association. It would be necessary to use the same cards. The committee recommended that a sum not exceeding three hundred dollars be appropriated to carry out the collective investigation during the coming year.

REPORT OF JUDICIAL COUNCIL.

In the case of S. S. Good, Somerset County, Penn., it was decided that said society was not entitled to representation for the reason that it had not been recognized by the Medical Society of the State of Pennsylvania.

In the case of Dr. H. G. Sherman, Cuyahoga County, O., the protest was withdrawn, and the applicant permitted to register.

In the case of Dr. W. W. Day, the evidence in favor of reopening it was incompetent.

The address of the Chairman of the Section on Surgery was read by title and referred to the Section. Its subject was: "Effects and Results of Operation for Relief of Gun-shot Wounds of Small Intestines."

The address of the Chairman on State Medicine was, on motion, postponed until Friday.

FRIDAY, MAY 9TH—FOURTH DAY

The meeting was called to order by the President.

Dr. Davison, of N. Y. New York, offered supplementary resolutions concerning experimental medicine, that the Association desires to express its earnest conviction that

EXPERIMENTATION ON ANIMALS

is a most useful source of knowledge in medical science, and can be entrusted only to members of the medical profession, and that the committee be empowered to elect associate members. Adopted unanimously.
Dr. E. Grissom, North Carolina, moved that it be declared, as the opinion of the Association, that all vacancies which hereafter occur in the Board of Trustees for the Journal nominations be made by the Committee on Nominations. Ayes, 31; Nays, 20.

The Committee on Resolutions on the Death of Dr. Gross was continued, with power to report hereafter.

Dr. N. S. Davis, for Committee

ON PRESIDENT'S ADDRESS,

reported that no report on subject of declarations concerning medical ethics would be made, and asked for a committee of five to report at next annual meeting such explanatory declarations as said committee may deem proper. Adopted, and President made member of committee.

Dr. W. W. Allport, of Illinois, was elected Chairman of the Section on Oral and Dental Surgery, and Edward C. Briggs, of Massachusetts, Secretary.

Because gentlemen reported by Committee on Nominations were not in attendance on meeting of Association, Dr. Seth Gordon, of Maine, was added to Committee on Necrology; Dr. Thomas Anticicell, of Washington, was substituted for nominee reported by Committee of Nominations for Committee on State Medicine. Dr. Chancellor resigned as member of Committee on State Medicine.

The Permanent Committee on Invitation to International Medical Congress was as follows: Austin Flint, Jr., J. Minis Hays, L. A. Sayre, C. Johnson, G. J. Engelmann, J. M. Browne, J. S. Billings; H. F. Campbell, President-elect, was added.

Dr. J. H. Packard presented the revised amendment offered at St. Paul, viz., "That membership shall be acquired by any one invited to attend, and that he shall be eligible to delegate, in good standing in the Society from which he is sent, and keeps up his annual dues." Adopted after long discussion.

Dr. Von Klein, of Ohio, proposed an amendment to the Constitution, providing that graduates from medical colleges which do not require literary education as a prerequisite to graduation, shall not be eligible to delegate to the Association, but it shall not apply to the army and navy.

Dr. Keller asked that his resolution concerning Cremation be referred to the Section on State Medicine. Cremation in the near future, in large cities, will be a sanitary necessity.

Dr. Pratt, of Michigan, offered an amendment to the Constitution, to the effect that the Chairmen and Secretaries of Sections hereafter be elected by each section.

Dr. Cochran, of Alabama, offered an amendment that the Nominating Committee shall not nominate from their own number for officers.

Dr. Pratt, of Michigan, offered the earnestly urging Congress to legislate to prevent Immigration of Defective Classes to this Country.

Dr. Deering J. Roberts delivered an address on State Medicine.

He made a brief reference to the progress in State medicine during the past year. He then took up the subject of medical education and its relation to the State, and maintained that legislation did not help medical education. He asserted that in those States which had laws regulating medical education, the profession stood no higher than elsewhere. He cited the views of Dr. Drake and Prof. Hervey, and argued that every man had a right to have what medicine, or doctor, or person he liked. He defended the literary and scientific work of the American physicians. The speaker then urged the necessity of a better sanitary organization.

The contest between the National Board of Health and the Marine Hospital Service was unfortunate for each party, and each was somewhat to blame. He thought the organization of the national board unwieldy, and recommended the establishment of an independent health department.

W. A. H. Coop, of Tennessee, entered his protest against the go-as-you-please style of practising medicine advocated in the address.

Address of the Chairman of the Section on Ophthalmology, Otology, and Laryngology, by Dr. J. J. Chisolm, Chairman, on "Usefulness of Special Knowledge and Desirability of Using Well-defined Special Medical Truths by General Practitioners," was referred to Committee on Publication.

Address of the Chairman of the Section on Diseases of Children, by William Lee, of Baltimore, Md.

Opposed to specialities as they are generally practised, as many of the best and wisest in our profession are, it must be admitted, nevertheless, that the formation of a Section on Children's Diseases by this Association was eminently proper; for not only has our example been followed by the British Medical Association, but in these days, when the question as to division of labor in science of medicine, as well as in other fields of human labor, is engrossing so much attention, physicians must sooner or later be allowed to hold that independent position which it deserves. It is now four years since the establishment of this Section, and we believe the good effects of it are indisputable. Certain affections are met with in children only, and there are others common, it is true, to every period of life, but which are modified in peculiar ways in childhood. The time has come when the contributions to medical literature during the past year have been so numerous and important that I have thought best to confine my report entirely to the Infectious and Contagious Diseases of Children, and in order to give as complete a review as possible, have deemed it wise to go back of the present year, particularly as at the last year's meeting no written report was presented.

Diphtheria.

Dr. Carpenter, on the etiology and treatment of diphtheria, endeavors to show how by analogy diphtheria and potato disease may be allied to each other, and then, after mentioning the influence of sudden rise and fall of temperature, effects of sewers, impure milk, etc., gives facts to prove how the germ upon which he believes diphtheria to depend for its development may be suddenly brought into activity, particularly amongst the poor, who allow their families to remain on washdays in the steamy atmosphere of the rooms in which they not only do their work but likewise sleep.

He sums up this part of his article by classifying the conditions necessary for an outbreak of diphtheria under five heads:

1. The presence of certain forms of excreta.
2. Of an elevated temperature not much below blood heat, but below that requisite for the coagulation of albumen.
3. Of an atmosphere saturated with moisture, and probably also with (4) an excess of carbonic acid, or some other acid in the air by which the growth of the germ is determined, and (5) some other meteorological or electrical manifestation at present entirely unknown.

Dr. Reese has advised for the treatment of diphtheria a solution of bichloride of mercury in the proportion of one grain to four ounces of rain-water. He orders the patient, if old enough, to gargle and rinse the mouth every two hours, and take afterward in-
ternally a teaspoonful; should the disease be very severe it must be done every hour. Within fifteen or twenty-four hours the exudation will disappear, but will return unless the remedy is continued. This treatment must be kept up for a week or longer, the strength of the gargoyle and frequency of use being regulated by the effects produced, namely, nausea, vomiting, or purging. As long as the system is suffering from the poison these symptoms will be absent.

Dr. Selldon uses the cyanuret of mercury, one centigramme to one hundred grammes of water; dose, two teaspoonfuls internally every hour, day and night. Also, when children are old enough, allows them to gargle with a similar solution.

He also treated two hundred cases of angina of the tonsils and faucies with the same solution, and always with good results.

**SCARLET FEVER.**

Mr. R. W. Mullican, in a paper on the "Etiology of Acute Specific Disease," and also Dr. John Meredith, have brought forward some evidence to show that scarlatina may be evolved from diphtheria.

In a very interesting article Dr. Oxley attempts to show that scarlet fever is not a very infectious disease during the first two or three days, and says that this may be easily explained, if we only accept the theory that the fever depends upon specific germs being introduced into the body and bred there; and only becomes infectious after they are reproduced in the host and thrown off, either from the skin, throat, or other secreting surfaces. There are exceptions where the disease, when present even in a very mild form, may prove infectious very early in the illness; but this is probably due to the fact that, owing to the initial symptoms being mild, this disease is only discovered after making considerable progress.

Rheumatic fever he says may come on during the course of scarlet fever as early as the sixth or eighth day, or during convalescence, when we think our patient doing well.

In speaking of the treatment in this complication the doctor strongly interdicts the use of the salicylates, because the skin and kidneys are both desquamating and not in a fit condition to be called upon to do any extra work.

Tonge Smith, from an experience in treating 2,000 cases of scarlet fever, observed within the last three and a half years, has been convinced that the incubation period does not last more than three days.

**CEREBRO-SPINAL FEVER.**

Dr. J. Lewis Smith, in an exhaustive paper on the Etiology, etc., of this disease, reports that, according to Lyden and E. Sander, micrococci seem to be the cause of this disease; but proof is wanting that this germ bears a causative relation to it. The Chairman then gave a synopsis of Dr. Smith's papers published in the *Medical Record*, November and December, 1883.

**TYPHOID AND TYPHUS FEVER.**

Amongst the various forms of typhoid fever which occur in children, it is scarcely necessary to insist upon the importance of diagnosing that transient variety which so frequently escapes observation.

The premonitory symptoms are so vague, and the headache, restlessness at night, constipation, night fever are so ill-defined and so slight that it is no easy matter to discover them. When the affection is once declared, however, it remains for some time, the chief symptom being that the child does not sleep, while the tongue is somewhat red, and the abdomen is slightly swollen.

The spots are often difficult to see on account of the local applications which have been employed, but at a later stage the fever becomes well defined, with morning remissions until the fifteenth day, when the patient begins to convalesce.

Ashby says typhoid fever more often aborts in children than in adults, that is, the disease runs a course of two weeks instead of three or four.

The onset in the majority of cases is very gradual.

**Mortality.**—Barthez and Rilliet, Hillier, Gerhardt, and others, place the death-rate of children from two to twelve years at ten per cent.

**Treatment.**—Little medicine is required, excepting for the purpose of lowering the temperature, unless complications arise.

**MEASLES.**

Dr. Meendidg records three cases of insanity which occurred either during the course of, or in convalescence from measles. The youngest of those affected was aged fifteen, and the oldest aged twenty-six.

Dr. Pelerean calls attention to the influence of malaria during an epidemic of roseola and measles.

In many cases of roseola, which appeared first, the fever would assume a remittent type, either preceding the rash for from two to eight days, or the rash would precede the fever. Then, again, both fever and rash would develop themselves simultaneously. The severe symptoms noticed were headache, heat of skin, furred tongue, and vomiting.

With the exception of quinia, in most cases the treatment was upon a merely expectant plan.

Professor Demme, in a report on an epidemic of measles and its peculiarities, mentions two cases—one a girl suffering from chorea, and another a boy, nine years old, suffering from prurigo—both of whom were freed of their respective diseases upon measles appearing; also that of a child, three years old, who had measles twice in ten weeks.

Dr. Keating gives a very interesting report of a recent epidemic of measles, and it calls especial attention to the following points, viz.: the microscopic examination of the blood and the constant association of micrococci with the general manifestation of malignity (a condition already well known), and the gradual but positive amelioration of all bad symptoms by treatment, which was directed to the micrococci as the *fons et origo* of trouble.

The Chairman also referred to cases and facts reported by Dr. Reid, in the Philadelphia Times, and Dr. Maclean, in the London Lancet.

**VARIOLA AND VACCINIA.**

Dr. Roger McNiels says that so far statistics go to show that under ten years the initial rash is extremely rare, and that comparatively few vaccinated children under that age are affected with small-pox.

Dr. Stewart refers to a case reported by Dr. Richard S. Stewart, in which a child was born with pustules over its body, and died on the fourth or fifth day of small-pox, the mother having been attacked two weeks before parturition with this disease.

Dr. J. E. Atkinson saw a woman, under the care of another physician, who immediately preceding her confinement was living in a room with a case of confirm small-pox. She was successfully vaccinated, and six days and nineteen hours after gave birth to an apparently healthy child. Three days after her labor her child was attacked with the disease, but of the discrete variety, and recovered without secondary fever or subsequent pustulation.

Dr. Page, on treatment, says: "I have been so much pleased with the apparently abortive action of acetanracemos on variola in the case of a negro man who had just moved to Baltimore," and on four of his children, all of whom had the disease coming out in rich profusion—that I made a note of the fact.

"Under the use of this drug the cases progressed to the popular stage, and in the case of the father putulis-
tion took place only on the face; but in the cases of the children the secondary fever and purpura did not take place. The actea racemosa was administered in the form of the tincture with simple elixir. I have had no opportunity to try the medicine except in that one family."

Rosenthal, acting on an article by Boyer, has employed salicylic acid in many cases with good results.

He confirms the statement that salicylic acid in small-pox reduces the temperature, is sedative, and modifies the eruption.

MUMPS.

MM. Cabitun and Chartrain, at a recent meeting of the Biological Society of Paris, gave an account of the investigations, in which they have for some time been engaged, on the presence of minute organisms in the blood of persons suffering from mumps. These are multiple by cultivation of Liebig's broth, and are found to consist of minute bacterium, but chiefly of microcoeci, all in a state of motion. These minute organisms, they consider, corrobore the clinical observations which tend to place mumps among the infectious diseases.

The absolute proof that this disease is due to these minute bodies by reproducing it by inoculation of the cultivated forms has not been attained by the experiments made to that end.

Attention is called to the fact of the great frequency of meningitis as a metastasis and to the combination of this with orchitis. This combination, the writer believes, has not been recorded.

INFANTILE DIARRHEA.

Ballard, on the "Etiology and Pathology of Summer Diarrhoea in Children," says: "The disease cannot be considered a simple dyspepsia, but rather an affection of the system at large, which can, in less than twenty hours, produce lesions of considerable greatness."

The influence of elevated temperature is undeniable efficient in producing this disease, and that influence remains even after the months of autumn.

Speaking in general terms, it may be said that in great cities the maximum of heat in July will have a direct bearing upon the maximum of mortality from infantile diarrhoea. The putrid exhalations of sewers have been accused by certain bronchialists as the cause of this trouble, and admitting that there may be some room for such a charge, it is to be observed that Nottingham, which possesses no sewers, has a high death-rate from infantile diarrhoea.

ERYSIPelas.

Dr. Lawrence draws our attention to the importance of bearing in mind the frequency of infantile erysipelas. It may originate from either puerperal fever or some epidemical influences prevailing at the time of birth. Again, erysipelas may occur as an idiosyncratic expression of a blood infection. More frequently, however, it has a traumatic origin, the starting-point being the umbilicus, but any abraded cutaneous surface renders the disease possible, as eczema, intertrigo, impetigo, cicatrizating vaccinia, pustules, etc.

W. A. Macleod reports a case to substantiate the infectious nature of erysipelas.

WHOOPING-COUGH.

Prof. Rossbach says, in regard to the essential nature of pertussis, that bronchial catarrh must not be regarded as a mere complication, but as immediately connected with the very existence of whooping-cough. The disease has its seat especially in the larger bronchi.

He further says that the attacks of coughing are not alone produced by the mucus but also by the irritation of the violent draughts of air accompanying forced respiration. One of the essential etiological conditions is the existence of a reflex neurosis, and he thinks it probable that in whooping-cough the coughing centre in the medulla oblongata is in a state of abnormal excitability owing to the presence of some specific virus. The results of treatment, he considers, support these views.

M. Gueneau de Mussey has constantly found enlargement of the mediastinal glands and compression of the recurrent laryngeal nerves in children that have died of whooping-cough. He considers whooping-cough to be an eruptive fever in which the eruption is internal.

Prof. O. Heubner has tested the comparative action of five of the most common remedies in this disease, viz.: bromide potassium, quinine, hydrate chloral, salicylic acid, and belladonna. In none of the twenty-three cases in which the bromide was given was the duration of the disease lessened. Chloral was given in divided doses in two, and an enema in eight cases. In two the duration of the disease was lessened, and the intensity and length of the paroxysms in six cases. Salicylic acid was given by inhalation in sixteen, and as salicylate of soda internally in one case. In two the duration of the disease, and in ten the length and severity of the paroxysms were lessened. Belladonna was given in eight cases. In three the termination of the disease, and in one case the intensity of the paroxysms were lessened.

Thus salicylic acid and chloral tend to relieve the paroxysms; belladonna and quinine to shorten the disease.

Dr. John Dewar calls attention to ergot as being the safest and best remedy.

He says ergot seldom fails to cure whooping-cough in from one to three weeks, the cases longer in getting better being those complicated with bronchitis or with troublesome bronchial catarrh. The dose used was 4 to 15 minims of the fluid extract every three or four hours to a child of three months and upward.

While being able to endorse Dr. Dewar's statements in regard to ergot in the treatment of whooping-cough, it must be borne in mind that there often arise stages of the disease in which other remedies must be used at the same time.

The address was referred to the Committee on Publication.

ADDRESS OF THE CHAIRMAN OF THE SECTION ON ORAL AND DENTAL SURGERY.

Dr. T. W. Brophy, of Illinois, touched upon the advances and improvements made during the past year, chiefly upon the advisability of establishing professorships in this department in medical schools.

Referred to the Committee on Publication.

Dr. Toner, of Washington, D. C., offered his "Report on Necrology."

A resolution was presented from the Section on State Medicine, recommending that the several societies represented in the Association use their influence with their State representatives to secure laws requiring persons entering the profession to pass a satisfactory preliminary examination.

Carried.

Dr. C. Seiler, of Philadelphia, offered an amendment to the Constitution, dividing the Section on Ophthalmology and Laryngology.

REPORT OF TREASURER.

The Treasurer made his annual report, showing that there was a balance of $2,212 in the treasury.

Dr. William Brodie moved that the payment of $5 dues annually be made essential to permanent membership. Carried.

---

1 London Practitioner, vol. viii., page 920.
The report of the Librarian was read and referred to the Committee on Publication.

Dr. W. Beach, of Ohio, presented a resolution asking Congress to complete its legislation upon pleuro-pneumonia. Carried.

THE PRESIDENT ELECT, DR. CAMPBELL, was escorted to the platform and introduced by the President. Dr. Von Klein offered a resolution to the effect that hereafter

THE ASSOCIATION DISPENSE WITH PRAYER at its opening session. Tabled unanimously. Dr. Q. Ott, of Pennsylvania, offered a resolution urging Congress to take proper care of the

UNITED STATES MEDICAL MUSEUM AND LIBRARY, and to secure an early completion of the “Index Catalogue.” Carried.

Dr. LASURE, offered a resolution, that the Association protest against any of its members endorsing, by signing certificates, mineral waters and pharmaceutical preparations. Carried.

A communication was read from the West Philadelphia Medical Society, with regard to the Code of Ethics, expressing the Society’s adherence to it, and

URGING MEMBERS TO SEND PUPILS ONLY TO THOSE COLLEGES WHERE THE ETHICS OF THE CODE WERE MAINTAINED, which was referred to the Judicial Council.

Dr. F. E. Daniel, of Texas, offered a resolution urging that caustic potash, concentrated lye, and similar commercial preparations be rated as poisons. Carried.

A resolution from the St. Louis Medical Society was read upon the subject of

ADVERTISING THROUGH THE AGENCY OF MEDICAL COLLEGES and college announcements and circulars. Referred to the Judicial Council.

Dr. Kwott, of Texas, offered a resolution of respect to the memory of Dr. J. Marion Sims. This was, through mistake, not acted upon.

Dr. A. L. Gihon moved that a committee of five be appointed to consider the subject of erecting a

MONUMENT TO DR. BENJAMIN RUSH. Carried.

The following were next appointed as

GENERAL IMPRESSIONS OF THE MEETING—WHAT IS THOUGHT OF THE ETHICAL QUESTION—NOT WORTH HAVING A QUARREL OVER—THE JOURNAL OF THE ASSOCIATION OF SOME GOOD.

(By Telegraph to The Medical Record.)

To the Editor of The Medical Record.

SIR: The meeting of the American Medical Association has been a successful one, and enjoyable to those attending. There were no serious dissensions in the meetings, although small clouds occasionally arose. The President’s address was well received; but excited less comment than might have been expected. It seems to be a general impression, especially among Western delegates, that the ethical question is, after all, only a technical and minor one not worth having a quarrel over. There is not any real difference of opinion among the mass of intelligent physicians upon the subject of consultations. An old member of twenty years’ standing, who had signed the “Pledge,” told me that he recently consulted with a homoeopath, and with benefit to the patient. The great thing, he said, which keeps homoeopaths alive out of the antagonism and opposition it meets from us. We ought not to antagonize, but to absorb it.

The President in his address deprecated the criticisms upon medical colleges and medical men which have been so uniformly made of late. The subject of medical education came up, however, and it was shown that the members were not in sympathy with the President upon the subject. A decision was made that the subject be laid upon the table; but when it was shown that this decision had been made, without having the President’s calling for the nays, on a full vote, the subject was kept before the Association, but not very much was done except to pass a resolution.

It required some courage for Dr. Packard to organize an opposition to the journal management. He secured a hearing and a vote, however, despite some parliamentary opposition. I hear but one opinion as to the character and management of the journal but it is unpleasant to antagonize a gentleman so respected as its editor, and besides, it is said that if not a model journal it has done some good, and is better than the “Transactions.”

I have seen a large number of Western men here; New York was also well represented, even better than Philadelphia, while Boston men were very few.

The work on the Sections was very uneven. There was a considerable change from the printed programmes, many of the best papers announced not being read, owing to the absence of the authors.

The Section on Practice was unusually good, the sections on Surgery and Obstetrics were above the average. The other Section meetings were, on the whole, poor. There were about 1,250 members registered.

* * *

THE ASSOCIATION OF AMERICAN MEDICAL EDITORS.

The annual meeting was held in Washington, May 5th. The annual address was delivered by Leartus Connor, M.D., Editor of the Detroit Medical News. It was entitled ‘The American Medical Journal of the Future, as Indicated by the History of American Medical Journals in the Past.’ Remarks were made by Dr. Shoemaker. The President received a vote of thanks.

Dr. N. S. Davis, of Chicago, opened the discussion on “How Far Can Legislation Aid in Elevating the Standard of Medical Education?” He was participated in by Dr. Henry O. Marcy, Dr. William Brodie, and Dr. A. N. Bell. Dr. J. M. Tonner invited the Association when it adjourned to meet at his house to discuss special subjects and things. Accepted. Officers for the ensuing year: President, Dr. H. O. Marcy, of Massachusetts; Vice-President, Dr. J. V. Shoemaker, of Pennsylvania; Secretary, Dr. Thomas F. Wood, of North Carolina. The meeting was well attended and was a success.
SECTION ON PRACTICE OF MEDICINE.

(by telegraph.)

TUESDAY, MAY 6TH—FIRST DAY.

The Section was called to order by the Chairman, Dr. John V. Shoemaker, of Philadelphia.

The first paper was read by Dr. Edward G. Jane-way, of New York.

SIMULATION OF PATHOGENOMONIC SIGNS AND SYMPTOMS.

In opening his paper, the doctor referred to the many mistakes which he had seen resulting from placing too much reliance on so-called pathognomonic signs. It is not many years since choked disk was considered pathognomonic of cerebral tumor. Now this sign is limited to an indication of increased intracranial pressure.

Tremor is often relied on as indicating multiple sclerosis. It is necessary first to exclude metallic poisoning and effects of alcohol before admitting that tremor is a sign of multiple sclerosis.

The speaker then referred to indications from coma. Some signs that change in temperature indicate whether the coma is due to anemia or to hemorrhage, but some claim an elevated temperature and others a normal temperature for the former. When the temperature is lower at the onset, and afterward becomes elevated, it has, in the author's experience, been a very positive sign of hemorrhage into the brain. Some would rely on presence of albumin and casts, but these are often present with hemorrhage.

In regard to pulmonary signs, the doctor had seen marked vocal fremitus in pleural effusion. He had also noted bronchial breathing in pleural effusion which could not be distinguished from the bronchial breathing of pneumonia.

The author also called attention to a condition of normal pectoriography.

In regard to double arterial murmur, supposed to be diagnostic between aneurism and a tumor pressing on the artery, the author had found this same sign in several cases of tumors pressing on the aorta. He then referred to the dyspnea of Bright's disease, which is liable, from the cyanotic and great difficulty of breathing, to be referred to cardiac disease.

The presence of albumen in the urine was then spoken of, the author having found this condition in cases in which no other indication of renal disease was present. He reported a case in which albumen was sometimes present and sometimes absent. Hyaline casts are very probably be occasionally present without indicating disease of the kidney.

Dr. Donaldson, of Baltimore, thought that there were points of distinction between the bronchial breathing of pleurisy and that of consolidation. The bronchial breathing of pleurisy is more pronounced in inspiration than in expiration. There may be serious disease of the heart without murmur. This is not only the case in large insufficiency of the mitral valve.

Dr. Lynch, of Baltimore, described a case of pleurisy in which bronchophony was very marked and in which he attributed the sign to the fact that the lung was bound down by adhesions to the diaphragm.

Dr. Austin Flint, Sr., of New York, read a paper entitled

THE CLINICAL STUDY OF THE HEART-SOUNDS.

He referred to a paper on the same subject which he had read before this Association twenty-six years ago. He described five distinct sounds, two accompanying the diastole and three accompanying the systole of the heart, the diastolic sounds being the aortic and the pulmonic, the systolic sounds being the mitral, tricuspid, and the sound of impulse produced by the impulse of the heart against the thoracic walls. The doctor then described the position of these murmurs, illustrating his remarks by means of a diagram.

He next took up each sound separately and described the significance of various alterations in their force and character.

Dr. F. C. Shattuck, of Boston, referred to the fact that it was supposed that the sound made by the contraction of the cardiac muscle was the formation of the first sound of the heart. He also referred to the fact that in some cases of mitral stenosis in which there was no murmur there was reduplication of the second sound.

Dr. James C. Wilson, of Philadelphia, had been teaching this subject for some time in a way very similar to that described by Professor Flint. He had divided the sounds of the heart into four.

Dr. McSherry, of Maryland, referred to the pulse in disease and compared our present knowledge of diseases of the heart with that of thirty years ago.

At this point, a telegram announcing the death of Dr. S. D. Gross, was received. A motion to adjourn the Section was made but was not adopted.

Dr. John S. Lynch, of Maryland, referred to the alteration of the second sound, especially the aortic sound in Bright's disease and in other degenerative diseases of the kidneys. He maintained that the booming character of the first sound of the heart was due to the vibration of the aortic walls.

Dr. Garland, of Massachusetts: In referring to cardiac murmurs, Dr. Flint said that they were either coincident with or replaced the heart-sound. It is at times difficult to distinguish between the two, and yet it is often important to do so in regard to prognosis and treatment. He spoke of the importance in studying these cases of eliminating the respiratory movements, relating cases in which murmurs disappeared when the patient held his breath for a moment. Another deceptive murmur is one which is heard to the right or left of the sternum, up and down its border, and which is systolic in time. The peculiarity of this murmur is that it disappears on deep inspiration.

Dr. Donaldson thought it seemed questionable whether the impulse of the heart can produce a sound. He thought that it had been proven by experiment that the first sound of the heart was produced by the closure of the mitral and tricuspid valves. In regard to the so-called presystolic murmurs, it had been asserted with some plausibility that these were really not presystolic, but systolic.

Dr. Flint, in closing the discussion, stated that many of the points suggested had been in regard to the mechanism of the production of the heart-sounds and in regard to murmurs. He had intentionally not included these in his paper, and therefore waived any discussion of these points.

Dr. Louis A. Duhring read a paper entitled

DERMATITIS HERPETIFORMIS,

in which he described a rare disease, of which he had seen fifteen cases. The affection shows itself in a variety of ways, by patches of an urticarial or erythematous character, by herpetiform vesicles, by blebs, by pustules, and by papules. All these lesions tend to take a herpetiform type. These different conditions may be present at one time, or they may succeed each other. The disease is remarkable for the multifority of its lesions. The author then went on to describe the different varieties of dermatitis herpetiformis—papular, vesicular, bullous, pustular, and multiform. These different eruptions are accompanied with violent itching and burning. It was considered to be a neurotic affection. The treatment is very unsatisfactory, and the disease may continue for years.

The paper concluded with the following résumé:

1. The existence is shown of a distinct, clearly defined, rare, serious, herpetic disease of the skin, manifesting itself usually in successive outbreaks, characterized by more or less systemic disturbance, a variety of pri-
mery and secondary lesions, and severe itching and burning.

2. The disease is capable of appearing in many forms, having a tendency to run into one another irregularly, the principal varieties being the erythematous, vesicular, bullous, and pustular, which may occur singly or togethet in various combinations.

3. The disease is protean in character and is remarkable for its multiformity.

4. The pustular variety is the same manifestation as that described by Hebra under the name "impetigo herpetiformis."

5. The term "dermatitis herpetiformis" is sufficiently comprehensive and appropriate to include all varieties of the disease.

6. It may occur in both sexes, and in women independent of pregnancy.

7. It usually pursues a chronic, variable course, lasting years, and is very rebellious to treatment.

The next paper read was by Dr. James T. Whittaker, of Cincinnati.

**THE ETIOLOGY OF PERICARDITIS.**

This disease frequently escapes recognition because its local symptoms are, as a rule, not marked. In order to show the frequency of its occurrence, some statistics were introduced showing that pericarditis occurred once in every 7300 cases of all diseases. In 6 out of 32 cases it followed rheumatism, while in 26 cases it was dependent on other causes. Males are more liable to be attacked than are females. It is also a disease of youth and adult life. It is more frequent in those who work hard.

Two forms are described, consecutive or mechanical and infectious or mycotic. Any disease produced by micro-organisms may have pleurisy associated with it. The micro-organisms attack especially the serous membranes. This, perhaps, explains why pericarditis is so frequent in rheumatism.

Dr. Burris, of Florida, agreed with the author in that impurities of the blood caused pericarditis or affections simulating it.

Dr. Prentiss, of Washington, being prevented by sickness from being present, his paper was read by title and referred to the Committee on Publication.

Dr. Black, of Illinois, read a paper entitled

**THE PRODUCTION OF POISONS BY MICRO-ORGANISMS.**

in which, after an extended review of the subject, he summed up in the following conclusions:

- **First.**—All cognizable forms of life are dependent upon the products of molecular change in matter for their continued existence.

- **Second.**—Every cognizable form of life, capable of independent existence, must have the power of digestion, for the preparation of food-material for the nutrition of its material structure.

- **Third.**—Each living cell must appropriate to its nutrition food-material prepared by a digestive body of its own, or by the appropriation of material prepared for it vicariously by some allied living cell.

- **Fourth.**—Every living cell must support its life and material structure by a continued inhibition and remolecularization of matter within itself, except during special provisions of rest, as in the seed, egg, etc.

- **Fifth.**—Every living cell must, as a result of the remolecularization of matter within itself, throw off waste products of two classes, a respiratory waste, rich in oxygen, and an urinary waste, poor in oxygen. All waste products are poisonous to the lives from which they emanate.

- **Sixth.**—The natural organic poisons are uniformly waste products of the organisms in which they are formed.

- **Seventh.**—Pathogenic micro-organisms by their remolecularization of matter, form poisons analogous to the vegetable alkaloids which are the active agents in the production of disease.

**Eighth.**—While I should not class the digestive ferments as diastase, etc., as organic poisons, they may act as irritants when applied to another form of life than that which produced them.

**Ninth.**—Normal tissues resist the invasion of the micro-organisms by throwing out matter calculated to destroy them or dissipate or nullify their action, aroused thereto by the presence of an irritant agent given out by the micro-organisms.

Dr. Traill Green, of Easton, Pa., read a paper entitled

**THE NEW OFFICIAL CHLORATE,**

in which he insisted on the great superiority of the chlorate of sodium over the chlorate of potassium. The former salt is much more soluble than the latter, being dissolved by one and one-tenth its weight of water. It is applicable to all the conditions in which the potassium salt is of service. The doctor went on to describe some of the special diseases in which he had employed it.

Dr. Caldwell, of Baltimore, had also used chlorate of sodium with satisfaction.
cult to decide whether or not such causes exist. The author then went on to speak of the analogies between hysteria and epilepsy. Both these affections represent conditions of central nervous irritation, without pain. In hysteria, the ganglionic gray matter is especially vulnerable, while epilepsy is probably dependent upon an unstable condition of one or more areas of the gray matter within the brain.

The most prominent factors in bringing about this condition are, heredity, nervous exhaustion, shock or sudden powerful impressions, sunstroke, purely psychical shocks, disturbed nutrition of the brain from instability of the circulation, as in heart disease and anaemia, possibly minute emboli, and peripheral irritation especially of the gastro-intestinal canal.

A consideration of the different cases usually classed under the head of epilepsy shows that these cases are not afflicted with a single, definite disease, and that they exhibit in common merely impaired nutrition and irritability of the gray matter. The effects of habit have a decided influence in keeping up attacks of epilepsy.

The degree of instability varies in these cases. Some are only affected by a very powerful influence, while in others the slightest cause is sufficient to induce the symptoms of excitement. The provoking causes occur in all cases of epilepsy, yet if they are carefully sought for they will frequently be found. Among the most common provoking causes are indiscretions in diet and improper food. These may act by exciting local irritation, or possibly may induce a condition of toxemia, from the entrance into the blood of imperfectly elaborated materials or of certain injurious products. A close analogy was traced between many of these cases of epilepsy and certain cases of vertigo in lithemic patients.

Where the trouble with the nervous system has resulted from insolation, exposure to the rays of the sun or intense light may induce the attacks. When there is an associated cardiac lesion or cerebral excitation of the circulation may bring on the seizures.

Dr. Pepper took exception to the statement frequently made that epileptics are in full health. He usually found derangement of some important function.

The principles of treatment follow from the consideration of the points referred to. No one plan of treatment applies to all cases. The primary and provoking causes should be removed when possible. Asthenia, neurasthenia, and morbid susceptibility are to be relieved. Intestinal irritation is to be cured. In such cases nitrate of silver is often of great benefit. Over-exertion, especially in cardiac cases is to be avoided. Counter-irritation with the actual cautery is of decided value, especially in those cases in which intracranial irritation is suspected. Where circumscribed lesion of the cranial bones is supposed to exist, trepanning may often be used with advantage. Irritation of the genital organs is to be relieved. The attacks should be arrested, for if they are allowed to continue they increase the liability to subsequent attacks. Particular attention is to be paid to the diet, which is to be suited to the needs of each particular case.

Among the drugs mentioned as of service are the bromides, Belladonna, assafetida, chloral by enema, iron, and tonics. The bromides are of decided value, but in their use caution is to be exercised, for they frequently fail, are often abused, and may even be injurious.

Dr. Austin Flint, Sr. of New York, maintained the doctrine that many of the cases of epilepsy are dependent upon a toxic agent of some kind produced somewhere within the body. He presented the following points in favor of this view.

1. The absence of any generally received pathological doctrine.

2. There is close analogy between the phenomena of epilepsy and other diseases known to be produced by toxic causes.

3. Certain facts pertaining to the clinical history are more readily accounted for on the view of a toxic agent.

4. Facts pertaining to the therapeutic results of epilepsy favor the doctrine of toxic causation.

Dr. Eugene Grissom, of North Carolina, referred, in speaking of the treatment of functional epilepsy, to the importance of careful attention to diet, regulation of exercise, and avoidance of fatigue. The remedies to be used depend in part upon the provoking cause.

Dr. James F. Hubbard, of Indiana, stated that he thought that if all cases in which an exciting cause was discovered were put to one side, epilepsy was never cured. Certain drugs, notably the bromides are useful in ameliorating the condition. A toxic causation has been suggested, but even if this be so there must be some underlying convulsive diathesis.

Dr. J. J. Caldwell, of Baltimore, thought that Dr. Flint could not consider those cases which lasted for years as due to a toxic cause, for toxic causes must have an ending sometime. He referred to cases in which epileptic seizures had disappeared upon the occurrence of attacks of gout.

Dr. James Tyson, of Philadelphia, referred to the value of the use of a seconal by the name of the nek in certain cases. He has found that in one case fifteen years had elapsed since the last seizure.

Dr. Bartlett, of New York, had also seen good results from the seconal, and reported cases which had remained well for four years. He deprecated the injudicious use of the bromides.

Dr. Fattor, of Massachusetts, spoke in reference to the use of the bromides in cases of epilepsy according to the condition associated with epilepsy. In pellagrric cases he employs bromide of potassium; in anemic cases, bromide of sodium or iron, and in cases associated with gout, the bromide of lithium. In other cases associated with gastric or intestinal irritation, he has used wine of ipecac in five-dose doses every three hours, with advantage. He has cured cases by means of purely psychical influences, as for instance, the use of the spirometer.

Dr. Peffer, in concluding the subject, stated that he was glad to be supported by the distinguished gentleman from New York as regarded the toxic character of certain cases, but did not think that this would explain all the cases of epilepsy.

Dr. James C. Wilson, of Philadelphia, read a paper on the diagnosis of tumors of the anterior mediastinum, in which he considered the various forms of tumors which invaded the mediastinum, and, taking up each separately, gave the points of importance in its differential diagnosis.

Dr. William H. Welch, of New York, read the next paper, the pathology of myocarditis.

He referred to the want of attention which had been paid to affections of the muscular wall of the heart, and of those diseases of the cardiac muscle which had been considered, the most important had been the least studied. This is myocarditis. He then described the different forms of this condition, and gave the microscopic appearances. He directed attention to the importance of partial obstruction of the coronary arteries in the causation of this condition of the heart-muscle, which is not strictly the result of inflammation, but of atrophy and degeneration, due to insufficient blood-supply. A number of cases were related in support and in explanation of his views.

Dr. Austin Flint, Sr. of New York, had met with cases in which the most careful examination revealed no physical signs of disease. In one case he had judged the examination a number of times with negative results. The patient died suddenly, and at the autopsy obstruc-
tion of the coronary arteries was the only condition found to explain the sudden death.

Dr. McSherry, of Baltimore, reported a case supporting the views of Dr. Welch.

Dr. Donaldson referred to the great advantage which would follow some method of diagnosing this condition, and asking if some information could not be obtained by means of the sphygmograph or an examination of the other arteries.

Dr. Janeway, of New York, thought that the most that could be done in the way of diagnosis was to discover weak heart. If there was endo-arteritis in other arteries, it would favor the idea that the same condition was present in the coronary arteries.

Gaspard Griswold, M.D., M.R.C.S., New York City, read a paper entitled

IRREGULAR APOPLEXIC ATTACKS FROM OTHER CAUSES THAN HEMORRHAGE OR EMBOLISM.

In introducing the subject the doctor stated that in his paper he should apply the term apoplexy to denote the sudden onset of a set of symptoms of which unconsciousness, hemiplegia, and convulsions were the most marked. In using this term apoplexy he did not refer to any special cause for these symptoms. Apoplexy may be due, as all know, to cerebral hemorrhage, embolism, and thrombosis. In such cases pathology has enabled us to differentiate with considerable certainty between these different affections, but in the case of functional interference with the circulation of the brain, post-mortem studies cannot afford much assistance. It is therefore necessary, in considering affections due to this cause, to depend on experiment and clinical observations. Heart-failure, or vaso-motor nerve disturbance, will cause anaemia of the brain, and this may show itself by coma and convulsions. In such cases the symptoms often resemble those due to hemorrhage, thrombosis, or embolism, and this is not at all surprising, since in these latter cases the symptoms are to a large extent due to disturbance of the cerebral circulation. It is often difficult, from the symptoms alone, to differentiate between apoplexy due to an organic cause, and apoplexy due to functional derangement of the circulation. There is, however, a great difference in the persistence of the symptoms. In the early stages a mistake is almost unavoidable, and often the recovery of the patient is the only thing which enables a correct diagnosis to be made. Four cases were then related in which an erroneous diagnosis had been made either by the doctor or by the other physician. In all these cases there was a distinct attack of apoplexy, and in all the patients recovered.

Dr. Janeway, of New York, reported two cases similar to those related by Dr. Griswold, in which the apoplectic attacks resulted from the excessive smoking. In both recovery followed the giving up of this habit.

Dr. Austin Flint, Jr., of New York, thought that we were coming to attach more importance to alterations of the circulation of the brain, and he reported some physiological experiments in animals, which showed that when the blood-supply of the brain was diminished convulsions frequently ensued.

The paper of Dr. W. L. Schenck, of Kansas, was read by title. The following is an abstract:

OCCULT CAUSES OF DISEASE.

He gives a review of the history of germs in disease, and says that if bacteria be the cause of disease, we should expect these diseases produced by germs to be universally present, because the germs are found at all times. The ground where yellow fever patients have been buried has been found a year later to be teeming with the bacteria, and he asks, if the cause was present why was not the disease?

He next referred to the fact that any effects attributed to germicides administered internally could not be due to their action, for it would take eight pounds of car-

tholic acid to make a mixture in the body of five per cent. strength, and of the mercuric bichloride twenty-three grains would be required to put the fluids in the body in a condition to be injurious to these germs. The success of germicides in the treatment of disease must be attributed to some other action.

The best success has been attained by surgeons and obstetricians who have not used antiseptics with any germicide intent. If germs are not even occult causes of disease, it is well to recognize the fact that microscopists may seek more efficient fields of labor than classifying micrococci, and therapeutists larger game than microzomes.

THURSDAY, MAY 8TH—THIRD DAY.

Dr. A. Flint, Jr., read a paper on

THE DIETETIC TREATMENT OF DIABETES MELLITIS.

In the first place the writer referred to the fact that in a small proportion of cases sugar in the urine is found in apparently healthy individuals. Sugar may be present in urine of normal or low specific gravity and quantity. He believed that the liver was a sugar-producing organ. The sugar thus washed out by the blood as rapidly as it formed. He believed that if the case were taken in time, and the patient would submit to certain measures, it is possible to effect a cure, or at least remove the symptom, with the exception, perhaps, of the occasional appearance of sugar in the urine. He divided treatment into dietetic, general, and medicinal. Dietetic consists in avoidance of all substances containing sugar or starch; after sugar has been absent for two months the patient may gradually return to the use of ordinary diet. During this time the urine should be examined every five or six days, alcohol must be avoided, regular muscular exercise should be insisted upon. The doctor has found the solution of arsene of bromine of service, but the most reliance must be placed on diet. If these points are attended to, the prognosis in recent cases in adults is favorable. The most unfavorable cases are those in which disease appears before puberty.

PHTHISIS, ITS SUCCESSFUL TREATMENT, was read by title by J. P. Miller, M.D., of Buckhannan, W. Va. After briefly referring to the bacillus tuberculosis and the theory of Koch, and stating his belief that his theory would not aid in preventing or curing phthisis, the author went on to describe the climate and position of the region in which his practice lay. Buckhannan is situated 1,600 feet above tide-water, and the climate is remarkable for its humidity and the sudden and great changes of temperature which occur. These are especially marked during the winter and spring. A fall or rise of from 35° to 50° F. in twenty-four hours is not uncommon, and a rise of 64° in nine hours has been noted. Owing to these climatic conditions diseases of the respiratory organs are of frequent occurrence, and on account of the success which he had obtained in the treatment of phthisis the speaker placed himself in opposition to the common belief that phthisis was an incurable affection.

The treatment was next spoken of. In the treatment of high temperature of phthisis Florida, the salicylate of sodium, in doses of grs. xvi. to grs. xxiv., had been found to be the most servicable antipyretic. When diarrhea was present, from one-fourth to one-half a grain of morphia was added to each dose of the salicylate. The antipyretic should be given during the remission of the fever and shortly before it relapses.

To relieve nausea and vomiting the following prescriptions are used according to circumstances:

1. Acidi carbonici .................. 3 j.
   Tinct. iodii ................. 3 j.

2. Sig.—Three drops in water, before food, three times a day; or,
THE MEDICAL RECORD.

May 10, 1884.

THE MEDICAL RECORD.

B. Strychnise......................... gr. j.
Acid. nitrimuriat. dil. ........... 5 ss.
M. Sig.—From four to eight drops, given as in the previous case; or,

Fowler's solution in doses of not more than three drops when have the desired effect. If there is diarrhoea, from the second six drops of distilled water should be added to each dose. Mustard plasters over the stomach may also be used. Digestion may be assisted by the use of dilute hydrochloric acid before meals, followed with pepсин after meals.

The speaker then referred to the good effects which he had obtained from the use of yerba santa in causing the softening, absorption and extraction of serous or tuberculous matters. For these purposes it has no equal in the Materia Medica. In the early stages of phthisis where there is gastro-hepatic and duodenal catarrh, it answers every purpose. In cases of pyrexial phthisis, where various antipyretics had been tried without effect, the continuous use of yerba santa has reduced the temperature from 105° to 99° in the course of a week. Yerba santa has the effect of inducing sweating, and in this way serves to reduce fever. In cases where the temperature is normal or below normal, picrotoxin, or strychnine and atropia, may be used if the night-sweats are copious.

Counter-irritation is of the greatest importance, and even when the patient is weak and anemic good results will often follow the use of a blister. In incipient cases iodide of iron and cod-liver oil are of service in causing the disappearance of the exudation. This may be administered with Trommer's extract of malt.

When there is a catarrhal process extending to the alveoli from the bronchi, the iodide and carbonate of ammonia have a beneficial influence. They may be given as follows:

B. Ammon. iodidi..................... 3 j.
Ammon. carbonis.................. 3 jss.
Syrup. toli,...................... À, 5 j.
Aque, àâ........... 5 j, ij.
M. Sig.—A teaspoonful every four hours.

The doctor then referred to the fact that in addition to administering drugs it was important to protect the patient from outside influences which would tend to depress the mind, such as the anxiety of friends and the superstitions of neighbors.

In concluding the author said: "Time and other observers may reverse the verdict, but I cannot help feeling that this case has been successfully guarded against, conjoined with the remedies and methods herein recommended, boldly, skillfully, and persistently applied, will prove the means of curing a high per cent. of that form of thoracic degeneration which has hitherto baffled our science and is a standing opprobrium to our profession."

The following papers were then read by title: "The Milk Treatment of Disease," by Dr. James Tyson, of Philadelphia, and "Bright's Disease of Malarial Origin," by Dr. J. E. Atkinson, of Maryland.

Dr. Henry F. Formad, of Philadelphia, then read a paper on TUBERCULOSIS.

He first considered the question of the contagiousness of tuberculosis, and after presenting an extended review of the evidence of pro and con on this point, concluded that tuberculosis was not a contagious disorder, and those cases in which such appeared to be the case could be explained on other grounds. In regard to Koch's theory and the bacillus tuberculosis, he admitted that Koch's observations were correct, but he thought that his conclusions were not warranted. A great deal more work is necessary before this question can be considered settled. It has been shown by competent men that the bacillus is not invariably present in tuberculosis matters, and further, that it is not usually present in the beginning of the disease, but is found firstly in the disintegrating products of tubercle. The bacillus is often found in only very minute quantities. It is not proved that the disease produced in animals is identical with that which exists in man. Some of the products produced in these experiments may not be tubercular but simply be mistaken for tubercles. Tubercles may be produced by other things than the bacillus tuberculosis, and conditions presenting the anatomical and other characteristics of tuberculosis may be present without the bacillus being discovered. He thought that the parasitic etiology of tuberculosis was not proved and that the adoption of this view was liable to do more harm than good.

Dr. Austin Flint, Sr., thought that it was pretty positively proven that the bacillus tuberculosis held a causative relation to tuberculosis, and it is opposed to all analogy to suppose that tuberculosis could be produced by any other cause. Other causes may, and undoubtedly do co-operate with it, but the presence of this specific agent is essential to the production of the disease.

Dr. William H. Welch said that Koch had claimed that all the essential conditions had been complied with in his experiments. He thought that tuberculosis was caused by the bacillus, and in all probability by that alone. When the difficulty in which the discovery of detection of the bacillus is considered, it is not to be wondered at that at times it might escape notice. Of late Koch has found it in all tuberculous lesions examined. The essential question is, whether tuberculosis can be produced by nothing else than the bacillus. The weight of evidence is in favor of the view that phthisis can be produced by the inoculation of no other than tuberculosis matters.

Dr. George M. Sternberg, U.S.A., had performed some experiments, but they had not satisfied him in regard to this matter. He thought that the view that the bacillus might act as a local irritant was worthy of consideration. He referred to the possibility that in the experiments of Formad the animals in whom tuberculosis had followed the inoculation with other substances than bacilli, might have the condition developed in consequence of improper surroundings. He was not satisfied that Koch's culture experiments on the surface of sterilized substances were to be relied upon.

Dr. R. P. Fitz, of Massachusetts, thought that pneumonia and other conditions found in the lung might be due to the bacillus.

Dr. Tyson thought that the evidence in favor of Koch's view was very strong, but before deciding in the matter it would be necessary to wait until it was decided whether the views of Koch as formed were the correct ones.

Dr. Janeway stated his belief in the contagiousness of phthisis, and cited cases supporting his opinion.

Dr. Chas. Dennison, of Colorado, exhibited a chart showing the geographical distribution of phthisis and pneumonia in warm and moist climates, while in cold and dry atmospheres these diseases were more rare.

Dr. Belfield could not accept the view that phthisis was due to bacteria.

Dr. Shakespeare, of Philadelphia, thought that it had been proved that nothing but the tubercle bacillus could produce tuberculosis. Dr. Formad had in another paper attributed the liability of certain animals to tuberculosis to certain peculiarities of the lymph-spaces, but he had in the same paper stated that in such animals the perivascular lymph-spaces were not altered. It is well known that these are not all of the same character, and in these spaces that tubercle first makes its appearance.

Dr. G. C. Smythe, of Indiana, thought that tuberculosis might belong to the local infectious affections, such as syphilis and leprosy.

Dr. H. C. Ernst, of Massachusetts, agreed with the views expressed by Drs. Welch and Fitz, and added some remarks in regard to the different methods of staining the tubercle bacillus. In these investigations nothing less
than an immersion lens and a substrate illuminating apparatus was to be relied upon.

Dr. W. M. PEPER's belief in the contagiousness of phthisis remains unchanged.

Dr. G. TRAILL GREEN did not accept the view that consumption was due to a parasite, and he referred to cases in which consumption had developed in perfectly healthy individuals in consequence of working in a grindstone manufactory.

Dr. FORMAD, in concluding, said that he would not occupy time, except to say that the animals on which he had experimented had been kept under the best hygienic surroundings.

Also the following:

The writer considered that we had a specific for diphtheria in the corrosive chloride of mercury. In order to obtain this effect it is necessary to give the remedy in large doses in the early stage of the disease. The dose for a child three years of age is from one-twentieth to one-twelfth of a grain; for an adult, one-twelfth to one-eighth of a grain every three hours. In mild cases it should be continued for three days, and in malignant cases for two or three days longer. It is best given in solution, and a good vehicle for administering it is elixir of pepton or elixir of pepton and bismuth.

If this treatment be instituted at the commencement of the disease no tonics or sustaining treatment will be required; but if the disease has lasted for some time, brandy and iron are to be also employed.

In cases where the membranous layer invades the larynx, there may be danger of suffocation, but this is due more to spasm than to the presence of the membrane. For this condition the author considers the chloride of gold to be a specific. It has no taste, produces no nausea, and acts like a charm. The dose for a child two years of age is from one-fiftieth to one-thirtieth of a grain, every hour until relieved. It should be given dissolved in distilled water, and should not be brought in contact with a metallic vessel, for it is a mere simple cure. The author regards this as a specific. In diphtheritic croup the bichloride of mercury should be associated with it.

MUSCULAR HYPERTRROPHY OF THE STOMACH, by DR. ALEXANDER MARCY, JR., of Riverton, N. J.

He described the post-mortem appearances of a case of this affection coming under his own observation. The stomach was greatly reduced in size. It was 12.5 c.m. in length, 3.75 c.m. in diameter at the pyloric extremity, and 3.2 c.m. at the cardiac end. The capacity of the organ was not more than 60 c.c. In the centre of the organ was a constriction through which the little finger could scarcely be passed. This was due to a fibrous band, on each side of which there was a stellate cicatrix. The wall of the stomach was much increased in thickness. This thickening had also involved the duodenum and extended to the common bile duct, so that it was completely occluded. The microscopic examination showed the thickening to be principally due to a great overgrowth of the muscular tissue, which was about three times its normal thickness. Newly formed connective tissue was also found. In the submucous layer there was found, in addition to some increase in the connective tissue, an overgrowth of smooth muscular fibre.

The writer considers this a rare condition, and one not usually referred to by authors. In conclusion, he referred to the fact that there were no symptoms peculiar to this disease, and that the treatment could be only palliative.

TREATMENT OF TYPHOID FEVER, by S. K. JACKSON, M.D., of Norfolk, Va.

The author stated that he desired to call attention to a method of treating typhoid fever which was based on a pathological condition, the existence of which had long been recognized, but which had never been taken as an indication for treatment. For thirty-five years he had been treating all cases of typhoid fever in this manner, and had never had any reason to be dissatisfied with it.

In the author's estimation the most prominent and important pathological condition in typhoid fever was the nitrogenous waste, the deficiency of all the nitrogen excretion. The non-excretion was no proof of the retention of these products in the system. If such were the case, symptoms of uremic poisoning should be developed. These products were not excreted because they were not formed. This non-formation was attributed to two factors. The first was that, owing to the deficiency of the gastric secretions, nitrogenous acids could not be digested. The second and most probable cause is the consumption of nitrogen by the parasitic organism which is the acknowledged etiological factor in the production of enteric fever. This parasite is a nitrogen feeder. It thrives on nitrogenous matter. This is further shown by the ammoniacal exhalations of the typhoid-fever patient. These exhalations result from the decomposition of nitrogenous products by the parasite. This waste cannot be replaced with nitrogenous food, for the stomach is unable to digest such articles. The author therefore attempts to overcome the difficulty by the free administration of ammonia, giving it even to saturation. The great variety in the therapeutical action of the different salts of ammonia makes it possible to use one or other of its combinations at any stage of the disease.

Ten or twelve grains of the nitrate of ammonia, administered every two hours, is sufficient to reduce the temperature to 102°, and to keep it there. After the disease is further advanced, the acetate of ammonia may be used. If there is diarrhoea, acetate of lead and opium should also be employed. When these simple measures could not show themselves, the carbonate of ammonia with chlorate of potash was recommended. If coma appears, five grains of chloride of ammonia exerts a remarkable effect, and in no case had coma occurred where this plan of treatment had not been adopted at the outset. The delirium is relieved by the use of ammonia, provided it be given in sufficient amount.

The use of the chloride of ammonia to relieve the coma of typhoid fever was suggested by the theory that this condition is due to thickening of the envelope of the blood corpuscles to such an extent that the brain was not sufficiently well nourished. The object of using the ammonia salt was to dissolve this thickened envelope. Although this might not be the manner in which the chloride of ammonia exerted its effect, still its action was decidedly beneficial.

The doctor had abandoned the use of quinine. He did not consider it a proper germicide for typhoid fever. It was well suited to destroy the malaria parasite, because this organism was a carbon feeder. Quinine is rich in carbon, and was given in accordance with the law that no organism can destroy its own excreta, in the results of its own life processes. If, as in typhoid fever, ammonia is the excreted product, then ammonia is the best germicide.

The doctor went on to state that if the disease were recognized by the third day, it might subside at the end of the first septicemia; if the disease is not recognized until the fourth or fifth day, it will not be destroyed but will subside on the second septicemia. If the treatment has not been begun before the beginning of the second septicemia, the fever will not yield before the twenty-first
day, but it is almost absolutely certain that it will yield then.

In regard to diet, the doctor insisted on an exclusively milk diet. No starchy matters should be allowed, and animal broths should not be given until the latter stages of the disease, or until there are evidences of the secretion of the gastric digestive fluids.

Dr. Henry O. Marcy, of Boston, presented a Review of the Germ Theory of Disease, in which he related a number of original experiments which had been undertaken to prove the truth or falseness of certain theories in reference to the action of the liquids. It has been asserted that unless a well-washed bacillus be placed in a sterilized nutrient fluid, it was impossible to determine what was due to the germ and what to the liquid ambient matter. In about fifty experiments Dr. Marcy employed different kinds of nutrient matters, including blood-serum, the white of fresh eggs, and fresh milk, and tried to determine their germinal qualities. These experiments failed to show that these materials possessed any germinal powers, and that they simply served as nutrient fluids. Previous experiments made by filtering the fluids from anthrax and injecting them into healthy animals had proven the same thing.

In order to establish the relation between these germs and disease, it is necessary to separate the organisms from other matters and prove that they produce the particular disease. The best method to free the germs from surrounding matters was considered to be the culture test. If, as had been shown by the author, the liquid ambient matter did not reproduce, in two or three generations, the germs would be practically freed from the original matter which surrounded them. Taking a geometric series of one-hundredth, the third bulb would contain only one-millionth of the original matter.

The methods employed by the doctor had been various, sometimes the mechanical occlusion of blood-vessels, sometimes deoxidization of the blood, chemical changes, and so on. Particular attention was directed to the condition of the individual attacked, the most favorable conditions being those of debility. Especial reference was made to tubercle, diphtheria, and erysipelas. In reference to the last a series of original experiments were reported, including a number of culture tests, inoculation experiments, and so on.

The Section then adjourned.

SECTION ON SURGERY AND ANATOMY.

(By telegraph.)

TUESDAY, MAY 6TH—FIRST DAY.

First day's session held at the National Rifle's Armory, 920 G Street, Tuesday, May 6, 1884, at 2:30 P.M., Dr. C. S. Parke, Chicago, Chairman, presiding.

After a few remarks upon the subject by the Chair, the Section by vote decided that the time allowed each member in which to discuss any paper read should be limited to five minutes.

Dr. Frederick S. Dennis, of New York, read the first paper of the session, on Treatment of Compound Fractures, and laid down as the three short but great rules of successful treatment: 1. Immediate fixation; 2. Absolute cleanliness; 3. Free drainage when necessary. These carefully maintained were, he thought, better than the unnecessary minutes of Listerism, and in good hands sure to produce the best results.

He claimed that many fractures with simple laceration of soft parts were called compound when they really did not belong to that class, and it should always be remembered that entrance of air to the seat of bone injury is a necessary condition in a compound fracture. Dr. Den

nis reported 128 cases of compound fractures recovering sufficiently from shock to allow his treating them in two of the large hospitals of New York, dividing them into regional injuries, the classes being as follows: 23 of the cranium, 17 recovering; 3 cases of the thigh, no deaths; 48 of the leg, all recovering, in 3 cases the protruding bone requiring excision by the saw; 10 of the arm, all recovering; 13 of the forearm, all recovering, save one; 50 miscellaneous, all recovering; 95 of all kinds occurring consecutively without death.

Professor S. D. Gross was announced as having died three hours before, and on vote the Chairman appointed Drs. Kellar, of Arkansas, Sayre and Flint, of New York, and Kinloch, of South Carolina, as a committee to prepare resolutions of respect and sorrow, suitable to the occasion, and present them to the Section at the next day's session.

By unanimous vote the Section then adjourned as a mark of respect to the memory of the lamented surgical teacher.

WEDNESDAY, MAY 7TH—SECOND DAY.

Dr. T. R. Varick, of New Jersey, read a paper on Railroad Injuries of the Extremities of the Human Body, with Observations on the Site of Amputation and Subsequent Treatment of the Stump.

in the course of which he said that traumatism is not confined to the immediate part struck, but usually extends far beyond, and great care should be taken to thoroughly examine the parts for bruised subcutaneous tissue, at a considerable distance from the apparent seat of injury. Two causes for this were,

First.—Muscles ruptured by their own contractile efforts, as the victim in immovably fixed at one point, struggles to free himself.

Second.—The pulsation of the tissues, producing a scattering of the liquids contained therein.

He believed that the common cause of death in railroad injuries, when shock occurs, is due to the forcing back of the venous blood to the right side of the heart, producing paralysis of that organ. The after-dressing of the stump by almost hot water, the keeping open the flaps after amputation as long as any oozing is perceptible, free drainage by tubes, irrigation by means of a thymol solution, and an outer dressing of ointment, was the general form of practice adopted by the writer, and he felt that his statistics would bear criticism, or comparison with those of other surgeons. The doctor concluded by reporting twenty-one major amputations without a death, all but two being compound comminuted fractures produced by railroad injury.

Dr. Quimby, of New Jersey, made a few remarks in relation to the concussion of the internal organs from railroad injury.

THE DEATH OF PROFESSOR GROSS.

Prof. Lewis A. Sayre, of New York, then read the report of the special committee appointed to draw up resolutions in relation to the death of Professor S. D. Gross, as follows:

Resolved, That the members of the Surgical Section of the American Medical Association have received with a sense of profound regret the intelligence of the death of Prof. Samuel D. Gross, of the State of Pennsylvania, one of the greatest ornaments of this Association, and one of the most distinguished teachers and authors in the medical profession of the United States.

Resolved, That the memory of the deceased deserves to be cherished with love and veneration by the members of the medical profession as that of a man profoundly versed in medical science, and worthy to be ranked with the greatest and ablest of our age and country.
He had mastered the vast learning of his profession, and the natural kindness of his great and generous heart was such, that throughout his long and successful career as a practitioner he was continually experiencing the most intense satisfaction and pleasure in relieving by his science the suffering of humanity.

Resolved, That these resolutions be entered upon the journal of the proceedings of this Section, and that the chairman transmit a copy to the family of the deceased.

Dr. J. Kellar, Chairman.
Dr. Austin Flint, Jr.
Dr. Lewis A. Sayre.
Dr. R. A. Kinloch.

The report was adopted by the Section and the committee discharged with thanks.

Dr. J. W. S. Goulkey, of New York, by special vote of the Section, presented a specimen of pieces of a

CALCULUS FRACTURED SPONTANEOUSLY IN THE BLADDER

of a patient, and evacuated per viam naturalem, and explained at some length what he thought might be the cause of the so-called spontaneous fracture of stone in the bladder, namely, molecular action.

Dr. Lewis A. Sayre, of New York, thought that a calculus could not fracture spontaneously, and then asked the doctor some questions in relation to the fracture.

Dr. Ford Thompson, of Washington, who attended the patient from whom the calculus came, announced that he had some doubt of this being a case of spontaneous fracture.

Dr. J. C. Hutchinson, of Brooklyn, also reported a case of what he believed to be undoubtedly a spontaneous fracture of a mulberry calculus.

Dr. Frewitt, of St. Louis, did not believe in the possibility of fractures of stones he had seen.

Dr. Pollock, of Pennsylvania, reported a case which might have been one of fracture.

Dr. Dawson, of Ohio, thought spontaneous fracture could not occur.

Dr. Goulkey then replied to the criticism offered by some of the members.

Dr. C. A. Wheaton, of Minnesota, read a paper on

AMPUTATION AT THE HIP-JOINT,

with a review of the various methods of controlling hemorrhage, in the course of which he gave a history of the different important devices for preventing bleeding from the iliac during and after the amputation. He did not like digital pressure as sometimes employed, and thought that the abdominal tourniquet was too apt to make pressure on the important organs, nerves, etc., of the parts. Lever instruments were spoken of, and reference made to peritonitis being induced by the rectal lever. The instrument known as Trendelenburg’s trocar was noticed and its use explained. Jordan’s amputation was fully explained—it being a modification of Dr. Abernethy’s method. Lloyd’s mode of using an India-rubber glove for stop pulsation in the femoral, and in branches of the iliac, was carefully explained. He thought very highly of this method, as it was applicable both to amputation at the joint and excision of the head of the femur, and he had used it himself successfully in two cases within the past year, availing himself additionally of the means of safety given by Esmarch’s bandage. He believes that Lloyd’s method will prove a great boon to the surgeon, giving him more ease and boldness, as well as being the means of saving many lives.

Dr. Varick, of New Jersey, made a few remarks upon the paper just read, and exhibited a Trendelenburg’s rod or trocar, which he had had made from a description of the instrument which he had read in foreign journals, and which he believed to be the first one made in this country. He had used the instrument successfully in one case, modifying in a slight degree the method of using it recommended by the inventor.

Dr. Byrd, of Illinois, has used Lloyd’s bandage as described, but uses a larger tube or elastic, and is very decidedly in favor of its use, fully agreeing with Dr. Wheaton in the great benefit to be derived from this method.

Dr. Murdock, of Pennsylvania, discussed hip-joint operations, referring to Shipman’s mode of operating.

Dr. Dawson, of Ohio, in a case of the kind used an assistant’s hand in controlling hemorrhage, and thinks that in future operations he would be made free from much of the risk of bleeding heretofore incurred.

Dr. McGraw, of Michigan, gave his experience in hip-joint amputations, giving a case where he had used the rectal lever with success. In his last three cases of this operation, two had made a good recovery.

Dr. McLean, of Michigan, uses the abdominal tourniquet in his amputations at this joint, and always succeeds in controlling the hemorrhage during the operation.

Dr. Roberts, of Pennsylvania, made a few remarks concerning the date of using different means of preventing bleeding during this amputation.

Dr. Wheaton, in closing the discussion, gave his reasons not using some of the means suggested by other members.

Dr. William A. Byrd, of Illinois, read a paper on

AN EARTHLY CALCULUS IN THE SUBSTANCE OF THE LIVER,

in the course of which he gave a full history of this very unique case. The patient was a male, aged about thirty years, who had been ill four months, apparently from malarial fever. Dr. Byrd opened the painful point over the liver, supposing it a simple abscess of the liver. In the course of his probing it one day, he discovered the presence of a hard substance, and extracted a calculus weighing 115 grains. The reader did not wish to state positively what the origin of the stone was, and desired to know, but no member could give information on the subject.

Dr. W. Senn, of Wisconsin, read a paper entitled

ON BRANCHIAL CYSTS OF THE NECK,

and, after giving a list of the different forms of cysts of the region named, discussed the etiology and pathology of the branchial cysts. He gave the views of the origin of these structures held by the leading pathologists of Europe, and clearly defined his own thoughts on the subject. He believed they usually only contain the products of degenerated epithelial cells, unlike the mucous and dermoid cysts. The treatment of these cysts by excision is really the only sure method, but is sometimes not possible, and in such instances the thick creamy fluid usually found within is to be drawn off, and an attempt made to set up an adhesive inflammation of the walls by means of the injection of irritating solutions, which often require repeating. The German surgeons do not seem to expect much favorable result from injections.

Dr. Hyde, of New York, made a few remarks highly complimentary to the research of the writer of the paper.

Dr. Byrd, of Illinois, thinks highly of electrolysis in treating these cystic growths.

Dr. Parks, of Missouri, said that Dr. Senn’s views upon the origin of these cysts, although somewhat new to him, were undoubtedly correct.

Dr. Senn, in closing, said that he did not think electrolysis offered any hope in obliterating these cysts, and believed there was nothing equal to the radical operation of excision.

Several papers were read by title and referred to the Committee on Publication.
THURSDAY, MAY 5TH—THIRD DAY.

Dr. Charles A. Dalles, of Pennsylvania, read a paper on
THE TREATMENT OF HYDROPHOBIA, HISTORICALLY AND
PRACTICALLY CONSIDERED,
in the course of which he cited Aristotle, Pliny, De-
mostrius, Dioscorides, Galen, and other ancients upon
the subject. He showed that Celsus was well acquainted
with the disease, and that some points of his treatment
were not unlike those of the present day. The doctor
enumerated various curious medicines used and recom-
ended by the ancients, giving the period when the so-
called "mad stone" first came into use.
His time having expired, the reader was obliged to omit
the latter part of the paper.
Dr. C. D. Parkes, of Chicago, read an epitome of his
address as Chairman of Section on Surgery, etc, his pa-
er being based upon nearly one hundred experiments
upon abdominal cavities of animals, the injuries being
caused by gunshot. He thought the first thing sur-
geons should attend to in gunshot injuries of the abdom-
al cavity was hemorrage, as clots so seldom form in
unopened abdomen after such traumatism. The next
thing is the course of the bullet and the damage done
by it. He spoke of the very uncertain track taken by a
missile, illustrating this point by relating several exper-
iments, and warned his hearers against deciding upon its
course simply because the points of entrance and exit
are plainly to be seen. He illustrated by diagrams the
peculiar amount of damage done sometimes by a single
bullet, one of them showing fourteen inches of intestine
perforated in ten places by a twenty-two calibre ball.
The treatment he recommended was to cleanse the
intestines or omentum, if extruded, with warm water, and
return to the abdominal cavity as carefully as possible;
extract the foreign body, if it can be done, bringing
glasses of cut peritoneum together and stitching them,
and finally using continued suture to close outer wound.
If resection of bowel must be performed, every endeavor
should be made to save the mesenteric portion. His
diagrams showed in a very plain manner the condition
of the bowel after resection. He uses interrupted suture
of No. 2 carbonized silk after resection, and explained
at length his manner of introducing the suture, which
was Lamber's suture, somewhat different from that
commonly employed. He found in all his cases that extrava-
sation of blood occurred. He laid down the rule that if no
hemorrhage or sign of injury occurred, the division of
the bowel occurs after perforating gunshot wounds, the
points of entrance and exit will always heal quickly. He
claims that in the present condition of operative surgery,
many cases of severe gunshot injury of the abdomen
should and will recover under proper treatment.
Dr. Quick, of New Jersey, asked the reader some ques-
tions concerning sutures of the bowels, thinking that
a case of his own might have recovered if Dr. Parkes'
method had been adopted.
Dr. Lane, of Buffalo, mentioned some experiments of
his own in abdominal resection. He believed that, should
the cavity of the abdomen be more often opened after
injury, more lives might be saved.
Dr. Dunlap, of Ohio, related his treatment of a case of
severe intestinal traumatism, and criticised some state-
ments made by Dr. Parkes.
Dr. Thompson, of Washington, spoke of the German
mode of suturing the bowel, they using a double row of
stitches.
Dr. Connors, of Ohio, spoke of the difference between
operating in these cases in hospital service and in private
practice.
Dr. Byrd, of Illinois, reported a successful case in
which he amputated a portion of a Schaepelatized
intestine and omentum, and gave his method of operating.
Dr. Murphy, of Minnesota, moved a special vote of
thanks to Dr. Parkes for his able and instructive paper,
which was unanimously carried.
Dr. T. F. Prewitt, of Missouri, read a paper on a case of
CHRONIC SEROUS SYNOVITIS OF THE KNEE WITH ENOR-
MOUS COMMUNICATING POPLITEAL BURSA EXTENDING TO
TENDO ACHILLES.
After reporting the case he made some practical re-
marks concerning cysts in this region. In such cases
he recommends treatment by aspiration, counter-irritation
by tincture of iodine, etc., compression and fixation
of limb. He has no good opinion of the use of setons
in this trouble, believing they are liable to excite too
much inflammation.
Dr. Lee, of Pennsylvania, spoke upon some points
of diagnosis in such cases.
Dr. E. H. Bradford, of Massachusetts, made a few
remarks upon
TREATMENT OF OBSTINATE CASES OF CLUB-FOOT,
showing plaster casts of results of his special mode of
TREATMENT in this affection. He employs and recom-
mends his special apparatus in very obstinate cases,
after tenotomy has been performed; his instrument, con-
sisting of steel plate, with three points of pressure
applied, one over ses calcs, one over head of astragalus,
and one against metacarpal bones, is used, and he has
obtained excellent results even in cases of extreme
distortion.
The apparatus was exhibited and was examined with
close attention by the members present.
Dr. Prewitt, of Missouri, asked some questions con-
cerning the length of each patient's sitting, and was
answered by Dr. Bradford that he usually applied the
instrument ten minutes at one time.
Dr. Quimby, of New Jersey, thought that most bad
cases of club-foot had distortion of bony tissues, and in
such instances this apparatus could not bring the foot
into proper shape without fracture.
Dr. Gill, of Ohio, had found that perseverance in
the use of pressure by adhesive strips, etc., would often
bring about good results without tenotomy.
Dr. Lee, of Philadelphia, believed that deformity was
not usually bony, but confined to muscular and ligament-
ous tissues.
All the members present manifested their belief in
the practical value of the apparatus shown.
Dr. Geo. L. Porter, of Connecticut, read a paper on
ENTRANCE OF AIR INTO THE VEINS A SECONDARY CAUSE
OF DEATH,
and graphically described the condition and symptoms
of a patient under such a complication. He said
that although it probably had often occurred in former
days, the condition was not accurately determined until 1818,
and gave several post-mortems where air in veins had
existed before death.
The Section then adjourned.

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

(By telegraph.)

TUESDAY, JUNE 6TH—FIRST DAY.

Dr. T. A. Reamy, of Cincinnati, Chairman; Dr. J. T.
Jelkes, of Hot Springs, Ark., Secretary.
The first paper was read by Dr. R. S. Sutton, en-
titled
DESPERATE SURGERY AMONG WOMEN,
the proper field for it, who should and who should not
attempt it. Dr. Sutton dwelt upon the great responsi-
bility which devolves upon those who attempt abdominal
surgery, and the need there was of careful training and
natural skill for those undertaking it.
Surgical operations for cancer of the uterus, by Dr. W. H. Byford, of Chicago, was read by title.

Dr. Jos. Tabor Johnson, of Washington, D. C., read a paper on the effects of Trachellorrhaphy, showing the advantages and disadvantages of the operation.

Wednesday, June 7th—Second Day.

Dr. Throplilus Parvin, of Philadelphia, read a paper entitled Puerperal Septicemia, in which he urged the necessity of cleanliness and judicial antisepsis as a preventive of the puerperal fevers. Dr. A. Reeves Jackson, of Illinois, read a paper entitled a contribution to the relations of ovulation and menstruation.

Dr. W. H. Taylor, of Ohio, read a paper entitled the management of protracted labor. It was a paper of much physiological and pathological interest.

Dr. J. Herbert Claiborne, of Virginia, read a paper "On the Use of Chloroform in Labor."

Thursday, June 8th—Third Day.

The first paper was by Dr. I. E. Taylor, of New York, and was entitled, on the management and rectification in difficult cases of occipito-posterior presentations.

The writer reviewed Naegle's views on the presentation of the child's head. He also gave the opinions of several early writers as to the frequency of occipito-posterior presentation and their methods of rotation. This change is brought about, he said, naturally by a rotating action of the uterus. How this took place has never been satisfactorily explained. When artificial aid is required, the hands or the lever must be used. The temporary use of the forceps may be of value. The histories of several cases were given.

Dr. Busky then read a paper written by the late Dr. Samuel D. Gross, entitled causes and prevention of laceration of the female sexual organs.

The author apologized for attempting to discuss a subject belonging more to a special branch of medicine and surgery. He had, however, practised obstetrics specially during the early part of his life, and had translated and studied obstetrical works. Dr. Gross said that gynecologists were very ready to invent operations for lacerated parts, but rarely sought any way to prevent these accidents. Dr. Emmet had said that nearly every primipara suffered some laceration of the cervix. If this was so, then God ought to have made a gynecologist as a supplement to his creation of woman. Dr. Gross discussed the subject of the causes of lacerations. He spoke in the severest terms against the too frequent and maladroit use of the forceps. He urged very strongly the employment of venesection in order to relax the parts.

Dr. Robert Battey, of Georgia: Mr. Chairman, I would like to take a moment to put myself on record in confirmation, in part, of the views expressed by our late venerable and lamented ex-vice-president. Although a very much younger man than Dr. Gross, the summing up of my obstetrical experience has been—to put it in a few words, as I look back over it—in not a single instance have I reason to regret the use of my lancer in obstetrical practice. In many instances which I can now recollect, I believe that positive good would have grown out of the more frequent use of it. I use it still when I have occasion to do obstetrical work.

Dr. H. F. Campbell, of Georgia: I am glad of the opportunity to discuss this paper. The principles enunciated will, perhaps, not meet with the commendation of many of us, no matter how much we venerate the illustrious man who honored this Section with his last production. I am glad that I entertain views so entirely consonant with his. I am glad, too, that the gentleman who has just spoken, and who is from the same State as myself, agrees to a great extent, in the few remarks he made, with myself.

Blood-letting in labor, especially under certain circumstances, has, in my opinion, been most unjustly laid aside. Let us look back and see what has been given us in the place of blood-letting. Chloroform, chloral, baryte of potassium, and a variety of other remedies. The cause of convulsions is variously estimated. One will say that the cause is uterine, another will say uterine. Now let us look at the matter naturally and logically. If anemia of the brain is a cause of puerperal convulsions, why give those very remedies that produce exacerbation of the brain? In that case why give the chloral, why the oxide of potassium, or any other remedy that exasperates the brain? On the other hand, as to uterine, why does uterine collect in the blood? Because of the congestion of the kidneys. If congested kidneys arrest the flow of urine and retain it in the blood, which results in convulsions, exanguinate the kidneys, bring the kidneys down to a healthy point, eliminate the urine, that the blood may be free from it.

I have made some experiments in regard to the matter of bleeding producing convulsions. At one time it was claimed that convulsions arose from an irritation of the brain, now it is claimed that they result from anemia of the brain. I took two birds and cut all the tissue that were in front of the cervical portion of the breast. The birds bled, fell, and died without a kick. If anemia of the brain could produce convulsions, certainly they must have resulted in this case. The birds were ordinary farmyard fowls. Dr. Harvey, of Indiana: Mr. Chairman, I would like to say a few words in regard to the paper of Dr. Gross. While no one expects me to respect the name of the author of that paper, I take it now that the subject-matter is to be treated as freely as though the author was here among us, and especially do I deem it right and proper that we should discuss his paper when our doctrines and teachings have been given to us this afternoon.

It is a matter of necessity, it seems to me, that the proceedings should lead to an expression upon the other side of the proposition, because I know that such an expression and feeling exist. We are certainly not going to turn back in this stage of the world and begin again to bleed our patients, while I admit the necessity for the use of the lancet occasionally, in certain well-science cases. And I want to say that although I am a young man, I entered the medical profession in the days of blood-letting and followed the teachings of Dewes and White. I have seen good immediate results in labor from the use of the lancet, yet I have seen better results from the use of chloroform and opium, both in convulsions, and in relaxation and prevention of laceration, and in the accidents spoken of in the paper. I think that we ought to feel grateful toward our lamented friend Dr. Battey for considering the subject, and bringing it before us as it has been done; but I am certain that by the remedies now in use the accidents would be prevented much better than by means of blood-letting. Although the latter occasionally acts in a beneficial way, it certainly does harm to the patient in the long run.

Mr. Kinloch, of South Carolina: My friend who has just preceded me has somewhat anticipated the few remarks which I proposed to make. My whole impression
somely complimented and sustained me. I think, therefore, sir, in memory of that occasion that I should say this one word: That the truth lies as near with him as it does with us.

Dr. RAMSEY, of Ohio: As the time has nearly expired, and I find no one else on the floor, I will take this as the last opportunity I shall have to say a word during the session, to express two or three thoughts that have occurred to me. I think with my friend on the left (Dr. Harvey), that since this is a contribution to this department, and is the teaching of this great man offered to us, in spite of our veneration for his kindness of heart and his greatness of mind, his wonderful industry and his almost marvellous work in his profession—while we all subscribe to this and feel this, and together mourn his death, even in the ripeness of his years—still, when he offers us this paper, it stands upon the same ground that it would stand upon if he were living. It is to be published, and therefore I, with my friend on the left, could not let the sentiments uttered in this paper, though from so distinguished a source, go upon the record unchallenged.

Perhaps enough has been said with reference to the fallacy taught as to bleeding, but still there is a little point in the matter which has not been brought out. Summing up in this paper, the distinguished author states that he would bleed in threatened abortion. No distinction is drawn here as to the kind of threatened abortion, the causes leading to the threatened abortion might be; simply if the woman was threatened with an abortion he would bleed her.

I need not qualify the ridiculousness (if I may use such a phrase) with reference to that position. Granting that bloodletting could do no possible harm ultimately, granting that it did nothing, the very idea of its being practised is ridiculous, which need not be contradicted—it contradicts itself. He would also bleed in case of fever. If a pregnant woman had fever he would bleed her. He does not even make the distinction that the judicious obstetrician or general practitioner in charge of that woman may recognize the fever from which she suffers as the result of poison in her system before she is delivered. Why would he bleed such a woman as this? why would he lessen her vital power and take from her the blood which physiologically as well as scripturally is her life, in order that she may be the better prepared to fight with the poisonous germs in her system and resist their progress? Why bleed her to-day, in order that to-morrow, or next day, with these germs in her system she may die of it? How does he account for the amount of life the lancet has taken from her—bleed her simply because she has a fever? Rather husband every particle of strength that she has, knowing that it will be required to resist the influences with which she has to contend. He would bleed in a case of rigid os, he would bleed in a case of nagging fever.

I will not dwell upon this. An obstetrician in modern times, who has not been taught that the lancet is the grand remedy for all the ills that the parturient woman can enter upon, under circumstances of this kind, if she had nagging pains, would give her chloroform or something similar, let her go to sleep for three or four hours, and then return with a more hopeful aspect on, if his pulse is too high it gives her a sedative. He would not bleed in every case of puerperal convulsions, perhaps. While all cases are not alike, and while there is no gentleman present who would not bleed in some cases, yet I am very far from agreeing with the views expressed in this paper. In a certain proportion of these cases bleeding is necessary. Then I would say, I would be doubtful about it. At the same time it includes but few of the cases in which any man who has the hypodermic injection of morphia, and has seen a woman go into a tranquil sleep who was a few moments before in peril from convulsions, would wish for other treatment.

Just one word with reference to the forceps and I am done. The distinguished author ought to have sent to this Section a picture of the forceps that were used at
the time of which he speaks. He must remember that the instruments used in those earlier days, and used so unfortunately, were a very little improvement upon the pattern used by Chamberlain himself; he must remember that it is only a few years ago that obstetricians in some of the largest cities used an instrument long enough for a cart-hook. That is not the kind of forceps described yesterday by my distinguished friend upon the left, which he recommends and thinks so admirable in certain cases—a delicate instrument. Forceps are not now what they were; but what I want to say is this: Dr. Gross states that teachers of obstetrics have a fearful responsibility upon them for sending out obstetricians in competent to use the forceps indiscriminately, and who do with those instruments so much damage. Without doubt the use of this instrument simply for the purpose of saving the last resource. It is criminal to use the forceps so as to get to a good supper. There can be no doubt about that; but even the gentleman on my right, who has become more conservative, as he states, knows that that charge is not sustained.

The students who go forth now and are taught in this department are more competent to use this instrument and practice, and are instructed in its use, more thoroughly comprehend the principles, than the average practitioner of twenty years knew in those days. I do not refer to any single student or to any single college. I say the students that go out from the average medical college to day.

There is no question about it. The books which have been written in the last four years in discussing this subject make it very plain. It is a different proposition from what it was. Consequently I think these charges are entirely out of place. The obstetrical forceps is not the weapon of ruin that it is pictured here in this admirable paper to-day. It is not used indiscriminately by bungling men to tear the uterus as has been described. I must therefore enter my protest against this particular part of the paper.

First, I do not believe that the obstetrical forceps is used by the average practitioner, as stated by the distinguished gentleman, in great centres once in seven times. The general practitioner, the average accoucheur in city, country, and village in this country does not use the obstetrical forceps paper to-day. The delivery of a woman by the use of the forceps in seven labors. I speak from observation and from facts I have obtained from extensive correspondence on this subject during the last two or three years.

They are not in the habit of doing it. They do not use it on an average more than once in fifteen to twenty-five cases. The distinguished author is therefore simply laboring under a mistake. He is in error and the error ought to be corrected.

Dr. Wathen, of Kentucky: If the brain is in an anemic condition, certainly such remedies as chloral and chloroform would be far less injurious than blood-letting; in this case the brain would be depilated more by blood-letting than by the chloroform. I have never seen a case in my experience with labor, where the patient suffered with fever or with threatened abortion, where I could possibly conceive that blood-letting would be of any benefit. Blood-letting is certainly of benefit in cases of puerperal fever, where there is an excessive volume of blood, though there may be a depreciation of its quality, at the beginning of the convulsions, before other remedies could possibly act. The amount of blood that is taken away may prevent injury to the brain that would prove fatal. That would only be a means to prevent the injury until other means could act.

In regard to the remark in Dr. Gross' paper, that the abstraction of blood left the system in a better condition for the puerperal woman, that is certainly not in keeping with the writers of medicine in this day. With the blood of a poorer quality than it is at other times, physiologically, and with a woman who after she is confined is constantly losing blood, for a week or two or three weeks; a woman that wants everything that she can possibly get to enable her to go through with the puerperal condition properly; a woman who cannot take a very great quantity of good nourishing food for making blood; a woman who is to go through the process of involution; a woman who must furnish milk to the child—to say that this woman is in a better condition after having been bled profusely, as suggested, than one who has not been bled, is to my mind so absurd that I am sure the profession of the country will never adopt a theory so pernicious.

Dr. W. M. Findley, of Pennsylvania, read a paper entitled

A THOUSAND CASES OF LABOR IN PRIVATE PRACTICE, AND THE DEDUCTIONS TO BE MADE FROM THE SAME.

Dr. Wm. T. Lusk, of New York, read a paper on

SUDDEN DEATH IN LABOR AND CHILDBED.

The writer reported an illustrative case, and referred to the meager literature of this subject. He then discussed the possible causes: First, the entrance of air into the uterine veins. The inspiration of the vagina is greatest in the knee-chest, latero-prone, and lithotomy positions. The use of the vaginal douche is not free from danger, and its use had been forbidden in the public institutions under his charge. A second cause is that of thrombosis and embolism. Ordinarily, death from these causes is not instantaneous. Dr. Lusk doubted the suddenly formed cardiac thrombi ever existed—at any rate, such a cause of death was not positively demonstrated. In some cases, like that reported by the author, there is no entrance of air or embolism. Dr. Lusk was inclined to attribute the cause in these cases to shock. He thought that the pathology in childbed was just the same as that elsewhere.

Dr. Brown, of Baltimore, read a paper entitled

MALFORMATIONS OF THE FEMALE SEXUAL ORGANS.

A sketch of the development of the uterus was given, and some cases of sexual malformation were reported. In one case the uterus and ovaries were absent, and the vagina was present. In a second case there was an in-fantile uterus with amennorrhoea. The condition was relieved by faradization. Cases of anteflexion as the result of defective development were related.

SECTION IN DISEASES OF CHILDREN.

(By telegraph.)

TUESDAY, MAY 6TH—FIRST DAY.

Dr. Wm. Lee, of Baltimore, Chairman; Dr. Geo. N. Acker, Secretary.

The first paper, on

THE SIGNIFICANCE OF BLOODY DISCHARGES FROM THE BOWELS IN CHILDREN,

was read by Dr. Frank Woodbury, of Philadelphia.

The occurrence of blood in the alvine discharges of a young child, whether existing in small amount or large enough to constitute actual hemorrhage is a symptom that excites alarm. This accident in childhood is generally regarded as of more serious import than in adults. Systematic writers on diseases of children make no reference to intestinal hemorrhage in children, or to the presence of blood in the alvine discharges. Loss of blood coming from the intestines is merely symptomatic. The term melena was anciently used to indicate black discharges from the stomach or bowels, or both. This may be due to medicinal substances, as bismuth, as well as to the action of the intestinal fluids upon effused blood. Blood may appear in the discharges from a lesion in the stomach or in other parts of the alimentary tract; or even from without the body, being taken with the food, as a baby from nursing a bleeding nipple. The present consideration of the subject will be limited to bleeding from sources be-
low the pylorus. The first question asked by the clinician is as to the site of the hemorrhage, the second is, what is its cause? Vascular piles were found by Allingham in a secondary case condition caused by straining in members during bloody discharges from the rectum. Sedgwick calls attention to the existence of piles at an early age. Fixure of the rectum is given as a cause of a bloody discharge in a boy four and a half years of age. Prolapse of the rectum is less frequently accompanied by hemorrhage in children than adults. The descent of the bowel in a secondary case condition caused by straining in members from the sphincter from a prolonged diarrhea. Polyposis of the rectum is more frequent in children than is generally supposed, and is usually accompanied by bleeding. Bryant says that in children this is the principal cause of hemorrhage from the rectum. These polypi may be mistaken for hemorrhoids, but the treatment is much the same. It is rarely necessary to apply the ligature in children. The usual site of the polypi is inside the internal sphincter, from two to six inches within the bowel. The pedicles may be several inches in length. Foreign bodies may cause ulceration and hemorrhage, such as pieces of bone, glass, etc., swallowed by the children; for substances may be introduced with great difficulty. Dysenteric hemorrhage is another cause. Intussusception of the bowel is accompanied by the passage of blood. A discussion of the treatment of intussusception follows. Ulcers in the bowel may be due to sloughing of necrosed follicles in simple catarrhal inflammation, or it may be tubercular in origin. Such a hemorrhage may simulate that from typhoid fever. Some of the causes of the hemorrhage are less localized. Thus congestion of the mucous membrane is quite common in young infants with inflammation. This congestion may be a cause of a bloody discharge in children and unusually in the spleen or liver. In some cases of bleeding the pathological condition is not well understood. Meisna neonatorum was here referred to. In some cases purura hemorrhagica is a cause of the bleeding. Blood sometimes appears in the discharges during the specific fevers. Attention has recently been directed to cases of hemorrhage in children. The case last year in which two years, eight years old, and in an attack of acute articular rheumatism, was seized with obstinate constipation and a discharge of blood from the bowel.

Dr. J. Lewis Smith stated that in this affection the pathological conditions were very different. Intussusception was a most important cause of a bloody discharge, unmixed with mucus, and it is vitally important that an early diagnosis be made. It occurs chiefly at the ileocecal valve, causing the most intense passive congestion with oozing of blood. The intussusception may be in the large intestine alone. There is a little fecal matter passed, followed by dark-red blood. Tenesmus is generally present, which resembles dysentery, but no mucus is usually present. Purpura hemorrhagica is the next common cause, and the changes are apparently in the capillary walls and not in the blood, as well-nourished children are often affected. He had never seen hemorrhage from worms.

Dr. Fay had frequently seen blood in gastro-intestinal catarrh.

Dr. Adams thought that sufficient attention had not been given to the symptoms following the cessation of the hemorrhage; stimulants should then be freely given. In closing, Dr. Woodbury thought a digital examination should always be made.

The next paper was on CONGENITAL ENCEPHALOCLE, by Dr. John H. Duncan, of Kansas City. This affection is comparatively infrequent. He recently had a gratifying result in the treatment of a case. A review of the history of congenital encephalocle was next given. There are two varieties: 1. congenital; 2. traumatic. The former only was considered by the writer. The real cause is in the cranial cavity; the intumescence is usually perfect. The tumor usually occurs in the occipital region, or at the anterior fontanelle. Pressure on it causes cerebral symptoms. At present the tendency in treatment is to leave them to nature, while the older surgeons used the knife or ligature. The author prefers leaving the tumor alone if possible, if not, to use the ligature.

A case was then cited: Willis M——, born August, 1882, was brought to the doctor at the age of seven weeks. He had a tumor about three-fourths of an inch in diameter, situated at the anterior fontanelle, which was covered by skin, and pulsed synchronously with the heart. He was born after a very tedious labor, lasting twenty-four hours. His mother then noticed a very small swelling, which slowly enlarged. It continued very slowly to enlarge, until in December it rapidly increased in size, in two days attaining the size of an orange. Brain-tissue was now plainly to be detected in the tumor. The child showed signs of distress and crying, and severe fits of crying, caused by the absence of the mother from her child. There was much nausea present. The tumor was ligated, and almost immediately the nausea ceased. It was necessary to apply several ligatures, but the case was finally cured.

Dr. J. Lewis Smith asked if the internal part of the tumor had been examined.

Dr. Duncan replied that brain-tissue had been found in it.

Dr. J. Lewis Smith could not recall any case successfully treated.

Dr. Woodbury thought the case interesting from its resemblance to a malignant growth. Dr. Duncan at the start was in doubt as to the diagnosis, but later on its extremely rapid growth had made its nature clear to him.

Dr. Latimer found it difficult to realize how much cerebral matter could be removed without nervous symptoms, and suggested that most of the tumor may have consisted of blood with only a little brain-tissue included.

Dr. Duncan replied that cases had been recorded in which much brain-tissue had been lost without marked symptoms.

The next paper was DIPHTHERIA BASED UPON ANALYSIS OF 120 CASES, WITH A MORTALITY OF 7.

by Dr. J. W. Brown, of New York.

He did not wish to discuss the symptoms, diagnosis, etc., of diphtheria, but how to lower the mortality. His cases extended over a period of fourteen months, and occurred in a country of wells and old-fashioned backhouses. The invasion was generally sudden, and in a few hours the patient was dead. The cases were not complicated.

It was quite contagious and the doctor contracted it twice. In the seven fatal cases, three died from the disease and four from complications. The average age was under sixteen years. The doctor regarded the disease as constitutional with a local lesion. The latter part must not be overlooked in treatment. He began treating his cases with calomel, five grains every three hours until the bowels freely moved. Salt pork was applied externally to the neck. He did not swab the throat but gently touched it with a solution of the persulphate of iron, 1%, to 3% of vinegar and glycerine. He never forcibly tore off the membrane. In the atomizer he used persulphate of iron, gr. x., to % of vinegar and glycerine. The membrane should be removed. As a constitutional remedy he used a mixture containing tinct. ferri mur. and potas. chlorat. He also gave quin.
sulph. and potas. chlorat., of each gr. iij, every four hours. Do not allow the patients to swallow the membrane, as it produces symptoms resembling arsenic poisoning. Give stimulants from the first and let in plenty of fresh air. He frequently poured the air by burning sulphur. He did not believe in tracheotomy or lime-water. The cases had not been selected.

Dr. Samuel Smith said that follicular tonsillitis and pharyngitis often resembled diphtheria. He formerly believed the disease to be primarily constitutional, but after noticing very many cases in which vigorous local treatment conducted from the first seemed to check the advance of the disease, he had changed his mind. He gave no quinine, stimulants, nor beef-tea, but milk diet, tinct. ferri chlorid., and thorough local treatment.

Dr. A. Behrend noticed that when diphtheria began with hoarseness, nearly all the patients died.

Dr. Franklin had seen many cases in Ohio and used iron and quinine with gargles. He thought there was an element of rheumatism in many cases of diphtheria, and quiaicum was here indicated. He does not lose five percent of his cases under this treatment.

Dr. J. Lewis Smith regarded the disease as primarily constitutional, or at any rate it became so almost immediately.

Dr. Bussey, of Washington, recognized three forms of diphtheria, the simple, the more severe, but in which treatment is availing, and the malignant.

Wednesday, May 23rd—Second Day.

It was moved and carried to continue yesterday's discussion on diphtheria.

Dr. J. Lewis Smith uses alcohol in large doses without any symptoms of intoxication. Although he uses iron and quinine he regards alcohol as the most important. He regards with distrust the so-called antiseptic method that uses germicides. The micrococci are as tenacious of life as the white blood-corpuscles. Some leading New York physicians are now looking with favor on the use of alcohol and quina in small doses, and he intends giving it a fair trial. Dr. Smith regards with suspicion statistics on diphtheria, as, like scarlatina, the tide varies so much in different localities and years, although, considering the disease as constitutional, local treatment is very important to prevent septic absorption. When the nasal cavity is affected he uses a solution of oxalic and acetic acid, a teaspoonful being injected every two hours.

Dr. Burroughs feared that injections might cause otitis media. He uses sulphur by insufflation with good results.

Dr. Free, of Pennsylvania, asked whether the chloride of potash was not injurious in large doses. He has had two cases in which children with diphtheria got up fatal nephritis, caused probably by the continuous use of large quantities of chloride of potash. In the district where he practised physicians considered they did well if they saved eighty percent of their cases. He uses alcohol in large doses from the first, and insists on cleanliness being strictly observed. He uses a solution of lime-water and carbolic acid applied directly to the nose and mouth by the hand atomizer. He omits quinine, as it disturbs the stomach, and he does not consider it a very powerful disinfectant. In his county there never has been a recovery from laryngeal diphtheria, and one peculiarity about the attacks of diphtheria is that in nearly all cases they are followed by paralysis. He gives rye whiskey, 5 as. to 1 lb., every two hours as long as the symptoms demand these large doses.

Dr. Hicks, of Virginia, looked upon laryngeal diphtheria as almost necessarily fatal. He had never seen but one case recover. He could not see how a catarrhal inflammation could ever degenerate into a diphtheritic. He also asked why physicians so universally use the chloride of potash in its tincture or ferri muratic mixture, as he had never derived any particular benefit from the combination. He regarded chloride of potash as objectionable from its action on the kidneys. He had come to the conclusion that in laryngeal diphtheria we can do nothing, and that simple cases often get well if left to themselves. He thought the important question to find out is, how the disease would behave if allowed to run its own course. Physicians practising in hospitals had better opportunities to test this question than country practitioners. Pneumonia was formerly treated most gorgiously and not left much to itself; now the mortality is less without so much medication. His plan of treatment consisted of nourishment and the use of antiseptics. He found a weak solution of the hydrate of chloral to be a good antiseptic gargle.

Dr. Holton, of Vermont, firmly believed in the contagiousness of diphtheria. A country physician can often follow out the contagiousness of a disease better than one practising in the city. He formerly believed the disease to be constitutional, but he now regards it as local, and hence he would emphasize the importance of local treatment. In a former epidemic in his county, among 113 cases there were 13 deaths, and of the latter, 2 were untreated, through the prejudice of parents, and 9 were under the care of homoeopathic physicians, he therefore believed that good treatment was of great avail in this disease. He does not give quinine, on account of stomach irritation, but uses stimulants. Chlorine mixture is likewise employed.

Dr. Hicks thought there were circumstances in which diphtheria was contagious and others in which it was not. There must be favorable conditions for its development.

Dr. Park, of Pennsylvania, said that he practised in the coal regions, where he has lately had a number of cases of diphtheria. He considered the disease more local than constitutional. He had not seen many cases die except from laryngitis. He used a gargle of crystallized carbolic acid, tannic acid, and glycerine, and did not regard the disease as very contagious.

Dr. William Lee regarded the statistics presented in Dr. Brown's paper as marvellous and questioned the correctness of his diagnoses. There is no disease so difficult to diagnose as diphtheria. He quoted Hessod as saying that he never made a positive diagnosis on his first visit. Catarrhal angina often simulates diphtheria. If the membrane can be removed without bleeding it is not diphtheria. In all cases he has the membrane extended up back of the uvula. He believes the disease to be general from poisoning by micrococci. He gives alcohol freely and resorcin internally, and locally powder of resorcin and sulphur, which can be placed upon the child's tongue, and is readily swallowed. He regards mopping the throat in young children as highly dangerous, and likewise efforts to detach the membrane. He always considers diphtheria as contagious, and most cases he has treated began as a simple catarrhal angina.

Dr. Bussey thought the diphtheritic poison was very apt to be ingrafted upon a simple catarrhal inflammation.

Dr. S. Smith cited two cases that seemed to him to prove that diphtheria is primarily local. If he could not wash off the membrane without pain, it was probably diphtheritic. He uses a wash of borate of soda, which destroys bacteria.

Dr. Brown, in closing the discussion, said that the object of his paper was to show the benefit of the persulphate of iron in his cases. He thinks the vinegar assisted in dissolving the membrane, but the general hygienic surroundings of the country may have assisted him in obtaining such good results. The temperature curve was valueless as a diagnostic point in his cases. He had no experience with the bichloride of mercury.

Dr. M. P. Hatfield next read a paper on SEPTIC JAUNDICE IN CHILDHOOD.

This affection is very rare and is a symptom of a dis...
THE MEDICAL RECORD.

THURSDAY, MAY 8TH—THIRD DAY.

The first paper, on

THE FEEDING OF SCHOOL-CHILDREN,

by Dr. Louis Altke, was in his absence read by Dr. Woodbury.

The greatness of a State depends on the vigor of the people. The physicians are partially responsible for the health and strength of the people. We see too many pale, thin children, showing imperfect nourishment. Too often a light breakfast is taken and then the brain is exercised all day. Lunch consists of cake or fruit, and the foundation is thus laid for future disease.

CHILDREN ARE NOT SO MUCH OVER-EDUCATED AS UNDER-FED.

The brain is kept stimulated by intellectual work while the rest of the system suffers. This is a matter of great moment, and the object of the paper is to attract attention to the subject.

Dr. Burge, of New York, thought some children were over-fed, and that the paper was too general to be of practical importance.

Dr. Woodbury thought the great trouble was from injudicious feeding. Each age must have its appropriate food, and the rich often suffer as much as the poor in this respect.

Dr. Lee had often noticed, when a School Commissioner, that children of the richer classes often brought a less substantial lunch than the poorer people. The trouble was not from excessive study, but from inferior food.

The next paper was on

ENLARGED TONSILS, AND HOW THEY SHOULD BE TREATED,

by Dr. Dudley S. Reynolds, of Kentucky.

Enlarged tonsils nearly always coexist with chronic thickening of the nose and pharynx, and constitute a great source of anxiety. The tonsils are lymphatic glands, and their enlargement has the same significance as that occurring in other lymphatic glands of the body.

It is a part of a general lymphatic obstruction due to a state of perverted nutrition. We must not attack one lymphatic gland that is engorged with lymph. There is nothing to show that enlarged tonsils are due to inherited struma. Often children are taken to specialists, who cut or burn the tonsils, entirely ignoring constitutional treatment. In 9,012 persons he had examined with nasopharyngeal trouble, 8,062 had enlarged tonsils, and in 8,554 of the cases the patients lived largely on food containing artificially produced glucose that does not nourish well. In his region maple syrup and sugar were largely taken, and he found them to aggravate any engorgement of the lymphatic tracts. If oils, fats, and animal food were taken more by children, instead of so much sweets and cooked fruits, which deprecate the system, enlarged tonsils would not be so frequent. Starvation is found to produce lymphatic engorgement. Many disasters, as impairment of voice, etc., follow cutting. Local treatment alone never can cure, but a combination of local and constitutional measures gives relief. Often it is only possible to produce an amelioration of symptoms. Frequent bathing, milk and animal food, and plenty of out-door exercise were recommended.

Dr. Chancellor, of Virginia, had seen in some cases a decided hereditary tendency to enlargement of tonsils. He did not believe in instrumental interference. Treatment should be constitutional.

Dr. Reed, of Ohio, thought that general treatment was not sufficient to overcome enlargement, which predisposes to other throat diseases. Cutting might save years of trouble. Diphtheria tends to attack enlarged tonsils.

Dr. Daly, of Pennsylvania, said the best treatment was abscessation of the tonsils. He can give assurance of relief if this operation is properly done. We must make as good a stump of a tonsil as we would of an arm or leg. If there is any ragged tissue trim it off, and if granulations afterward appear they must be snipped off. In two or three months after thus operating an expert cannot generally tell that an hypertrophy has existed. He never uses chloroform or ether.

Dr. Jones, of Illinois, thought that tonsils were often unnecessarily removed.

Dr. Jewett, of New York, does not remove tonsils now so frequently as formerly. He only removes them when the tonsils are becoming offensive. After the present age at sixteen years and men at twenty-five years they generally grow smaller. He has never had success with topical treatment.

Dr. Reynolds, in closing, said that generally there was no reasonable ground for tonsillectomy. Enlarged tonsils are not necessarily inflamed. Partial cutting, of course, will not produce the same disasters as complete excision.

The next paper was on

INCONTINENCE OF URINE IN CHILDREN,

by Dr. Samuel S. Adams, of the District of Columbia.

He has examined all the literature of the subject, including articles in German, French, Italian, and Spanish, from the year 1784 to the present date. In 1786 Mitchell wrote as clearly on the disease as any subsequent author, and its pathology was as well understood then as now. From birth the child instinctively voids its urine, as the act is reflex. About the eighteenth month the child begins to exercise complete control over the sphincter, after this time incontinence is attributed more to carelessness than to a pathological cause. He considers it a great injustice, particularly as children are often punished. All of his cases have had a specific cause. There are three varieties of incontinence.

Where there is a constant dribbling, this is not frequent. Two such cases he had seen were due to vesical calculi.
2. Intermittent incontinence, often met with in girls. They lose control of the sphincter before getting to the closet. 3. Nocturnal incontinence. The same causes that produce seminal emissions in adults bring on this condition in children. Enuresis is often superseded by seminal emissions, and the same remedies often relieve both conditions. It is a conservative process following undue irritation, occurs most frequently between eight and twelve years. Cases were then cited in which the causes were phimosis, calculi, ascariasis in the rectum and vagina, hip disease, and amorous dreams. He does not approve of choral for children. In exalted nervous conditions the bromides are to be given, belladonna is the best to allay irritability and relax spasm. Circumcision is often necessary.

Dr. Reed mentioned a set of cases in which the incontinence was due to a want of tonicity of the bladder with partial retention of urine. Here strychnine is of benefit.

The last paper of the Section was,

**PRACTICAL SUGGESTIONS ON THE TREATMENT OF THE MALIGNANT FORMS OF SCARLET FEVER**, by Dr. Bedford Brown, of Virginia. The marked features of malignancy were very high temperature, extensive prostration, defecitive renal action, a greatly weakened heart, feeble pulse, frequent vomiting, and a total suspension of the digestive functions. Can the type be modified by treatment? His plan of treatment was sedative and eliminative. The action of the skin and kidneys must be freely kept up to eliminate the poison while the system must be energetically supported.

**SECTION ON OPHTHALMOLOGY, ETC.**

(telegraph)

**TUESDAY, MAY 6TH—FIRST DAY**

Dr. Chisholm, Chairman; Dr. Seiler, Secretary.

Dr. P. D. Keyser, of Philadelphia, reported two interesting cases of NEAPLOMAS OF LACHRYMAL GLANDS in adults, both sarcomatous. One returned twice after operation. The gland was extirpated and recovery finally took place in both cases.

Dr. Williams, of Indianapolis, said ptosis was common after extirpation of the lachrymal gland.

Dr. Chisholm had had four or five cases of a malignant character, in two great deformity. One case of sixteen years' standing was calcareous degeneration.

In reply to a question of Dr. Keyser, he said the growth was not cystic.

Dr. Burnett, of Washington, believed all cases were adenomata originally.

Dr. Thompson, of Indiana, reported a case of large cyst removed from the eyeball and lachrymal gland. The patient returned in eight weeks. Microscopic examination showed it to be scirrhous. A second operation was permanently successful.

Dr. Seiler described the case as an inter-canalicular fibroma.

**DIAGNOSIS IN OPHTHALMOLOGY**

was the title of a paper read by Dr. Williams, calling attention to the necessity for careful discrimination between cases and the importance of early diagnosis. He called especial attention to strabismus.

Dr. Keyser excised a portion of a paralyzed internal rectus muscle in one eye with success, and straightened the eye.

Dr. Chisholm also reported cases of paralysis where muscles had been cut with good result.

Dr. Risley read a paper on

**SYMPATHETIC NEUROTETINIS**

Dr. G. T. Stevens said that sympathetic irritations may show themselves elsewhere, and related the history of a case in which irritation was located in the brain.

Dr. Fulton reported a case of sympathetic irritation caused by iridectomy.

Dr. McKay reported successful results from cases treated by atropia and mercurial ointment.

Dr. Jackson reported a similar case. After enucleation—dark room, atropine, mercurials.

Dr. Little reported a case of retinitis from secondary injury. It got well without enucleation.

Dr. Burnett said many cases escape detection, owing to opacity of vitreous being associated.

Dr. Thompson said that the affection was most frequent in the ciliary region.

**WEDNESDAY, MAY 7TH—SECOND DAY**

Dr. H. H. Hart, of Ohio, read a paper on the method of treating chronic otitis media, and reported a few cases.

"Irregular Astigmatism," by Dr. G. D. Thobold, was read by title.

**INFLUENCE OF CLIMATE ON TREATMENT OF CHRONIC CATARRH OF MIDDLE EAR**, by Dr. J. F. Fulton. He recommended a cold, dry climate for non-suppurative cases, but suppurative needs a warm climate—the peculiar characters of the climate of Minnesota offering special benefit.

Dr. Seiler said that hypertrophic catarrh was benefited by high altitude and dry climate, and atrophic by moist.

Dr. Williams and Turnbull also spoke of the advantage of change of climate.

Dr. Fulton, in concluding, said some cases got well without local treatment by climate alone, others require local application.

Dr. D. W. Rankin, of Allegheny, read a paper on

**EPISTAXIS**, recommending ergot and astringent washes.

Dr. Brown spoke of cases with hemorrhagic diathesis relieved by ergot. Extract of hamamelis was also very useful.

Dr. Daly, of Pittsburgh, advocated plugging the nostrils with cotton.

Dr. Jockey, of Illinois, reported a case requiring transfusion.

Dr. Murrall, of Iowa, had seen cases relieved by quinia. Malaria was a common cause of epistaxis.

Dr. Hart recommended a tournaulat applied to the thigh.

A COMBINED VISUAL AND ASTIGMATISM TEST was exhibited by Dr. Little, of Philadelphia.

**DISEASES OF THE EAR IN LOCOMOTIVE ENGINEERS**

was the title of a paper presented by Dr. Turnbull, who offered resolutions bearing thereon, which were not adopted.

**Report on CAUSES OF BLINDNESS,**

by Dr. Hobbs, of Iowa, based upon statistics of the College of the Blind of Iowa.

Dr. Reynolds said that fifty per cent. of cases were due to purulent ophthalmia.

Dr. Hobbs, in reply to a question of Dr. Little, said that in two cases of retinitis pigmentosa the parents had been related.

**RAPID OPERATION ON RIFENING CATARACT, OR ARTIFICIAL RIFENING OF CATARACT,**

by Dr. C. S. Bull, based on fifty cases. The operation consisted in large iridectomy with subsequent pressure
upon the cornea, but application only in cases with dense muscles.

In reply to a question the lecturer said that striation had not been caused by pressure upon the cornea.

Drs. White and Theobald reported cases.

THURSDAY, MAY 8TH.—THIRD DAY.

Dr. E. F. Ingals presented a paper on
OPERATION FOR REMOVAL OF NASO-PHARYNGEAL FIBROMATA,
and exhibited instruments, advocating hot or cold wire snare.

Drs. Shueliy, Chisholm, Seiler, Bosworth, and Turnbull advocated the operation and reported cases, Dr. Bosworth recommending cauterizing the stump with cautery.

Dr. Ingals, in closing, did not consider the galvano-cautery preferable to cold water.

CHROMIC ACID POISONING OF NARES AND ADJACENT CAVITIES,
was the title of a paper by Dr. Mackenzie, of Baltimore. He referred to perforation of the septum in laborers employed in chronic acid works. The Eustachian tube and middle ear were also discussed.

Drs. Turnbull and Bosworth inclined to a syphilitic origin of perforation.

Dr. Seiler had seen cases not syphilitic.

Dr. Bosworth read a paper on
SARCOMA OF PHARYNX AND SOFT PALATE,
removed by wire snare successfully.

Drs. Roe, Mackenzie, and Seiler preferred galvano-cautery.

Dr. Uhler, of Maryland, exhibited a remarkable set of instruments, made of tin, in a very crude manner. No discussion.

Dr. Cutler, of New York, read a paper on
PHYSICAL CAUSES OF ASTHMA.
Neuroses were due to irritation from various agents. Hay fever was due to gravel in lung structures, and the pollen added as the exciting cause where this condition is present. Aphonias was due to chronic alcoholism.

Drs. Morgan had seen a peripheral paralysis due to central disturbance.

TRACHEOTOMY IN SMALL CHILDREN.

Dr. Roe reported the case of an infant with an eggshell in the larynx, successfully treated by the method of Dr. Martin, without tube.

SECTION ON ORAL AND DENTAL SURGERY.

(By telegraph.)

Dr. T. W. Brophy, of Chicago, President.

Dr. John S. Marshall, of Chicago, Secretary.

Dr. George V. Black, of Illinois, read a paper entitled "Caries of Teeth and its Relations to the Germ Theory of Disease.

Dr. Jacob L. Williams, of Massachusetts, read a paper entitled "Importance of, and Treatment for, Assuring Healthy Dentine over Endangered Pulps."

Dr. Edward C. Briggs read a paper on "Sponge Grafting," in which he reported some successful operations. He thought the method might be useful in cases of cleft palate.

Dr. S. W. Harlan, of Illinois, read a paper entitled "The Removal of Stains from the Teeth caused by Administration of Medical Agents, and the Bleaching of Pulpless Teeth." He enumerated the various vegetable and mineral substances that discolor the teeth; these include all the preparations of iron except the dialyzed form, tobacco, and nitrate of silver. For the removal of stains he recommended tincture of iodine, liquor ammonia, and peroxide of hydrogen.

Dr. Jacob L. Williams read a paper entitled "Over-draft of Nervous or Vital Power as Affecting General Special Health." The author took the ground that an exhaustion of nervous force very markedly affects the healthy character of the gums and teeth. In the discourse the member brought out the importance of watching the condition of patients who are subjected to long or painful manipulation.

Dr. W. W. Allport, of Illinois, read a paper entitled "A Case of Vicarious Hemorrhage from the Gums associated with Pyorrhea Alveolaris, the Result of Amenorrhoea."

AMERICAN SURGICAL ASSOCIATION.

Fifth Annual Session, held at Washington, D. C., April 30, May 1, 2, and 3, 1884.

(Continued from page 405.)

THURSDAY, MAY 1ST—SECOND DAY.

The Association was called to order pursuant to previous adjournment.

A vote of thanks was tendered President Moore for his able and scholarly address at the opening of the annual meeting.

A paper prepared by Professor Gross, of Philadelphia,
ON WOUNDS OF THE INTESTINES,
was read by Dr. J. Ewing Mears, of Philadelphia, and followed with remarks by Dr. H. F. Campbell, of Augusta, Ga.

Dr. Joseph W. Thompson, of Paducah, Ky., read a paper on the
SURGERY OF THE HAND ESPECIALLY AS APPLIED TO RAILROAD INJURIES.

The next paper read was by Dr. James McCann, of Pittsburg. It was somewhat similar to the preceding paper, being entitled

CLINICAL OBSERVATIONS ON THE TREATMENT OF SOME RAILROAD INJURIES OF THE EXTREMITIES.

In the course of the paper he described a successful triple amputation—both legs and an arm—in the case of a boy who had been severely injured by the cars at Johnstown, Pa.

After recess a letter was read from Professor Baird, United States Fish Commissioner, inviting the Association to visit the Washington fish hatching establishment. The invitation was accepted, and the thanks of the Association were voted Professor Baird.

Dr. Basil Norris, of Washington, moved to omit the usual annual dinner this year. As a rule but very few members are present, having other engagements. Drs. Dawson and Byrd endorsed this view of Dr. Norris, whose resolution was adopted.

The papers of Drs. Thompson and McCann were then discussed at some length by Drs. Prewitt, of St. Louis; Tiffany, of Baltimore; Maclean, of Michigan; Conner, of Cincinnati; Nancrede, of Philadelphia; Campbell, of Atlanta, Ga.; Gregory, of St. Louis, and Packard, of Philadelphia.

Papers were also read by Dr. John H. Brinton, of Philadelphia, and Dr. N. Senn, of Milwaukee, after which the session adjourned to meet at 11 A.M., Friday.

FRIDAY, MAY 2D—THIRD DAY.

Association met pursuant to adjournment, President Moore in the Chair.
The first business of the session was the discussion of Dr. Senn's paper, read Thursday.

**ON TREATMENT OF BLOOD-VESSELS AND LIGATURE.**

Dr. Maclean, Campbell, Gregory, Byrd, Billings, Watson, and Nancrcrede participated. At the close of the discussion Surgeon-General Hamilton entered the hall, and was invited to sit with the Association.

Dr. Moses Gunn, of Chicago, read a paper on the

**PHILOSOPHY OF MANIPULATION IN THE REDUCTION OF HIP AND SHOULDER DISLOCATIONS.**

The paper was discussed by Drs. Dawson, Briggs, Conner, Pancost, and Campbell.

On reassembling after recess, an executive session was held, during which it was agreed that no papers should hereafter be read unless the authors are present. The next paper read was by Dr. George W. Gay, of Boston, on

**TRACHEOTOMY IN CROUP.**

The paper was discussed by Drs. Basil Norris, of Washington; Byrd, of Quincy, Ill.; Tiffany, of Baltimore; Dawson, of Cincinnati; Prewitt, of St. Louis; Sayre, of New York; Christopher Johnston, of Baltimore; Campbell, of Georgia; Gregory, of St. Louis, and Fifeild, of Boston. Taylor endorsed Dr. Gay's views on the treatment of croup, especially in regard to the use of steam as a remedial agent. He instanced a number of cases where complete cures were effected by the use of steam alone without result to tracheotomy. Several of the speakers expressed grave doubts as to the wisdom of tracheotomy in most cases of croup.

Dr. West, of Cincinnati, read an abstract of a paper prepared by Dr. John S. Coleman, of Augusta, Ga., on the **MULTIPLE WEDGE PRINCIPLE IN THE TREATMENT OF ORGANIC STRUCTURES OF THE URETHRA.**

Dr. Sayre thought it somewhat strange that the author of the paper claimed to be the originator of the multiple wedge system, since, to his personal knowledge, this system has been in use in Bellevue Hospital, New York, for at least twenty years.

A paper

**ONTRIFACIAL NEURALGIA**

was read by Dr. J. Ewing Mears, of Philadelphia, advocating the excision of a portion of the nerve involved in cases of this disease. The paper was favorably commented upon by Dr. Cheever, of Boston, and further discussed by Drs. Maclean, Gregory, Pancost, Briggs, Dawson, and Hutchison.

Dr. William A. Byrd, of Quincy, III., read a paper on

**TREPPANNING FOR INSANITY**

following a depressed fracture of the skull, after which the Association adjourned.

---

**Saturday, May 3rd—Fourth Day.**

The Association met pursuant to adjournment.

The first paper read was by Dr. William T. Briggs, and was entitled

**TREPPANNING FOR EPILEPSY.**

The paper was discussed by Drs. Sayre, Campbell, Mears, Roberts, Prewitt, Byrd, and Briggs, the author of the paper.

Dr. Basil Norris, of Washington, D. C., then read an interesting and valuable paper on

**EXTIRPATION OF THE TONGUE IN CANCEROUS AFFECTIONS,**

in which he gave the recorded cases of extirpation of the entire tongue, as being one hundred and twenty-six in number. It is only within the past thirty years that authors have ceased to regard extirpation as an impracticable and cruel operation. After describing operations in several cases of removal of the tongue, Dr. Norris gave instances in which the persons operated upon retained the faculty of speech. Statistics in one hundred and twenty-four cases show ninety-five recoveries and eighty-nine deaths.

After recess the election of officers for the ensuing year was proceeded with, resulting as follows: President—William T. Briggs, Nashville, Tenn.; Vice-President—J. C. Hutchison, Brooklyn, N. Y., and E. H. Gregory, of St. Louis; Secretary—J. R. Weist, of Richmond, Va.; Treasurer—John H. Brinton, of Philadelphia; Secretaries—J. Ewing Mears, of Philadelphia; Council—Henry F. Campbell, Augusta, Ga.; Hunter McGuire, of Richmond, Va.; P. S. Connor, of Cincinnati, and J. S. Billings, of Washington, D. C. Treasurer John H. Packard, of Philadelphia, declined a renomination owing to a pressure of business.

A vote of thanks to Professor S. F. Baird for the use of the lecture-hall was unanimously adopted.

Washington was selected as the place of meeting, April, 1885. Dr. J. S. Billings, of that city, was elected chairman of the Committee of Arrangements to prepare for the next meeting, and a vote of thanks to Dr. Basil Norris was adopted for his agency in making preparations for the present meeting.

Notwithstanding the determination of the Association to omit the annual dinner this year, twenty of the members, including President Moore, had a banquet at Wormley's Hotel on Friday night. The dinner was gotten up under the auspices of Dr. J. Ewing Mears, of Philadelphia, and Dr. L. McLane Tiffany, of Baltimore. President Moore acted as chairman and Dr. Mears as toast-master. The occasion was a very pleasant one.

---

More "UNUSUAL PARTURITIONS."—It appears that certain supposed unusual parturitions reported in The Record of December 29th, are not so infrequent after all. Dr. O. Bicknell, of Knoxville, Tenn., states:—"I attended on February 14th, Mrs. M. — aged twenty-five, rather delicate, mother of one child, in labor with twins—girls. She was delivered about an hour after my arrival, the one following the other almost immediately, and the last was expelled, child, membranes, placenta, all intact. The child was kicking violently within the membranes, which were so thick as to require the aid of scissors to open."

Dr. A. B. Mitchell, of Delaware City, Del., writes that he was called to see Mrs. E — aged thirty-three, multipara. He found a foot presenting, and soon delivered her of a good-sized male child. On examining the woman again he found membranes protruding from the vagina, and soon another infant was born, child, membranes, and placenta at once and together, the child completely enclosed.
Obituary.

SAMUEL D. GROSS, M.D., L.L.D., D.C.L.,
PHILADELPHIA, PA.

The life-work of this great man is finished, and how magnificent that work has been! Rather should we say, how magnificent it is, for though 'tis finished, and the great mind which wrought it has ceased to be, the perfected work will live on till there is no longer a place for the art of medicine. Even while we write there is sorrow in the profession throughout the length and breadth of our land; and wherever science is known and greatness and learning honored, his death will be deplored.

Samuel D. Gross, M.D., L.L.D., D.C.L., Oxon., L.L.D. Cantab., L.L.D. Edinb., died on Tuesday, May 6th, at his residence in Philadelphia, after an illness of some weeks. He was born near Easton, Pa., in July, 1809, and was therefore in the seventy-ninth year of his age. He received his classical education at Wilkesbarre, and at the High School at Lawrenceville, N. J., and began his medical studies at an early age, under the preceptorship of Dr. J. K. Swift, of Easton, after which he continued them for nearly two years under the celebrated Dr. George Jones of Philadelphia. He was graduated from the Jefferson Medical College in 1828, and entered upon practice in Philadelphia.

The leisure hours which fall to the lot of every young practitioner were spent by Dr. Gross in the translation of several standard French and German works. But his ability and activity removed him above the plane of the translator. In two able volumes making up his first original work upon "Diseases and Injuries of the Bones and Joints." At this time he removed to Easton, but was elected in 1833 as Demonstrator of Anatomy in the Medical College of Ohio. This position he accepted, and two years later was elected Professor of Pathological Anatomy in the Medical Department of the College in Cincinnati. Here he delivered the first systematic course of lectures on pathological anatomy ever given in the United States, writing meanwhile his second book, "The Elements of Pathological Anatomy," the first work of its kind published in this country. From this chair he was called to the Chair of Surgery in the University of Louisville, where for ten years he gave evidence of the ability which had made him so honored by the civilized world. From this chair he was called to that of Surgery in the University of New York, but returned at the end of one year, at the earnest solicitations of his former colleagues. Here he remained until 1856, when his Alma Mater called him to teach in the halls whence he had gone forth as a distinguished student.

Shortly after coming to Philadelphia he founded the Pathological Society of Philadelphia, being its first president. In 1867 he was elected President of the American Medical Association, and four years later was chosen Chairman of the Teachers' Medical Convention in Washington. In 1872 he visited Europe for the second time, not as an unknown or a rising man, but as a master in his science and art, a successful surgeon, and an author, whose reputation had circled the globe. While in England, the University of Oxford celebrated its one thousandth anniversary, and gracefully complimented the great surgeon and American medicine by conferring upon Dr. Gross the degree of D.C.L. In 1880 the University of Pennsylvania conferred upon the degree of L.L.D., which degree he had already received from the Jefferson College. On April 17, 1884, the University of Edinburgh, at its tercentenary anniversary, conferred the degree of L.L.D. upon him, and the University of Pennsylvania paid the same tribute to his learning on May 1st.

Not the least among his honors was his unanimous election to the presidency of the International Medical Congress, which met in Philadelphia in 1876. In 1880 he organized the American Surgical Association, of which he was president until 1885.

Of his greatest literary work, his "System of Surgery," it may be said that his success was so great, while his fame goes down to the posterity of succeeding generations as a blessed heritage, his great work on surgery will remain a tangible legacy to the students of many lands and tongues.

In four great cities Dr. Gross has been a teacher of surgery, and thousands of his pupils are now scattered throughout the Union. As a teacher of surgery he has long been recognized as the greatest which the country has ever produced.

At a dinner given to him in Philadelphia, in April, 1879, Dr. Gross said:—"After fifty years of earnest work I find myself still in the harness; but although I have reached that age when most men, tired of the cares of life, seek repose in retirement and abandon themselves to the study of religion, the claims of friendship, or the contemplation of philosophy, my conviction has always been that it is far better for a man to wear out than to rust out. Brain work, study, and persistent application, has been a great comfort to me, as well as a great help; it has enhanced the enjoyment of daily life, and added the value of leisure to the pleasures of life. Indeed, it will always be, if wisely regulated, be conducive both to health and longevity. A man who abandons himself to a life of inactivity, after having always been accustomed to work, is practically dead."

How truly he carried out these precepts is seen by the fact that, within a few weeks of his death, he has prepared two papers—one on "Wounds of the Intestines," for the American Surgical Association, which met in Washington last week; the other on "Lacerations of the Female Sexual Organs," for the Obstetrical Section of the American Medical Association, which met in the same city during the present week. Though well-nigh fourscore years of age, he has never allowed the great mind which has guided the surgical world to become for one moment idle.

As a companion and as a host Dr. Gross was one of the most genial and generous of men, and few who ever heard his voice will forget its majestic power and sweetness. As a writer he was most voluminous.

In 1843 he published "An Experimental and Critical Inquiry into the Wounds of the Intestines," and in 1851, "A Practical Treatise on the Diseases, Injuries and Malformations of the Bladder and Urethra;" in 1854, "A Practical Treatise on Foreign Bodies in the Air Passages," and the same year he issued a "History of Kentucky Surgery." In 1859 he published his noblest work, "A System of Surgery, Pathological, Diagnostic, Therapeutic, and Operative," the sixth edition of which was put out in 1882. At the outbreak of the war Dr. Gross issued a "Manual of Military Surgery," which passed through two editions and afforded important service in fitting young military surgeons for the better and more efficient discharge of their duties on the field and in the hospital. In 1861 he edited a large volume entitled "Lives of Eminent Physicians and Surgeons of the Nineteenth Century." In 1876 he published a "History of American Medical Literature from 1776 to the Present Time," and the same year an elaborate paper entitled "A Century of American Surgery."

In addition to the comprehensive standard works already mentioned, Dr. Gross also made many other noteworthy contributions to the literature of the medical profession, chiefly in the form of monographs and miscellaneous papers, contained in the current medical press of the country.

Dr. Gross leaves four children, upon one of whom, Professor Samuel W. Gross, now gracefully rests the
Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE BRITISH POOR-LAW SERVICE—DR. JOSEPH ROGERS AND HIS LABORS—COUNTRY GUARDIANS AND THE DOCTOR—TROUBLESOME PATIENTS—DEATH OF DR. J. PAT-TERSON CASSELS.

London, April 22, 1884.

A POST in the British medical poor-law service is by no means a sinecure. The pay is meagre and the work laborious and trying. All ordinary drugs have to be provided by the medical officer out of his salary, but quinine and a few other drugs are now generally allowed for extras. Extra fees are allowed for surgical operations, and cases of midwifery. The pay is so poor that in many cases the only reason the doctor accepts the appointment is—in isolated country districts—to keep another doctor out of the parish. In many villages there is only one doctor and he has the work of several miles. If he will not take the "Union" appointment a stranger will, and a rival practitioner will thus be introduced into the district, and the practice no longer be an "unopposed" one. If the salary is only twenty pounds a year some impecunious medical brother will be found willing to take it if the local Asculapius turns up his nose at it. Twenty pounds a year is what appears to have been the reward.

Poor-law guardians, too, are difficult personages to deal with. The doctor is no dignitary in their eyes. They look upon him as their servant and rather enjoy snubbing him. If he can be found to have neglected or maltreated a patient so much the worse for him. If he is careful and attentive to the patients but orders them too many expensive medicines he will be dealt with in a similar way. Between these two stools the poor doctor often gets a fall. He often has not sufficient spirit to stand his ground or fears to offend the guardians, who may be county magistrates. Perhaps some of them are his private patients, but are not on that account any the more disposed to take his part, but rather more likely to expect more attention in private on account of their public official position.

Here and there a parish doctor bolder than his brethren ventures to stand up for himself, and sometimes gets the better of the guardians. Dr. Joseph Rogers is a well-known poor-law medical officer who has been a very active defender of their rights and formed the "Poor-law Medical Committee," which has been in hot water several times with boards of guardians, but he never scruples to stand up for the right, even at personal inconvenience. He was recently suspended by the Westminster guardians (whose medical officer he is at present) and promptly appealed to the Local Government Board, who reinstated him but administered only a mild censure to the workhouse "master" with whom the difference had arisen, on the ground that the master retained the confidence of the guardians. Dr. Rogers has lately been triumphantly vindicated, as the guardians who opposed him have lately been rejected by the rate-payers. If the new Board are consistent they will dismiss the master whom Dr. Rogers showed had been guilty of cruelty.

In a country town frequently visited by me, about threescore miles from London, the guardians summoned their medical officer before them to reprimand him as they thought. They expressed their dissatisfaction with the expense he had incurred by ordering various "medical comforts." "We find you have been ordering so many pounds of beef," and so on. Quoth the chairman, "and we don't exactly understand it. You know this is very expensive," etc. "Exactly," replied the doctor, "but if you can inform me of any way of making beef-tea without beef I shall only be too happy.
to learn." The attack was then varied and the Board quietly informed the doctor that it was not their money that he was spending but the rate-payers. "Yes, gentlemen," replied the doctor, who was an Irishman, "it is not your money that I am spending; neither is it mine. It is the rate-payers' money, but to the representatives of the rate-payers. And, gentlemen, 'tis that giveth to the poor lendeth to the Lord.' Look upon me as your almoner. Good morning, gentle- men," and he took up his hat and left.

Patients, too, are very unreasonable, and generally those who are the least ill expect the most attention. This is not the case in an Eastern suburb of London, some years ago, a medical man I have known accepted the appointment of visiting medical officer to the parish. The work was new to him and did not suit him. On one occasion he was sent for in haste to see a patient said to be very ill. He went, and after toiling up a lofty flight of stairs arrived panting at the top to find a poor woman suffering from an attack of catarrh. "Why, it's only a common cold," roared the doctor, "what did you send for me for? Take a quart of gruel and tallow your nose," and he turned round and went home. The patient complained of want of attention from the doctor, so did others. In three months the doctor was no longer the parish medical officer. He had resigned. The poor-law medical service is not suited to medical men who are troubled with over-sensitiveness, either for the patient's comfort or their own ease.

Dr. Cassells, of Glasgow, has just died. He was a rising man as an aurist and personally one whom it was a pleasure to know. He had been in indifferent health for some little time, and he was lame. He was the author of several aurals papers and the translator of Politzer's work.

THE SKIN AND CANCER HOSPITAL.

To the Editor of The Medical Record.

Sir: As the impression seems to be more or less prevalent that the New York Skin and Cancer Hospital has abandoned the care of cancer, we deem it desirable to have the error corrected. The aim of this institution from the first has been to undertake the study and treatment of this disease, and over one-third of its beds have, from the opening of the present building, been set apart for this purpose.

A tract of land of nearly one hundred and fifty acres has recently been secured, just beyond the city line, and the plans for cottage pavilions have already been drawn. It is proposed to erect some of these at once, and to add to the number as they may be required, so as to afford unlimited accommodations for each and every case of cancer requiring assistance. Both early cases for operation are received and those which are chronic and hopeless.

Our city hospital, No. 243 East Thirty-fourth Street, will be continued, and clinics held there as follows: For skin diseases, daily from two to four P.M. For cancer, on Monday, Tuesday, Friday, and Saturday, at the same hours.

I. D. BULKLEY, M.D.,
Geo. Henry Fox, M.D.,
J. F. JANVIN, M.D.,
R. F. Weir, M.D.,
E. L. Keyes, M.D.

THE BAY VIEW CHARITY HOSPITAL at Baltimore is now to have its medical service administered by the Faculties of two of the Baltimore Medical Colleges. A great amount of clinical material, heretofore wasted, will now be utilized.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from April 27, 1884, to May 3, 1884.

HERER, Anthony, Major and Surgeon. From Department of Texas to Department of the East. S. O. 101, par. 2, A. G. O., May 1, 1884.

HAPPERSON, J. C. G., Major and Surgeon. From Department of Texas to Department of the East. S. O. 101, par. 2, A. G. O., May 1, 1884.

BENTLEY, Edwin, Major and Surgeon. From Department of the East to Department of Texas. S. O. 101, par. 2, A. G. O., May 1, 1884.

MIDDLETON, PASSMORE, Captain and Assistant Surgeon. From Department of Texas to Department of the Missouri. S. O. 101, par. 2, A. G. O., May 1, 1884.

KOOPPER, E. A., Captain and Assistant Surgeon. From Department of the East to Department of Dakota. S. O. 101, par. 2, A. G. O., May 1, 1884.

DICKSON, J. M., Captain and Assistant Surgeon. From Department of the East to Department of California. S. O. 101, par. 2, A. G. O., May 1, 1884.

GIRARD, A. C., Captain and Assistant Surgeon. From Department of Dakota to Department of the Missouri. S. O. 101, par. 2, A. G. O., May 1, 1884.

GIRARD, J. B., Captain and Assistant Surgeon. From Department of Arizona to Department of the East. S. O. 101, par. 2, A. G. O., May 1, 1884.

HALL, J. D., Captain and Assistant Surgeon. From Department of Dakota to Department of the Columbia. S. O. 101, par. 2, A. G. O., May 1, 1884.

HALL, WILLIAM R., Captain and Assistant Surgeon. From Department of the Missouri to Department of Texas. S. O. 101, par. 2, A. G. O., May 1, 1884.

CUNNINGHAM, T. A., Captain and Assistant Surgeon. From Department of the East to Department of the Missouri. S. O. 101, par. 2, A. G. O., May 1, 1884.

McCRERY, Groose, First Lieutenant and Assistant Surgeon. From Department of Arizona to Department of Dakota. S. O. 101, par. 2, A. G. O., May 1, 1884.

COCHRAN, J. J., First Lieutenant and Assistant Surgeon. From Department of the Missouri to Department of Arizona. S. O. 101, par. 2, A. G. O., May 1, 1884.

BARROWS, C. C., First Lieutenant and Assistant Surgeon. Relieved from duty at Fort Grant, A. T., and ordered to report for duty at Whipple Barracks, A. T., relieving First Lieutenant E. E. Hopkins, Assistant Surgeon, who, upon being relieved will report for duty as Post Surgeon at Fort Grant, A. T. S. O. 31, par. 1, Headquarters Department of Arizona, April 21, 1884.

PHILLIPS, John L., First Lieutenant and Assistant Surgeon (Fort Warren, Mass.). Ordered to report for temporary duty to the Commanding Officer at Fort Preble, Me. S. O. 81, par. 1, Headquarters Department of the East, April 28, 1884.

CULVER, John M., Colonel and Surgeon (retired). Died at Norristown, N. J., April 26, 1884.

Official List of Changes in the Stations of Medical Officers U. S. Navy, for the week ending May 3, 1884.

HARVEY, H. P., Passed Assistant Surgeon, detached from Naval Hospital, Chelsea, and ordered to U.S.S. St. Mary's.
McCarthy, R. H., Passed Assistant Surgeon, ordered to Naval Hospital, Chelsea.
Waggener, J. R., Passed Assistant Surgeon, detached from U.S.S. St. Mary's, and ordered to U.S.S. Hartford.
Wise, J. C., Surgeon, detached from U.S.S. New Hampshire, and ordered as member of Board of Examiners at Annapolis.
Craig, T. C., Assistant Surgeon, promoted to Passed Assistant Surgeon.

**Medical Items.**

**CONTAGIOUS DISEASES—WEEKLY STATEMENT.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending May 3, 1884:

**LIQUOR GUTTAE PERCHE AND CHRYSOPHIC ACID.**—A five per cent. solution of chrysophanic acid in liquor gutt perche is a favorable application for chronic eczema. Auspitz uses a ten per cent. solution of chrysarobin for psoriasis.

**TURPENTINE IN DIPHTHERIA.**—In Germany and France the value of large doses of oleum terebinthinae rectificatun in diphtheria is being much discussed among therapeutics.

**APOMORPHIA IN INFANTILE CONVULSIONS, in doses of two minims of the two per cent. solution, has been successfully used by Dr. Edward Cockrell, of England.

**RUE DE DARWIN** is the name recently given to a street in Paris by the municipal authorities.

**CHLORAL HYDRATE in the TREATMENT of GASTRIC ULCER.**—Dr. Landon B. Edwards reports success in three cases from the use of the above remedy.

**CREASOTE in PHTHISIS.**—Drs. Coze and P. Simon have made a series of experiments to test the power of antiseptics upon the tubercle bacillus. Their results, though somewhat indefinite, justify the use of creasote in phthisis.

**IODIDE OF SODIUM.**—Dr. H. W. Berg, in the *Archives of Medicine*, urges the substitution of iodide of sodium for iodide of potassium, as being less injurious to health and nearly as effective therapeutically.

**A PATENT LIFTER.**—Dr. Hase, of Hanover, has devised an apparatus which is attached to the bed, and by which a patient can be lifted bodily into the air, allowing wounds to be dressed and bandages applied with great ease.

**THE SIXTH REPORTED CASE OF DOWNWARD and BACKWARD DISLOCATION of the ACROMIAL END of the CLAVICLE.**—Drs. Cassius D. Wescott, of Chicago, Ill., sends us a report of the following very rare case: "Mrs. K., aged twenty-six years, while going down-stairs made a misstep and fell three steps, striking against the baluster in such a way as to drive the acromion process of the scapula over the end of the clavicle. I saw her twenty-four hours after the accident. There was little swelling and no pain, except upon motion of the arm; notable absence of the usual prominence of the clavicle in its outer half, but by bending my fingers deep in the neck, I could outline the bone to its extremity, as it passed beneath the acromion, and demonstrate the absence of fracture. With the assistance of my friend Dr. Luce, the patient was etherized and I reduced the dislocation by putting my knee between the shoulders and drawing them forcibly backward. Some difficulty was experienced in maintaining the reduction, but pain was covered without 'impairment of function' and with no visible deformity. Prof. Edmond Andrews in the 'International Encyclopedia of Surgery,' says that only five similar cases have been reported."

**CAPSICUM in three-grain doses is recommended for Vidal for piles. Capsicum in a bolus of twenty grains is a favorite army remedy for acute alcoholism.**

**GELENIIUM in AFTER-PAINS.**—Dr. L. E. Holt reports a case in which fractional doses of geleniium, frequently repeated, relieved after-pains.

**LACING UP SCALP-WOUNDS.**—Dr. S. J. Bauker, of Fort Edward, N. Y., reports to us a case in which the method of lacing up wounds described in *The Record* recently was very successful. A man received a severe injury to the scalp, it being torn for five inches. Being washed, shaved, rubber plaster applied and laced, it healed nearly all by first intention.

**MISSING THE PATIENT.**—A physician in the country being called to see a patient at some distance, took his gun along in hopes to amuse himself by shooting a little on the way. A friend meeting him asked: "Where are you going, doctor?" "To visit a patient." "Are you afraid you will miss him?"

**A PERILOUS TOY.**—The so-called "serpent's eggs" of the toy-shops contain, says Dr. George Hay (Medical Times), from one to three-tenths of a grain of sulphoncyanogen, quite enough to kill a child if he should happen to swallow it.

**ONE GOOD EFFECT OF LISTERISM.**—Since the introduction of antiseptics into Germany and Austria, German surgeons no longer, it is said, wear mourning under their finger-nails.

**PROFESSOR VOLEMANN, of Halle, is said to be an Anglo-maniac and a dude, but a brilliant surgeon for all that.**

**MICROCOCCI OF SYPHILIS.**—Barduzzi confirms the views of Klebs, Aufrecht, Birch-Hirschfeld, and Bergmann, that a peculiar micrococcus exists in the lymphatic vessels and glands of syphilics.

**CARBOLIC ACID IS THE BEST DISINFECTANT FOR PHTHISICAL SPUTUM, according to the experiments of Drs. Schull and Fischer. A five per cent. solution will disinfect an equal amount of spumum.**

**HOW DOCTORS DISAGREE.**—In *The Record* of April 25th, Dr. Boyland, writing of Florida as a health resort, thinks it of doubtful value in phthisis, except in the very worst cases. Dr. M. J. Halloran writes to the Medical and Surgical Reporter that "the temperature is favorable and the mean relative humidity is peculiarly adapted to the treatment of all forms of pulmonary disease."

**TREATMENT OF HOARSENESS IN SPEAKERS AND SINGERS.**—M. Corson advises the placing in the mouth of a piece of borax, about two or three grains; it produces an abundant salivation and the voice becomes clear. He also recommends the use of a couple of grains of potassium nitrate in a glass of sugar and water, or an infusion of forty-six grains of jaborandi, and—shortly before using the voice—of a gargle with six or seven ounces of a decoction of barley, one to two drachms of alum, and two drachms of honey of roses.
ON THE

METHODS OF STUDYING THE BRAIN.

ABSTRACT OF THE CARTWRIGHT LECTURES, DELIVERED BEFORE THE ALUMNI ASSOCIATION OF THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK, FEBRUARY 2, 4, AND 5, 1884.

BY BURT G. WILDER, M.D.,

PROFESSOR OF PHYSIOLOGY, COMPARATIVE ANATOMY, AND ZOOLOGY IN CORNELL UNIVERSITY, AND OF PHYSIOLOGY IN THE MEDICAL SCHOOL OF MAINE.

(Continued from page 450.)

LECTURE III.—PART I. (Concluded).

PORTA (FORAMEN MONROI).—Perhaps no single feature of encephalic structure involves a greater number of morphological considerations or stands more in need of elucidation than the communications between the aula and the procoelie; certainly there is none which better illustrates the defects of the current methods of regarding, manipulating, describing, and figuring the brain, and the superiority of the methods advocated in the present course.

During the last hundred years the "Foramen of Monro" has been variously and incongruously described and figured as a single orifice and as two; as a horizontal passage and as triradiate; as oval, semilunar, and nearly circular; as a hole and as a notch; as an independent foramen and as merely one end of the "great transverse fissure"; as both visible and invisible from the meson; as named after two anatomists, father and son, of the same name (which name is spelled in three different ways); and, finally, as having, in the human adult, a purely imaginary existence.

Its existence.—In 1785 Alexander Monro, secundus, described the orifices in question. Since Monro, it is to be considered that the practitioners have either failed to observe the orifices at all, or have carelessly confounded them with the artificial communication between the "lateral ventricles" and the "third," which is produced by removing the cerebrum from the subjacent parts. But it seems to have been reserved for a distinguished anatomist and physiologist to exemplify the outcome of imperfect morphological ideas and faulty manipulative methods by a formal and public denial of the existence of the "foramen of Monro."

As reported officially in Le Progrès Medical for 1879, p. 483, there was read by M. Mathias Duval a paper entitled "De la non-existence des trous de Monro," in which that author proved, to his own satisfaction at least, that the foramina in question had no actual existence.

Notwithstanding the reputation of Duval, the dignity of the learned society before which his communication was made, the tacit indorsement of his views by the society and the journals which have printed the paper, and the fact that, so far as I know, no one besides me has publicly protested against them, on the present occasion I shall content myself with briefly enumerating the various methods in which the porta may be demonstrated upon the brain of man or of any other mammal, bird, reptile, or amphibian.

MODES OF DEMONSTRATION OF THE PORTA (FORAMEN MONROI).—1. Inflation.—If a brain is properly supported, as upon cotton, and air blown cephalad from the metacele, or any other cecilian division caudad of the mediomammis, the hemispheres will be coincidently expanded; or, if it be blown into one side of the procele, the expansion will be produced in the opposite hemisphere, especially near the end of the temporal lobe; if the brain be under a liquid, and the procele be opened, the air will escape as bubbles.

2. Injection of liquid.—A colorless liquid serves the same purpose as air, but, if it contains colored particles in suspension, the staining of the ceilian lining will enable the observer to determine the course of the liquid and the non-rupture of the parietes.

3. Injection of material capable of solidifying into a cast.—As stated in Lecture II., wax casts of the human ceiliae were made by Welcker in or before 1788, when he published his figures. Prior to my acquaintance with Welcker's paper, with the aid of Professor Gage, I had made plaster casts of the ceiliae of a cat and sheep, and the porta of the latter was represented on each side as a narrow neck. More recently, the ceiliae of the cat were injected successfully with the three compositions named in Lecture II. The only precaution to be observed is to refrain from using force.

Mental exposure.—This is the method usually employed; yet it is perhaps the least desirable, for the simple reason that the porta in man, the cat, and mammals generally, is invisible when the meson is squarely viewed. By looking obliquely, from caudal of the fornicoolumna, the porta may sometimes be seen as an interval between it and the thalamus.

Removal of the mesal wall of the precornu.—As indicated in "Anatomical Technology" (p. 456, Plate IV., Fig. 16), if the mesal wall of the precornu be removed by successive thin slices not quite reaching the termas and fornicoolumna, then a headed bristle or a probe may be passed from the cornu to the aula, or in the opposite direction.

Transverse section.—If transsections are made, they may be thick, excising in the alicular region (nearly dorsal of the chiasma), where they should be so thin as not to include the cephalic and caudal walls of the porta in the same slice. The best results are obtained by combining transsection with dissection after the plane of the porta is nearly reached.

Horizontal section of an alcoholic brain.—If either the dorsal or the ventral region of a brain be removed in successive slices, it will be seen that the porta at each side opens from the mesal aula into the corresponding lateral portion of the procele. This method is best applied when the ceiliae have been anilinized.

Lateral exposure.—The brain is supposed to have been hardened and the ceiliae anilinized. The lateral wall of the medicornus is first removed in successive slices, and its course followed by cutting obliquely until the precornu also is opened. The striatum is removed with the lateral wall of the precornu by an incision just lateral of its plane of junction with the thalamus. The porta then appears as a perfectly distinct orifice, through which a bristle may be passed into the aula and dissece, and, if the opposite porta be treated in like manner, into the corresponding cell.

Fresh dissection.—As a rule, as stated in Lecture II., the examination of any difficult feature upon a fresh brain should not be undertaken until skill has been gained upon alcoholic preparations. If the parts can be kept from tearing, the fresh brain has the advantages of displaying the natural color of the several portal boundaries,
THE MEDICAL RECORD.

[May 17, 1884.

and of yielding, to a certain extent, so as to exhibit their coro-

nary arc by a better light.

The porta does not appear at the meson.—In most fig-

ures of the mesal aspect of the hemiencephalon the "for-
amen of Monro" is represented by an oval or semicir-
cular dark spot. Judging from the preparations made or
examined by me, the porta is invisible when the human
meson is perpendicularly viewed, and I have yet to see it
in any other mammal. This is due to the obliquity of
the corresponding surfaces of the thalamus and the forni-
colunium.

Form and direction.—I have not yet satisfied myself
as to the precise form of the undistorted porta in the
adult human brain. It is certainly narrower than a cir-
cle and wider than a slit. Provisionally, it may be de-
scribed as an elongated, somewhat irregular ellipse.

The direction of the axes will, of course, vary with
the position of the brain, but, for convenience, the sides
may be regarded as cephalic and caudal, and the ends as
dorsal and ventral.

Dimensions.—In an adult human brain, the colloie of
which was injected with alcohol, the length of the porta
was measured from point to point, 4.5 mm. in the brain
he employed. Its width is more variable and less easily
determined, but seems to vary from 1 to 7 mm. The points of reflection of the endyma
upon the plexus are not always directly opposite, so that
the fornical or the thalamic border of the porta may be
longer than the other.

The length is of the whole brain, the porta is much
larger in the cat than in man. In the former its
width varies from 0.5 to 1 mm., and its length from 3 to
4 mm. Its boundaries are essentially the same as in man
in all mammals examined by me. Its limits are most
satisfactorily exhibited in vertebrates where the rima is
not formed.

Superiorities.—Passing over the confused or erroneous
descriptions of earlier works and some recent ones, each
porta is correctly described in Quain and Gray, as be-

tween the anterior end of the thalamus and the correspon-
ding pillar of the fornix. Its caudal boundary is the thala-
mus, its cephalic boundary is the fornicolunium, and its
ventral limit is formed by the continuity of these parts.

Here the description ceases. So far as I know, the
dorsal limit of the porta, the upper end of the foramen
of Monro, has never been indicated outside of my pub-
lifications, nor, indeed, does any other anatomist appear
in have been impressed with the necessity of determining
what that limit is, or even of ascertaining that one exists.

That the porta is a completely circumscribed orifice is
manifest; but the site of its entrance into the fornical en-

closure, or that of the material being injected per larum as described in

Lecture 11. The manner of its circumscription at the dorsal
end may be determined by careful dissection in any of
the ways above indicated. Since the ventral end is
simple enough, it may be opened from any direction.

The interval between the thalamus and the fornix will
then be seen to be the porta, occupied by a fold of pia,
the portiplexus. The ventral border of this plexus hanga
free, but, if the syringotomy or some similar instrument
of exploration is employed, and the plexus carefully
pushed aside, first one way and then the other, it may
be ascertained that the smooth endyma which lines the
porta, like all other colian divisions, is reflected from
the fornix upon the cephalic face of the plexus and from
the thalamus upon its caudal face, and that in this way
the dorsal end of the passage is closed as really and as
effectually as if the plexus were not there at all, and the
endyma were continued directly across from the fornix
to the thalamus, as presumably it did in the embryo.

The porta, then, is a completely circumscribed orifice,
a fornix, and one end are bounded not only by endyma but
by substantial masses, the dorsal end is limited only by the
endyma as it is reflected upon the intruded plexus.

The porta and rima are different and distinct.—This

follows from the foregoing description of the former, and
from the now generally accepted description of the latter.
The porta is a primary, fundamental, and essential com-

munication between the mesal and lateral parts of the
proplexus; the rima is merely a thinned-out line of the
medicoronal parietes through which the pia intrudes as
the proplexus, and the latter hangs within the cornu just
as the portiplexus hangs within the porta.

LEAD PARALYSIS IN CHILDREN.

BY HENRY D. CHAPIN, M.D.,
ATTENDING PHYSICIAN TO OUT-DOOR DEPARTMENT BELLEVUE HOSPITAL
CHILDREN'S CLASS.

The rarity of lead paralysis in early life is shown by the
statistics of Tanquerel des Planches, who found among
one hundred and two cases only two below the age of
twenty years. I have had under observation for the past
years two cases, the first of which was occurring in
children who came to Professor J. Lewis Smith's clinic.
The histories were begun in the latter part of May, 1883.

Robert W., aged five years, and Thomas W.,
age seven years, had always been healthy and had never
had any disease except pertussis. The first thing wrong
with both was noticed was that just before New-Year's day,
1883, Thomas began to complain of stomach-ache. This
was not very severe at first, and on the following day
Robert began to suffer from similar pain. This grew
more severe in several days, and lasted about four weeks.
The pain was not continuous; at times it would grow
worse, but it was never severe enough to double them up.

Occasionally they would have a slight feeling of crying,
and ask for water. They now began to complain of pains
and soreness in the legs, and were averse to walking.

One morning in the latter part of January their mother
found they could scarcely get out of bed, and when put
upon the floor they could with difficulty sustain the
weight of the body. This soon increased to almost
complete paralysis. After a few days they began to get
better, and could soon walk with difficulty, but the in-

procedure did not increase beyond a certain point, as
their gait continued uncertain. They remained fairly
well for a month or more, when they were again seized
with abdominal pains and an additional loss of power is
the lower extremities. They slowly improved from this
state, but, for weeks, were unable to move. Altogether,
the state of partial paralysis of the extensor muscles.

About the middle of May they were seized with a third exacerbation
of symptoms, which were severer than the previous ones.
The paralysis of the lower limbs was more complete than
usual, and the mother noticed that the older boy could
drop objects well.

It was noticed that the cases came to the clinic.

Thomas had a blue line at the junction of the incisors
with the gums in the lower jaw. He was unable to raise
his hands, and could with difficulty extend the second and
third phalanges of his left hand, and was utterly unable
to extend these phalanges in the right hand. The supin-
ators were not affected. He could walk with difficulty,
and his mother said she had hard work to get his shoes
and stockings on, as his toes bent under so. His eyes
were normal, and he was passing water freely. Robert,
the younger boy, suffered from a milder grade of symp-
toms. He had no blue line on the gums, and his upper
extremities were not affected.

On examining the premises in which these children
lived, I found their father was a painter, and that for two
years some remains of paint had been kept in a closet
immediately adjoining the sleeping-room of the children.
There was some white lead and turpentine, and a few
bottles with coloring matter. At Christmas the father

He continued slowly to improve for the next month or so, and is now quite well.

The connection of lead with this case may have been simply a strange coincidence, but I have been interested in seeing that Seeligmuller, in Gerhard’s ‘‘Handbuch der Kinderkrankheiten,’’ quotes Duchenne fils as having cited a case in which a child of three years got spinal paralysis by drinking water contaminated by lead. In fact, I think it is very reasonable to suppose that some of the cases of spinal paralysis in children are caused by lead. We know that at this period of life the spinal centres are extremely active and susceptible, and there are many ways in which children may be exposed to the toxic influences of lead. It is also known that lead is often present in the spinal cord.

A Contribution to the Pathological Anatomy of Lead Paralysis,” Dr. W. R. Birdsall has cited an instance in which an autopsy was made in a case of lead paralysis, and a mild grade of subacute myelitis was found to exist. The same writer has collected records of fourteen cases in which autopsies were made and the spinal cord examined, and in six of them changes were found to a greater or less degree, and changes similar in character, that is, a subacute myelitis in different regions. Again, he states that because changes have sometimes been found in the muscles and muscular nerve-branches before they could be detected in the cord, it is not safe to consider this as a conclusive argument against the theory of a central origin of the changes.

Thus, interference with the nutrition of centrifugal nerves and organs is more apt to be caused by impairment of function in the spinal centres than the former are to react upon the latter. There are also clinical considerations tending to show that lead paralysis is frequently, at any rate, of spinal origin. Thus, Ross calls attention to the value of the spinal reflexes in groups, as they are associated in their actions, and not according to the distribution of a particular nerve, such as the musculo-spiral. The mode of invasion of lead paralysis also corresponds to that which occurs in infantile paralysis and progressive muscular atrophy, both of them spinal diseases, and differs from that of paralysis of peripheral origin. In the “Transactions of the American Neurological Association for 1882,” Dr. Seguin is mentioned as reporting a case in which the symptoms of lead paralysis were absolutely identical with those of poliomyelitis, and this was but one of a number of cases he had seen in which it was impossible for any neurologist to make a diagnosis between the two diseases.

As seen at the present time, with somewhat atrophied lower extremities, they bear a close resemblance to the common spinal paralysis of infancy and childhood. In fact, I am not sure but that lead may sometimes form a factor in paralyses of children that are called by other names. An interesting case that recently came under my observation may be cited in this connection. Francis S., aged two years and three months, a healthy and well-nourished child, was brought to me with a cellulitis of the thumb and adjacent part of his right hand, due to the irritation of a splinter. I made a free incision and ordered a poultice. The mother did not appear with the child for some weeks, when she brought him to me with his lower extremities paralyzed. I found that after continuing the poultice for a few days, she had called in another physician, who had ordered a solution of acetate of lead (3 ij. Oj.) to be constantly applied to the raw surface. She had faithfully followed his instructions for a week, using wet cloths, and at times keeping in the hand dipped in the solution, when she brought him to me with his legs. The paralysis increased gradually until in three or four days it was complete. When I saw the boy, a week or so after this, improvement had begun to take place, but he was still unable to stand. I could not tell whether he had pains in his legs, as he was very fretful on every occasion I saw him, and cried most of the time.

Veratrine Treatment of Pruritus.—Dr. Cheron highly recommends the following ointment where the pruritus is localized to the axilla, the vulva or thighs, or the abdomen. He declares that if this pomade is applied morning and evening, the affection will yield to its influence. Veratrine (grs. iij.; axungeo, 1 1). When the pruritus is general over the body, he advises the veratrine to be given internally in pills. Veratrine, one-third grain; liquorice powder, q. s. For forty pills, two to six a day.
THE MEDICAL RECORD.

BY ROBERT T. MORRIS, M.D.,
LATE HOUSE SURGEON TO BELLEVUE HOSPITAL, NEW YORK.

As ordinarily treated, burn cases give very little satisfaction to the practitioner, and most of the physicians with whom I have talked on the subject express a decided dislike for them. If we analyze this repugnance we shall probably find that it arises from the expectation of the necessity for frequent dressings and from the supposition that profuse suppuration and disagreeable odors cannot be avoided in severe cases. In fact a good many persons seem to be able to estimate burns in terms of smell only. The patches of weak granulations which may remain for months in the midst of extensive scars also have a tendency to destroy the doctor's love for the beautiful in the way of reparative processes.

Thanks to the antiseptic method of wound-dressing, it is now possible to do away with almost all of the disagreeable features which were formerly connected with the treatment of an extensive burn, and such a case may be made to arise from the insignificance of a nuisance and to assume the dignity of an object of sanitary interest. Frequent dressing is not only uncalled for but is very injurious. Odors need not be produced, and as for profuse suppuration, that may be relegated to the past as a pathological curiosity. Nature need not become discouraged and refuse to help the timorous epithelium of the skin to pass over the stepping-stones of her granulating surfaces; and repairs may be made to go on so rapidly and with such vigor that lagging seldom occurs.

The constitutional treatment in severe burn cases offers a wide field for observation, and few suggestions are made in this article, because even with a long list of histories at my disposal, it is difficult to present any particular classification.

The classification of the varieties of burns into six degrees is Dupuytren's, and is probably the best descriptive classification extant.

Burns of the first degree, in which the skin is hyperemic but is not destroyed at all, are usually of not much importance, but the stinging, burning pain always calls for relief, and this may be promptly and completely relieved by the following method: 1. Towel any convenient soft fabric into strips a couple of inches wide, and spread them thickly with a mixture of carbonate of lead and vaseline in equal parts. 2. After the strips of painted cloth have been applied smooth over the burned surface cover the whole with a piece of gutta-percha tissue or cloth, and this makes a free moisture, and the carbonate of lead is mixed with vaseline there is no danger of absorption, but if any animal or vegetable oil should be used, there might be some risk in applying this dressing. I have, however, used ordinary white paint on several occasions without getting any symptoms of lead poisoning. The gutta-percha tissue prevents the dressing from drying, and adds an element of neatness which is quite important.

In burns of the second degree, where the cuticle is destroyed, the antiseptic method of wound treatment comes into play, and the proper management of these cases will insure the most pleasing results.

If a small portion of the body have been burned, as, for instance, the forearm and hand, the plan to be carried out would be as follows: 1. Anesthetize the patient. 2. Pull off all of the cuticle which is loose, and all that has been raised in blebs and vesicles. 3. Lay the arm on a towel which has been wrung out in bichloride of mercury solution (1 to 2,000), and carry a rubber blanket underneath all; arrange the rubber blanket in such a way that blebs can be made to run into the receptacle. 4. Scrub the burned area and the skin in its vicinity very thoroughly with a soft brush and at the same time bathe the parts copiously with bichloride of mercury solution (1 to 2,000) or with a solution of salicylic and boric acid in the proportion of one grain of the former and six grains of the latter to the fluid ounce of water. 5. Cover the burned surface everywhere with strips of protective oiled silk which have been stored in an antiseptic solution. 6. Sprinkle iodoform along the margins of the strips of protective. 7. Place several layers of carbolized or sublimated gauze over the protective and cover still further with a thick wadding of borated cotton placed between layers of antiseptic gauze. 8. Apply snugly a carbolized roller bandage. 9. Keep the bowels open. 10. Quiet constitutional disturbance with bromide of potassium and chloral hydrate. The dressing should not be disturbed until the eighth day, and then it is removed it will be found that everything is completely healed and no further treatment is necessary. Of course the brush which was used to be mixed in an antiseptic solution, and the surgeon's hands must be most carefully prepared before he touches the case.

Dr. Woodward, of Bellevue Hospital, who treats burns scientifically, tells me that he has seen two cases in which the bichloride of mercury wash caused a great deal of pain, and on account of his experience he always uses salicylic acid and the combination which is commonly used, in the place of the bichloride of mercury. In my own cases I have never seen any disagreeable result from the employment of the latter.

In another class of cases, where a very large surface of the body has been burned to the second degree, we shall often find it impossible to use any of the dressings which have just been described, and the subnitrate of bismuth treatment, which stands next in value, should be applied as follows: 1. Anesthetize the patient with chloroform. 2. Remove all clothing, and whatever may adhere to the burned surfaces. 3. Wash all of the injured area with an antiseptic solution. 4. Apply an all loose cuticle, and as fast as it is removed sprinkle the parts beneath thickly with subnitrate of bismuth. 5. Cover lightly with a single layer of soft cloth or sheet-lint. 6. Remove the cloth covering once or twice daily, and wherever any of the subnitrate of bismuth has been loosened by the discharge sprinkle more of the powder on the place. 7. During the period of depression and congestion, sustain the heart and relieve the shock of the nervous system by the use of hypodermic injections of morphine. 8. During the period of inflammation, support the heart and aid the inflamed kidneys with digitalis. Quiet the disturbed stomach with belladonna, and give refreshment in the shape of acid drinks. Feed the patient by the rectum, and use perhaps the injection of the bladder. 9. The dressing of reaction continue feeding by the rectum, and for the first time cause a free movement from the bowels, using a saline cathartic. 10. When reaction is well established, commence to stimulate the patient with sherry wine, and gradually coax the stomach to bear light, varied diet.

In a very extensive burn there will very likely be considerable dermatitis in the vicinity of the burned portion of skin, but this is a matter of no significance and will pass away in a short time. The discharge from the burns will be so small in quantity that it is very easy to keep the entire injured surface covered with subnitrate of bismuth, and the neatness of this method of treatment will make the nurse your friend.

I have recently treated a case of burns of the second degree, where considerably more than one-third of the body was involved. The head, trunk, legs, and arms were denuded of cuticle in large patches, and the patient suffered from delirium tremens for a week. This patient recovered completely, with hardly a scar, and at no time during his confinement in the hospital was there enough discharge produced from the wounds, or to call for any dressing for the reception of the discharge from his wounds.

In this connection it may be well to state that I had five burn cases in one ward at one time, and all of them...
were very severe. The patients were burned to the second, third, and fourth degrees, but so little odor was given off that no one would have suspected that there was a single case of the sort in the ward.

When we have to deal with a burn of the third degree, in which the true skin is destroyed through a part of its thickness, the following course is the best one to be pursued: 1. If the burn is small, including a few square inches only, apply the antiseptic dressing which is used for limited burns of the second degree. 2. Do not remove the dressings until the end of the third week, and then if the slough has not been absorbed pull it away and irrigate the granulating surface with an antiseptic fluid. 3. Hurry the reparative processes by doing a plastic dressing; then, when the latter is to be done, graft according to the following directions: Shave and scrub with an antiseptic solution any portion of healthy skin which you may choose. Raise small pieces of cuticle from the cleansed skin, on the point of a needle, and cut them away with a sharp scalpel. Place these severed pieces of cuticle near the margins of the granulating surfaces. Carefully lay a piece of antiseptically prepared protective oiled silk over the grafted area. Over the protective place eight or ten layers of sheet lint, which have been wrung out in a saturated solution of boracic acid. Cover all with a piece of gutta-percha tissue or any other waterproof material. Change the dressing on the third or fourth day, and after waiting six days the highest grade of saturated boracic acid solution, add more grafts and dress as before. If no attempt is made to improve upon this method of grafting almost every little piece of cuticle will "catch."

When we have extensive burns of the third degree they are almost invariably found to be associated with burns of the fourth degree, more sensitive. To illustrate, the following two of our methods of dressing. At first apply the same dressing which we should apply in limited burns of the second degree, and allow it to remain undisturbed until a odor of beginning decomposition is noticed. This odor will first appear about the twelfth day, and calls for immediate attention. A serious discharge may make its way through the dressings before we wish to change them, but by sprinkling iodoform over the moist place and by bandaging on an additional pad of borated cotton, or sublimated gauze, or a peat bag, we can shut off the entrance of spores which would cause early decomposition.

When it becomes necessary to change the dressing, remove the sloughing under antiseptic irrigation and sprinkle the granulating surface thickly with subnitrate of bismuth. Where sloughs remain attached rub them full of iodoform and subnitrate of bismuth, and then allow the whole wound to dry; a single layer of sheet lint being all that is required for extra covering. The sloughs will soon become of a horny consistence and they may be trimmed off from time to time. Bismuth should be sprinkled over the exposed surface beneath as fast as the sloughs are removed. Do plastic operations or grafting early and give the patient stimulating diet.

Burns of the fourth degree in which the true skin is entirely destroyed should be treated by the dry method from the very first: 1. Rub the burned surface full of subnitrate of bismuth and iodoform, and continue doing this as long as any moisture remains. 2. Cover with a single layer of soft cloth or sheet lint. 3. When the dead skin has become dry and hard, and begins to slough away, aid the separation by trimming with scissors, and complete the case as if it were one of the third degree.

Burns of the fifth and sixth degrees do not call for attention in this article.

In closing, I should like to suggest that burns be classified among the wounds, so that instead of five varieties of wound we shall have six: namely—contused, lacerated, incised, punctured, poisoned, and burned.

HYPERÆSTHESIC BRAINS.

BY J. T. SEARCY, M.D.,
TURCULOPAH, ALA.

The following physiological principle so pervades the rest of this article that I prefer to begin with its statement.

Action in any of the organs or structures of the body always occasions metamorphosis of structure—disintegration of structure. In natural, functional action the metamorphosis is a disintegration that the structure has the faculty of reintegrating promptly from the nutritive fluids in contact with it. How this faculty has been obtained or acquired it is not in the province of this paper to discuss, but it accepts the proposition that this is an established fact. To repeat: functional action disintegrates, but because it is functional or an established mode of procedure, the disintegration is readily reintegrated from the pabulum. This process we call nutrition.

All nerve-centres have awakened, produced in them by the currents of afferent action, coming into them from the periphery, certain receptive actions; and further, these centres have the faculty of emitting outgoing currents of action adjusted by them to the incoming currents.

These receptive, adjusting, and emissive actions are common to all nerve-centres, but like the centres they vary in grade according to the variety, the kind, or complexity of the adjustment required.

The receptive action in the body is that of sensation, which high grade of functional action is the faculty only of a proportionally high grade of structure, namely, the high brain; and here it is principally confined to the cortices of the hemispheres. There is probably no definite line of demarcation in the nervous system between those actions that are sensitive and those that are not sensitive. The gradation is uniform. The hemispheres have the highest grade of this function—sensation—peculiarly their own. The difference is altogether one of grade.

In the high brain functional action makes metamorphosis of structure, which disintegrating, changing action, makes, constitutes, is sensation. The high brain has this faculty—how obtained we don't discuss. The normal, functional, receptive action here as elsewhere in the body is a disintegration that can be reintegrated from the nutritive fluid. To be functional the action has to be the established mode of procedure that disintegrates only in the mode or way that can be reintegrated.

In the high brain not only the receptive actions produce this sort of metamorphosis called sensation, but all the actions of the sensorium disintegrate in this way, and, to extend the same idea of the term further, are sensated. The metamorphosis produced in this high structure by all its actions constitutes consciousness, a broader term than sensation, which is usually confined to the receptive actions.

The term sensation is usually limited to the receptive acts produced by the currents incoming from the sense organs. Further, we can say there are higher grades still of reception than the action awakened in the sensorium by afferent action simply produced in the sense organs by external action. We have means of intercommunication between individuals by which are transferred, through the sense organs and the sense organs only, through the channels of afibril—fibris, by means of written or spoken language, intellectual perceptions which we may say are receptions, or transfers, of the brain acts (thoughts) in this way from one individual to another. The necessity of the transfer always is that the second individual has to be capable of perceiving and himself, else he cannot perceive it or perform it. I digress to mention this higher grade of reception, intellectual perception, which we have not time to discuss.

All the actions of the sensating brain—the receptive, the adjusting, and the emissive efforts—are sensated. The organ has a sense, a metamorphic capacity of change.
called sense, of all its actions, which constitutes consciousness. How this high faculty is obtained we don't discuss. The sensorium is the ego.

With this sort of an understanding of the sensating functions of the high brain, we can probably arrive at some better idea of what its abnormal sensations are. The Greek word αγνωσία means sensation or feeling; by prefixing to the different prepositions, ἀγνωσία, over or above; ἀγνώσις, under; ἀγνωσία, alongside of; and α or αν, privative, we obtain several derivative words that designate varieties of sensation.

Parasesthesia designates a condition of brain in which the faculty of sensation is normal; hyperesthesia designates a condition that is over-sensitive; hypoesthesia, one that is under-sensitive, dull of sensation; and anesthesis, a condition where the functional faculty of sensation is lost.

A parasthesis brain is one normally sensitive; a hyperesthesia brain is one over-sensitive; hypoesthesia is dull of sensation, and an anesthetic brain has lost the faculty of sensation.

In a parasthesis, normally sensitizing brain the incoming currents of action, in producing sensation (and not in loss of sensation), disintegrate in such a degree that the reintegration is readily done. The "tone" of action is good, prompt, and efficient.

In a hyperesthesia brain the disintegrating metamorphosis is in a structure too easily disintegrated, too sensitive. The reintegration is for the same reason less prompt — the "tone" of action is poor.

In a hypoesthesia brain there is less functional action for some reason, less disintegration, less sensation.

In an anesthetic brain there is a loss of functional action, no disintegration (functional), no sensation. It has always to be functional (accustomed) disintegration to be sensation, of the kind that can be functionally reintegration.

Here, I think, we might venture on a definition of pain—that it is excessive functional disintegration of the sensorium. An excessive, abnormal disintegrating metamorphosis, from some cause or other, going on in the peripheral tissues at the distal extremity of an afferent nerve, produces similar disintegrating action in its axis cylinder, and is transmitted to the high grade of sensitizing brain structure and produces excessive disintegrating metamorphosis there; which kind of action constitutes what we call pain.

A great deal has been written of late years on the "nervousness" of the day. A number of names have been suggested to designate the condition. We hear a great deal about the great weight of such troubles and about their proportional increase of late years. There are said to be in our day and generation a large number and an increasing number of persons (of brains) to whom I prefer to give the generic name of hyperesthesia. I prefer hyperesthesia to neurasthenia as better designating the true condition. Such brains, in fact, and per se, are over-sensitive, are painfully sensitive.

The incoming afferent currents of nerve-action that reach them, which they ought to be capable of receiving and adjusting without discomfort or pain, without excessive disintegration, they are incapable of receiving. Physiologically speaking, the receptive acts are ahead of the adjusting and the emitting ones. Anatomically and physiologically, adjustment and emission are built up upon and are the results of reception; so that when the receptive faculty is defective or faulty we have defective and faulty emissive acts. Objectively considered, we are only acquainted with the emitted acts of the brains of other persons, and because we have been thus accustomed only consider them objectively. The terms nervousness and neurasthenia have been used to designate only the external exhibitions of a condition of the nervous system or the brain; they are usually used to include only its emitted acts. The receptive function is prior to all, and physiologically considered is first at fault; the rest come as results from it. This is the rule—there may be exceptions.

The condition usually known as neurasthenia, or popularly as nervousness, is therefore, more properly speaking, hyperesthesia. Hyperesthesia is a term more properly designating the physiology of the condition in the majority of cases.

My own observation leads me to confirm the statement made by the highest authorities that this is a largely prevalent deficiency or defect in brain function, and that it is on the increase. Statistics seem to show that the graver forms of brain failure exhibited in the multiform varieties of insanity and idiocy are on the increase. I think if we could have means of detecting and recording the milder forms as readily as the graver, they would soon show a larger proportion. This seems to be a very general opinion among neurologists.

I propose to consider briefly some of the causes of this very general trouble. How prevalent it is, and how much (if any) on the increase, we can leave for further observation. I think, from the standpoint I have taken, we can discuss it more intelligibly and scientifically than in any other way.

First.—Among the causes of acquired hyperesthesia I mentioned pain or worry. A parasthesis brain, normally proficient in its action, has a receptive faculty which, as a result of exercise and practice, individual and ancestral, is accurately, properly sensitive. Its proficiency, its perfectness, is shown thereby. A sensate, properly sensitive brain is not hyperesthesic. When from any cause the structures in the periphery are abnormally disintegrated, and disintegrating action is transmitted to the sensitizing brain, producing pain, if the adjustment cannot promptly be made to correct or remove the cause, there necessarily results a disturbed condition of brain leading to pain. "Worry," "anxiety," "alarmed," "worried," "tense," "tired," like the like, which conditions are always disintegrating, and hyperesthesia results. A "happy" state of brain exists when all the internal and external conditions of action are equilibrated. Evidently, then, a parasthesis brain much more readily and efficiently adjusts to external or internal disturbances than an hyperesthesia, but the circumstances can be so excessive of internal (painful) or external (worrying) disturbances, that no matter how parasthesis the brain may be, it will be unable to promptly adjust to them, when as a sequence it will become hyperesthesic; but, we can add, because of the same original proficiency or "tone" of action belonging to it in the first place, on the removal of the disturbance the brain will recover its original proficiency and efficiency. The disintegration may set it down as a distinguishing characteristic or mark of a parasthesis brain not to be easily pained or worried, and of a hyperesthesia brain to be easily pained or worried.

Second.—A cause of acquired hyperesthesia can be over-brain-work. Brain-tire or fatigue means hyperesthesia. Exercise up to capacity makes development, i.e., up to the point of the disintegration not exceeding the re-integrating capacity. During enfeebled conditions of system, to attempt to make the enfeebled brain work up to even its usual capacity does harm. The sick man ought not to do brain-work any more than other body-work beyond easy capacity. When respected, the sensations are a good guide to go by. The necessity of the case for an enfeebled man to keep up his usual or any unusual brain-work will always injure his brain, in the same way that it would other structures. "The effort sense" of all brain-work is the guide. In excess of work or action this "effort sense" of all the brain acts is painful, and means a hyperesthetic condition. Fatigue is.

Third.—The constant use of hypothoetic drugs produce the condition of acquired hyperesthesia. I prefer the term hypothoetic to designate these drugs. The terms anodyne and anesthetic denote a deeper degree of the
effect of these agents than is usually sought after or obtained. Hypoesthetic is a better term.

Hypoesthesia of the sensorium is, so far as immediate consciousness goes, a pleasant condition, even if produced artificially. The brain is "happy" when in a condition of rest ("oblivious," "insensible" to), not affected by incoming currents of action needing adjustment. In a normal brain, one paresthesia, as the condition of perfect adjustment is approached (we may say it is never perfectly obtained) there is the consciousness (the all-over sense) of equilibrated security. There is a "happy state of equilibrium." Even if this condition is obtained by the use of a drug it is pleasant.

The exceedingly delicate colloidal matter of the high sensorium is so delicately tuned up to a condition of harmony and the effect of hypoesthetic or anesthetic drugs. Take into the circulation they do not so easily "hydrate," "coagulate," "thicken," "dense," "paralyze" the cellular structures of lower orders in the body, nor even so easily the lower grades of nerve-centres, but the sensorium is peculiarly exposed and susceptible to these effects.

There is a long list of such medicines in our materia medica, and because sensations play such a part in "the complaints" of men they are in most frequent and ready use—much too frequent and too ready use. Small doses, small amounts, taken into the circulation produce degrees of hypoesthesia; while large doses produce an entire arrest of functional disintegration, or sensorium. The one is an abated, a slightly cessoed condition of functional action; the other is a complete cessation.

Whether the true modus operandi is described by their "hardening," "coagulating," "stringing" action or not, the evident effect of all such agents upon these structures, as evidenced by the sequences of their constant or excessive use, is hypoesthesia. The senile union with these delicate structures they tend to disintegrate, not functionally, but chemically, physically, and after their hypoesthetic effect is passed off a paresthetic brain is made more or less hyperesthesis, and one hyperesthesis is made more so.

A number of such drugs are in very common and general use among men, and their consumption is increasing. For instance, to obtain the hypoesthetic pleasure produced by them, men consume immense and yearly increasing quantities of tobacco and alcohol, to say nothing of a number of other such drugs. To consider the quantities of these two drugs alone used in this day and generation affords a ready explanation for a large portion of the hyperesthesis, which has been explained of in modern civilized society. By the frequent use of either of these agents a person originally paresthetic can render his sensorium so hypoesthetic that unless his hyperesthesis is constantly overcome by the "hardening" effect of the drug, he is uncomfortable. Even using such a drug as tobacco, which is much less toxic than the opium or alcohol, there is kept up a constant hyperesthesis unless the brain is kept constantly hypoesthetic by it. If we leave off the introduction of the drug for a while, until the brain-structure has time to rid itself of its union and contact, we at once find the real condition is one of hyperesthesis. The sensorium is over-sensitive. It is pained with receptive acts to which it ought to be fully capacitated, and even the effort sense of all its brain-work is painful. Unless "hardened" by the drug, it is irritated, warned, pained, easily fatigued. I am perfectly willing to admit the remedial value of such drugs when needed and when judiciously administered.

I have shown that pain or worry is injurious, and the fatigue of excessive work is also injurious, both mean excessive disintegration. To remove the cause of the pain or the worry or stop the excessive work is the indication for treatment, and ought always to be done when it is possible. Sometimes this indication for treatment cannot be followed when to harden the structure, or in whatever way you suppose it is done hypoesthetic the sensorium, is the indication; it may be necessary even to anesthetize it. You can in this way prevent the injury of the excessive disintegration of the pain and the worry, or even the fatigue; but you are dealing with a two-edged tool. The traumatic effect of the drug should always be remembered, and its administration dropped as soon as possible. Its sequelae can be less than the other at times, but the fact that it has sequelae should not be forgotten.

I am not decrying or denouncing the judicious administration of these drugs as medicines, as indicated above, but am declaring that their constant and indiscriminate use, simply for the pleasure of their hypoesthetic effect, by a large number of persons, is attended with widespread and broadcast harm. Hyperesthesis is a sure sequel to be acquired by this abuse of their use as luxuries. The ignorant are always led by immediate pleasurable sensations, without knowledge of their sequences, or of accumulated wisdom of others. It is time, I think, some instruction should be given on this point. There is a vast amount of ignorance as to the sequelae of such concoctions.

I have been speaking heretofore of acquired hyperesthesis. There is a large proportion of the hyperesthesis of the day transmitted or inherited.

Under the laws of heredity, nothing seems more positive than that "like begets like." Particularly this seems the case with respect to certain pain-sensations. A hyperesthesis is liable to transmit hyperesthesis. I think a little observation will confirm this statement. The parent ordinarily or usually paresthetic is liable, during a period of acquired hyperesthesis from which he may recover himself, to transmit a permanently hyperesthetic brain to his offspring. For instance, the hyperesthesis acquired during a period of pain, or of worry, or of overwork, or by the use of a hypoesthetic drug, is liable, through a temporary condition in the parent, to be transmitted as a permanent state to his child. When both parents are hyperesthetic liability is very strong. I think very cursory observation will show all this.

When, as is a frequent occurrence, the one parent, the mother, is a "worried" hyperesthetic, and the other, the father, a hyperesthetic from the use of hypoesthetic drugs, the combination is a very dangerous one for the offspring; and simple hyperesthesis is not always the transmitted defect, but more serious conditions, exhibited by all the phases of idiosyncrasy, crankiness, insanity, epilepsy, which are not of sensations alone, but of capacity for adjustment.

Why there should be any increase of the proportion of hyperesthesics in the present day or generation I don't think is explainable satisfactorily by the statement that there is more pain, more worry, more overwork to-day in the world than there have always been. That this more civilized generation has reason or cause to be pained more, worked more, or worried more than the preceding I think is very doubtful, since the very object of the "struggle that civilizes" is to rid individuals of these causes of distress. If there is any increase, I think the abuse of the use of hypoesthetic drugs, as luxuries, so largely prevalent will come in as a principal item in the reckoning to account for it.

If I have properly drawn attention to that condition of brain I designate as hyperesthesis, and if I have properly pointed to the causes of this very prevalent condition, my object in writing this article is accomplished.

A New Method in Adherent Placenta.—Dr. J. Feld, of Kansas City, reports in The Clinique that in six cases of adherent placenta he has saved the woman by pumping cold water through the umbilical cord. In one case the patient was in convulsions when the after-birth came away.
LEPROSY IN THE VIRGIN ISLANDS.

By B. BONN, M.D.,

ACTING MEDICAL OFFICER OF THE VIRGIN ISLANDS, ROADTOWN, TORTOLA, V. I.

The following cases have occurred in my practice here:

CASE I.—Tubercular leprosy.—William H., aged thirty-nine years, colored, born in the West Indies, fisherman, lives at Virgin Gorda, Virgin Islands, W. I.

Family history.—His father, a Cornish man, went to Virgin Gorda to work the mines. He died of bronchitis at an advanced age at this place. William's mother was a native of Virgin Gorda. She died of consumption. Her sister, aged seventy years, has survived her, and is free from all skin affections. William's sister, a healthy woman of thirty-seven years, takes care of him.

Previous history.—When William was fifteen years old he spent two months at St. James, a small island in the Virgin group. On this island there lived a boy who had tubercular leprosy, in the early stage of ulceration. These two lads had free intercourse with each other, went out in the same fishing-boat, and, it is said, slept in the same bed. This was the only leper with whom William ever came in contact. He has always lived at Virgin Gorda, making occasional trips to St. Thomas, W. I., where he has been much longer than two days. He acknowledges having had gonorrhea many years ago, but denies syphilis.

Present condition.—Seven years ago the disease first manifested itself. He had the usual constitutional symptoms, followed by spots and tubercles on the face, ears, and hands. Next his fingers and toes swelled. At present his face is covered with numerous tubercles. The superciliary ridge is swollen, the forehead is deeply furrowed, the eyebrows and cilia are entirely absent; the lobes of his ears are very much enlarged; the lobe and alae nasi are the seat of large tubercles. Smaller tubercles, some ulcerated, are scattered on the uvula, pharynx, faucies, and mouth. His voice is hoarse, and his beard is lost. He presents a hideous figure, with the distal phalanges of his fingers and toes are ulcerating. Large blebs form on the soles of his feet. These are very painful, but cease to be so after rupturing and emptying their contents. His trunk is entirely free of skin lesions. He says that some time ago he had intermittent fever, for which he was successfully treated. The disease is steadily progressive. His general health is pretty fair.

Before the disease was well marked he occupied a room in his aunt's house, but since then has had a small hut to himself. His personal habits are cleanly; diet is principally vegetable, with fresh and salted fish occasionally.

CASE II.—Anasthetic leprosy.—John Maloon, aged thirty-four years, negro, born in Tortola, V. I., where he still lives, farm laborer.

Family history.—His mother is alive and in perfect health. She says that there was never any leprosy in her family. Her husband, who died of cholera asiatica in 1867, was not a leper; but it is not known whether leprosy existed in his family.

Previous history.—John was suckled in the absence of his mother by a woman who subsequently died of leprosy. This woman had a son who was also a leper. John spent some period of his boyhood on an estate, at the west end of this island, where three lepers lived. With these he associated without restraint, often sleeping in places where they slept, etc. Eleven years ago the disease first appeared and has been continuous. He admits excessive venery, but denies ever having had syphilis.

Present condition.—The first skin lesions were on the internal aspect of the right foot. These were bullae, which ruptured, dried up, and formed anasthetic spots. After these were formed many others formed on these spots. The great toe of this foot is entirely absent, and the remaining toes are swollen and present the appearance of claws. Not long after the left foot was similarly affected.

The phalanges of the toes of this foot spachetated. His hands are mutilated, but his face is intact. Locomotion is very awkwardly performed. General health is good. He lives together with his mother and four other persons in a small hut, using everything in common except bedding. Their personal habits are nasty; diet is like that of Case I.

CASE III.—Anasthetic leprosy.—Anne M., twenty-one years of age, negress, born in St. Thomas, single (has a child), lives at Kingston, Tortola, V. I.

Family history.—Abraham D—married Susan J. They were, together with many others, captured by a British man-of-war from a slave craft, brought to this island, where they settled. In course of time Susan bore her husband, who was a faithful mate, four children. After the birth of these Abraham manifested symptoms of tubercular leprosy, of which he died many years after. Nothing is known of his parents, but his widow, who is alive and well, enjoying a good old age, attributes the cause to exposure to very inclement weather whilst doing prolonged guard-duty. Two children were born to them after Abraham became a leper. One of these, a boy, died of some internal injuries sustained by a fall at the age of eleven. At the time of his death he had no signs of disease. The other child, a girl, has knowledge of womanhood, got married, and gave birth to Anne M. When Anne was a nursing her mother died of cholera asiatica, at the age of thirty. She, too, was not a leper. Anne's father was of a leprous family, but nothing is known of his health.

Previous history.—Anne was two years old, and her grandfather was many years dead, when it was noticed that she was getting leprosy. I have been unable to ascertain the manner of its invasion. However, in a year's time the disease was well pronounced. She was then removed to Kingston. She menstruated at the age of fourteen, and continued to menstruate regularly until four years ago, when she became pregnant. She gave birth to a healthy child. She reappeared and has remained well. After weaning the baby, her menses reappeared and continued until eight months ago, when she became pregnant from another man.

Present condition.—Her hands and feet are mutilated. Macule are scattered over her back and posterior parts of legs. No skin lesions on the face whatever. General health is very good. The disease has been stationary for some years.

Her first paramour, a middle-aged man, is free from all skin affections. The present, a youth of eighteen, is absent from this island.

Kingston, where Anne lives, is a small fishing village of 127 inhabitants. It is a malarial locality. Anne has for the past eighteen years had great care of her two aunts. They occupy the same wretched hut, situated but a few feet from a swamp. Their personal habits are filthy in the extreme, they rarely wash their persons, and they seldom change their garments. They eat the same food, using the household utensils in common. Their dietary consists for the most part of sweet potatoes, bananas, fresh eggs, fresh fish, and potatoes sometimes. Very seldom do they eat wheat bread.

Anne is the only leper in this village. She has never been isolated.

Remarks.—The main points of interest in these cases are: 1, that the disease in Cases I. and II. can be traced to contagion or infection alone; 2, that it was hereditary and developed at a very early age in Case III.; 3, that it did not prevent her development to maturity, as is usual when the disease is manifested prior to puberty; 4, and that, although the families and friends of Cases II. and III. have had unrestrained intercourse with them for many years, yet none of them have contracted leprosy; 5, and finally, that there is no history of syphilis in any of these cases.

There are six cases of tubercular and anasthetic leprosy in these islands, which have a mixed population of
six thousand persons. At no time in the history of this colony were any means taken to arrest or eradicate (by isolation or segregation) leprosy, which existed to a great extent in former years. Although it existed under the most favorable circumstances for propagation, yet it is on the decrease. Perhaps this can be accounted for, in part, by emigration.

It will be observed that no mention is made of any treatment. These poor wretches believe their condition beyond all hope of alleviation, and therefore do not seek medical treatment. Alms are all they crave for.

Progress of Medical Science.

The Treatment of Phthisis.—Dr. Kurz, of Florence, Italy, speaks in the following terms of phthisis: 'The hypothesis of the bacillary origin of tuberculosis and phthisis has nothing to do with its treatment, the antabicillary treatment having entirely failed. It is furthermore not proved that a healthy person living in normal circumstances will be infected by a tuberculous person, and in hospitals the phthisical are not in separate wards, as in other infectious diseases. If the bacillus Kochii needs for its development so many different conditions that the expectation that it must be a bacillus quite different from all the others, which develop in a short time and destroy the life. In the military tubercles of the peri toneum the bacillus has not been found. Lately arsenic has been recommended in the treatment of phthisis 'to break up the bacilli,' and one scientist has exactly described the way in which this is done in the body. But arsenic has been given in tuberculosis in Italy for hundreds of years, and its action has been long known, i.e., by improving the breathing and nourishing the nervous and muscular tissue, Milk diet has been recommended for a long time, and it has to be applied in the future, whatever the bacillus may do. Iodoform has had a good effect in some cases, but most patients could not stand the smell of the iodoform, and inhalations with it are a torture for patient and physician. In some cases of laryngitis and ulcers of the larynx, the powdered deodorized iodoform may be applied with good results, but only so far as it induces the lungs to gymnastic action. In hemorrhage the best remedy is ergot in large doses. Against the fever, quinacrine is recommended, salicylic acid, containing the effects of antivenom, and reducing other complications. In some cases where the fever was produced by resorption of pus, inhalation of carbolic acid acted promptly. Kairine was always followed by aggravated symptoms. It is not always commendable to reduce the temperature of the patient, there being certain conditions where a reduced temperature aggravates the other symptoms. The cough is treated with morphine and aponomorphine, each o.05 in 150.0 water. Oil of turpentine, carbolic acid, kroesote, and eucalyptus, used as inhalations, are in some cases of beneficial effect. The best inhaler is Oertel's, which works at a distance of two feet from the patient. Forced nutrition by the (stomach sound) esophagial tubes is very seldom applicable. The white sweat is readily converted by the old forgotten remedy, agamic albus, in doses of 0.5 to 1.0. The disease is a social evil, and it will not be reduced by microscopical or chemical examinations.'—Chicago Med. Jour. and Exam., March, 1884.

Reflux Urine Vomiting.—According to the experience of Dr. Gaily Hewitt (London Lancet, January 5, 1884), reflex urine vomiting, when of an obstructive character, is very frequently associated with great weakness and want of toxicity of the uterus, and a flexed condition of the organ is almost invariably also present. There are undoubtedly, cases of reflex urine vomiting in which the cause is a different one, but they are exceptional and occur rarely. The unduly soft uterus readily bends, and any temporary increase in the degree of the flexion is attended with aggravation of the reflex disturbance viz., the vomiting. The several factors concerned in the production of this gravity order may be enumerated as follows: 1. A general enfeebled of the body, the result of a low condition of the nutritive process in which the uterus participates. 2. The physical weakness and pliability with which the uterus is consequently affected. 3. The flexed condition of the uterus, liable to be intensified by certain movements or positions of the patient. The sickness and vomiting appear to result from the irritation of the uterine nerves consequent on the temporary or permanent compression of the uterine tissues. It is almost certainly relieved, or for the time at all events removed, by measures having for their object the maintenance of the uterus in a normal position and shape.

There is no doubt that many cases of this affection escape true recognition, the sickness being erroneously attributed to the liver or the stomach being the seat of disease. Many cases of so-called "bilious" vomiting, and not a few supposed of gastric ulcer, turn out on investigation to be cases of uterine vomiting pure and simple. As regards the liver and the stomach, it will be found impossible to exclude these organs as causes of the cases of vomiting from the fact that the vomiting patient is vomiting; there is no symptom indicative of disease of the organs in question; while, on the other hand, there are generally marked symptoms indicating that the uterine functions are disturbed. One symptom specially indicative of the uterus as the cause of the sickness is the exagerration of the sickness, which is liable to occur with the least motions, on walks, or exercises otherwise. It may be added, also, that in cases of reflex urine vomiting, where the malady has been of long continuance, the stomach itself is liable to become affected. The secreting power of the stomach is enfeebled by the long-continued starvation; and it is no longer capable of producing gastric juice to any amount of the effect of fatigued of such cases. Hence a pseudo-paralysis of the gastric mucous membrane results. There are cases of this kind in which the extremest care is necessary to prevent a fatal issue, even after the tendency to vomit has been obviated or diminished by appropriate treatment.

Case of Poisoning from the Bite of a Copperhead.—Dr. H. C. Yarrow reports, in the April number of The American Journal of the Medical Sciences, a case of very severe poisoning from the bite of a copperhead, which was successfully treated. He reviews recent investigations concerning the effects of serpentine venom, and points out the means and remedies to be employed in cases of snake-bite, and he recommends, as a chemical antidote, the injection in the immediate vicinity of the bite of a one per cent. solution of permanganate of potassium.

Phosphorus in Diabetes.—Dr. Trivignot (Le Progrés Médical) claims good results from the use of phosphorus in the treatment of diabetes. He has employed it several times with patients who had been treated previously by alkalis and diet with temporary benefit. Ordinary food was allowed, and under the influence of phosphorus alone the general health improved and the quantity of sugar in the urine diminished gradually. The drug can probably be taken for a long time without danger. The best preparation is oleum phosphoratum in capsules; one milligramme (one-sixtieth of a grain) of phosphorus can be given two to six times daily with the food. Dr. Trivignot recommends also a combination of oleum phosphoratum and ferri carbonas, made into pills with pulvis altheae and oleum theobromine.

An American the First to Employ Estlander's Operation.—Dr. G. N. Monette writes to the Journal of the American Medical Association that Dr. Warren Stone advocated and employed thoracoplasty more than thirty years ago.
THE MEDICAL RECORD:

GEORGE F. SHRADY, A.M., M.D., EDITOR.

Published by
J.M. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, May 17, 1884.

THE CAUSATION OF NERVOUS DISEASES.

While the symptoms and lesions of the so-called "system diseases" of the spinal cord have been carefully studied, but little light has been thrown upon their etiology. Why an inflammatory process, acute or chronic, should extend longitudinally through the organ for several inches, but fail to involve cells or fibres lying in close proximity to it on all sides, has received no explanation. In 1881, Adamkiewicz discovered that the various capillary vessels lying in and supplying with nutriment the various tracts in the cord, and the various segments of its gray matter, were connected with different branches of the spinal arteries, so that a disease of one branch would affect but one tract, and not all parts of the cord indefinitely. His attempt to bring this fact into a causal relation with the system diseases was, however, unsuccessful; for it only carried the question a step farther back, and failed to explain why certain arteries, to the exclusion of others, were affected in certain diseases. Professor Strümpell, of Leipzig, in an inaugural address on taking the chair of Practice of Medicine at the Polyclinic, quite recently, has made a valuable contribution to this subject. His opinion is worthy of careful attention, as he is not only a well-known scientific worker and a man of very wide experience, but also the author of a work on Practice which is superseding that of Niemeyer throughout Germany. Admitting that anatomical structure furnishes no explanation for the existence of system diseases, Strümpell seeks their cause in physiological, embryological, or toxicological facts.

Any voluntary effort calls into play certain definite centres and tracts which are distinct from all others, not on account of their structure, but because together they form a physiological unit. All physiological action is accompanied by chemical change in the parts which act. If that action is excessive the chemical changes may pass the line of safety and go on to pathological changes. Such changes will be limited, however, to the parts which form the physiological unit; or, in other words will affect one system alone. There are numerous examples of diseases thus caused by overaction of a part. Writers' cramp and other occupation neuroses are examples of overstrain producing temporary inability without known lesion. Strümpell would also assign to this cause progressive muscular atrophy, bulbar paralysis, and amyotrophic lateral sclerosis, all of which are known to follow severe exertion, and to present definite pathological changes limited to the motor system in the gray matter or white tracts.

The researches of Hechsig have demonstrated that various tracts in the cord develop at various periods in the embryo, and that each system has its own time of obtaining its medullary sheath. This fact Strümpell brings into connection with two forms of system disease, both of which appear early in life, and both of which may be ascribed to a failure in the normal process of development; viz., the hereditary form of locomotor ataxia described first by Friedreich, and the congenital pseudohypertrophic paralysis recently investigated by Erb.

External agents manifesting a power of specific action upon certain parts of the nervous system form the third great cause of system diseases. These agents may be inorganic or organic. It is well known that strychnine excites the reflex centres, atropine the secretory centres, morphine the sensory tracts, conium the motor nerve terminations, etc. A selective action of poisons is therefore proven to exist. Strümpell cites lead and mercury as inorganic agents possessing a specific action upon the motor system of the spinal cord, and assigns lead palsy and mercurial tremor a place among the group of system diseases. But organic agents also show a selective action upon the nervous system. An epidemic of ergot poisoning occurred in Marburg not long ago. Those who were affected presented symptoms which resembled almost exactly the symptoms of locomotor ataxia, and the post-mortem examination demonstrated sclerosis limited to the posterior columns of the cord in all cases. In Northern Italy the peasants mix labthrus beans with corn when food is scarce. The result is a peculiar form of poisoning, in which all the symptoms of spastic paraplegia develop and a lesion of the lateral columns of the cord is found. These facts seem to Strümpell to prove that organic agents, germs, may cause nervous diseases of a systemic character. Following this line, he seeks to show that the connection between syphilis and locomotor ataxia may be due to a selective action of the syphilitic germ upon the posterior columns of the spinal cord. But if this is doubtful, there are numerous nervous diseases whose course and termination demonstrate a germ origin. Cerebro-spinal meningitis is infectious; hydrophobia is contagious; tetanus is best explained by the entrance of some external organic agent into a wound; trigeminal neuralgia is most frequently malarial in its origin, and is only affected by anti-malarial remedies. Further, there is a form of nervous disease, commencing with a chill and acute febrile symptoms, running an acute course for some days, with general constitutional symptoms, enlargement of the spleen, occasional albuminuria, etc.; in a word, presenting for a time all the features common to diseases which are known to be of germ origin. This form of disease is infantile spinal paralysis and its ally, acute infantile encephalitis. In these Strümpell finds examples of a germ disease in which a selective action of the germ upon certain motor-trophic cells is as evident as the selective action of lead upon other motor-trophic cells.

It is evident that under these three divisions, physiological overwork, embryological malformation, and ter-
have been much worse. Read Galen's description of his contemporaries; read his own ethical confessions; if he had lived to-day, he would have founded a World's Dispensary. What can one say for the seventeenth century physician, as depicted by Molière, or as criticised by Gyl Patin? A hundred years later the great doctors of London would sell their reputation at half-price to the credulous ones who came to them at the coffee-houses; and nothing could be more scandalous than the advice of a learned and representative physician, Dr. Mead, to a young man about to enter the medical profession. They were not saints in those days. There are not many saints now; but on the whole there is no decrease, but rather an increase, of honesty in the profession. Every decade it requires, to become a successful physician, greater learning, to which must be added human knowledge and sympathy. These are not the attributes of quacks.

LITHOLAPAXY IN INDIA.

The résumé of the litholapaxy operations given by Desnos in one of the numbers of the Revue de Chirurgie, for 1883, showed that of the 590 operations performed up to that time about seventy per cent. had been done outside of the United States, Guyon and Sir Henry Thompson heading the list with 226 and 101 operations respectively. In the Indian Medical Gazette for December, 1882, and February, 1883, Surgeon P. J. Freyrer, of the Bengal medical service, reported 20 cases operated on during the year 1882. In the same periodical, for March, 1884, he reports a further series of 57 cases in which litholapaxy was performed in 1883, with only two deaths.

During the year 107 cases of stone came under his observation; six of these were cases of urethral calculus, in which urethrotomy was successfully performed. There were 40 cases in male children under the age of fifteen years, lithotomy being performed in each case, with one death. In the remaining 61 cases, all of which occurred in adult males, save three cases in female children, litholapaxy was attempted, but in four cases it could not be performed. Of the two fatal cases, one died from peritonitis by extension of inflammation from the neck of the bladder. The calculus was impacted at the neck and some force was necessary in order to remove it. In the second fatal case death was due to pyaemia, the result of cystitis supervening on the operation, and caused by the irritation of a large fragment which could not be removed at the first sitting. In commenting upon this case Frey rer urges the advisability of removing everything at the first sitting; saying that an operation prolonged over several sittings involves all the dangers attending the lithotomy operation.

By reference to the table given by Frey rer, it is seen that large calculi were removed from three patients aged eighty-five years, and nine and one-half drachms of a very hard uric acid calculus were removed from a patient aged ninety-six years, the operation lasting one hour. He comments upon the ease with which very old patients stand the operation, stating that they are less liable to urethral fever than young and strong men, and that in his experience the older the patient the greater the prospect of success from litholapaxy as compared with lithotomy.
In one case a new method of diagnosis of stone is indicated by means of the aspirator. In this case, Sir Henry Thompson's sound failed to reveal the presence of the calculus. The aspirator was employed and a distinct click was at once felt during the exhaustion of the water, due to the impact of the stone against the eye of the cannula by the force of the outward stream.

Surgeon Freyer has now performed litholapaxy 79 times, 76 times on the adult male and three times on female children. Among these only three deaths have occurred!

Yet these results are by no means phenomenal for litholapaxy. Even from the single standpoint of mortality, to say nothing of the short time which the patients spend in the hospital, litholapaxy should certainly at once supersede other operations for vesical calculus. But how very few cases have been performed outside of Boston and New York! Even in India one surgeon, Freyer, has performed it oftener than, may we not say, all the surgeons in the Western, Middle, and Southern States!

THE SUCCESS OF NON-RESTRAINT IN THE TREATMENT OF THE INSANE.

In the recent report of the Bloomingdale Insane Asylum, it is stated that no mechanical restraint was applied to the patients during the past year. The non-restraint system has also been followed by Dr. MacDonald, of the Auburn Insane Asylum; and this, with the Kings County Asylum, makes three institutions in this State in which the humane and rational method of treating the insane has been adopted. There is no doubt that in some of the State asylums mechanical restraints are still used, simply because the superintendents are committed against it. And though every year reduces the number of cases restrained, they obstinately refuse to accept the whole system or to acknowledge any indebtedness to those advocating it.

In other States than New York the movement in favor of non-restraint is gaining ground very rapidly. Dr. Bryce, of the Tuscaloosa Asylum, Ala., says that he has almost entirely succeeded in discarding mechanical restraint of every kind. Dr. Richardson, of the Athens (Ohio) Asylum, states that the amount of mechanical restraint in his institution has been "almost absolutely nothing." Mechanical restraint has been almost entirely abandoned also in the Hospital at Norristown, Pa. The same may be said for the Eastern Hospital for the Insane, at Kankakee, Ill., and the Asylum at Danvers, Mass.

The charge has been made that those who have given up mechanical restraint have supplied its place with drugs; but this charge is refuted by the elaborate investigations of the late Dr. Wilbur, who showed that in the insane asylums both of Great Britain and the United States, with non-restraint a less amount of sedative drugs was used.

In fine, the opinions of American asylum superintendents upon the subject of non-restraint and occupation have undergone a surprising change in the last five years.

DR. THOMAS A. McBRIEDE has been elected a Professor of Diseases of the Mind and Nervous System in the New York Polyclinic.

News of the Week.

"THE PLANET."—The publication of the Planet has been discontinued. During its short life it fulfilled its purpose, being especially distinguished for its original, rare, and amusing reports of our New York medical societies. We are requested to ask that its exchanges be stopped.

A BALL FROM THE BRAIN.—On Thursday, May 22d, at three o'clock, Dr. W. F. Fluhrer will exhibit at Bellevue Hospital (amphitheatre) the patient from whom he removed a ball from the brain through a counter-opening in the skull.

THE NEW YORK CANCER HOSPITAL.—An error appeared in our last issue, whereby the donation of Mr. John Jacob Astor of $200,000 to the above hospital was assigned to another institution, together with other large contributions, which now aggregate the sum of $375,000. A site for the New York Cancer Hospital has been purchased on Eighty Avenue, between 105th and 106th Streets, facing the park. Ground has been broken, and the cornerstone will be laid, with appropriate ceremonies, on Saturday, May 17th.

DR. THOMAS H. SKINNER, formerly of the Bellevue Hospital medical staff, died suddenly in Hartford, where he had gone for medical treatment, on May 10th, at the age of thirty-two years. Dr. Skinner was born in Raleigh, N. C. He was graduated from the Medical College of the University of Maryland, in Baltimore. He practiced medicine a year in Baltimore, and came to this city in 1872, where he was a successful medical practitioner until failing health a year ago obliged him to give up his profession, and he moved to Brooklyn. His death was due to congestion of the brain.

DR. WILLIAM H. WELCH, of New York, has been elected Professor of Pathology in the Johns Hopkins University. Very sincere regrets will be felt by Dr. Welch's many friends in this city that he is going away. At the same time he is to be congratulated upon the honor tendered him.

A NEW MEDICAL COLLEGE IN BOSTON.—It is rumored that a new medical college is to be established in Boston. It is to be a branch of Tufts College.

DEATH OF DUMAS.—The death of Professor J. B. Dumas, member of the Académie de Médecine, and author of many scientific works, is announced.

THE KENTUCKY STATE MEDICAL SOCIETY.—The twenty-ninth annual meeting of the Kentucky State Medical Society will be held in the city of Bowling Green, Ky., from 12 o'clock a.m. of Tuesday, June 3, 1884, to Thursday, June 5, 1884, inclusive. Dr. S. M. Letcher, Secretary.

A YANKEE DEFINITION OF BRONCHITIS is the title of a critical article in the Medical Press and Circular upon an article written by a Canadian and published in a Canadian medical journal. This is the first time we have heard Canadians called Yankees. Certain English writers seem to have even looser geographical ideas than the French.
A PRIZE FOR AN ESSAY ON THE BACILLUS OF TYPHOID FEVER.—An attempt to isolate the bacillus of enteric fever will probably be made under the stimulus given by the munificent offer of a Fellow of the Linnean Society of New South Wales to give a prize of £100 for the best essay on "The Life-History of the Bacillus of Typhoid Fever." Compositions must be written in English, and delivered at the Society's house by December 31st next.

DIED IN THE DISCHARGE OF DUTY.—The physician who died from disease contracted in the discharge of duty is as much a hero as the soldier who falls in battle. Dr. A. Randolph Mott, resident physician at the Riverside Hospital, was attacked by typhus fever, which he contracted in attending to his duties three weeks ago, and died last week. He was twenty-six years old, and was born at Leesburg, Va., where his father is an eminent physician. Dr. Mott was graduated from the University of Virginia in 1878, and came to this city, where he was appointed a physician without salary at the work-house. From there he went to the Randall's Island Infant Hospital and Hart's Island Hospital. In 1881 he went to the Riverside Hospital as assistant to Dr. Chapin. He was Lecturer on Gynecology at the Polyclinic Institute.

WAS GUITTEAU INSANE?—The question as to the insanity of Guiteau appears to be a burning one in St. Louis. The Alienist Neurologist continues to present articles upon it and promises more.

A BIOLOGICAL ASSOCIATION has recently been organized in London under the auspices of Professors Huxley and Ray Lankester.

Sir William Jenner has been re-elected President of the Royal College of Physicians, London.

THE DEATH OF MR. SQUIRE, author of the "Comparison to the Pharmacopeia," and of the "Pharmacopeia of the London Hospitals," is announced. Deceased was eighty-five years of age. Mr. Squire was one of the founders of the Pharmaceutical Society of Great Britain and of the College of Chemistry.

MICROCOCCI OF PNEUMONIA.—Professor Purjes, of Buda-Pesth, states that he has found Friedländer micrococi of pneumonia in other diseases, and has not always found them in pneumonia. He denies the infectious character of the disease.

JOHN BRIGHT'S DISEASE.—Medical London has been exercised over the fact that John Bright, who is ill, has called on a homoeopath to attend him.

NEWPORT (R. I.) MEDICAL SOCIETY.—At the annual meeting the following officers were elected for the ensuing year: President—Dr. H. R. Storer; Vice-President—Dr. Samuel W. Francis; Secretary—Dr. Thatcher Goddards; Treasurer—Dr. Wm. C. Rives, Jr.; Librarian—Dr. C. F. Barker; Curator—Dr. Stephen H. Sears. The society is in a flourishing condition.

A GENEROUS DONATION.—Mr. George Stephen has given to the Montreal General Hospital the sum of $50,000, to commemorate the memory of Dr. George W. Campbell.

BEGUISTS TO MEDICAL CHARITIES.—The late Mrs. Oswald Ottenfodder bequeathed in her will $10,000 to the German Hospital and Dispensary, and $5,000 to the German Hospital in Newark, N. J.

THE CHOLERA BACILLUS.—A recent telegram from Calcutta states that Dr. Vincent Richards, civil surgeon of Goalundo, has caused the death of a pig from cholera by inoculating the animal with the virus. We are not informed, however, whether the "virus" means the cultivated bacillus or the cholera secretions. It makes a great deal of difference.

A DEATH DURING THE ADMINISTRATION OF AN ANAESTHETIC occurred in Bilroth's clinic recently. The operation was for removal of a goitre in a healthy young man. The usual anaesthetic mixture was employed. The patient ceased breathing, and artificial respiration was resorted to. During this process some air was sucked into the veins.

ADULTERATED MUSTARD.—Boards of Health periodically startle the laity by announcements of new adulterations in spices. Our city Board has recently been investigating mustard, and finds a kind of explosive dye in many samples. Everyone by this time knows that spices are greatly adulterated. We want a remedy.

THE MCGILL MEDICAL COLLEGE.—The Medical College of the McGill University has raised and had donated to it the sum of $100,000, and it is now one of the fortunate endowed medical colleges. Fifty thousand dollars was presented by Hon. D. A. Smith. At the commencement of the McGill College, March 29th, thirty-four students were graduated.

THE THIRTY-EIGHTH ANNUAL MEETING OF THE ASSOCIATION OF MEDICAL SUPERINTENDENTS for the Insane was held in Philadelphia the past week.

A STATE HOSPITAL FOR EPILEPTICS.—Dr. Carlos F. MacDonald, of the Auburn Insane Asylum, urges the State to give him a new building with a farm outside the city limits. His present building could then be used as a State Hospital for Epileptics.

APPROPRIATIONS FOR THE MEDICAL CHARITIES OF THE CITY.—The annual distribution of the portion of the excise fund set aside for charities has been made. The total sum this year was $38,710. Twenty-one dispensaries and hospitals received sums varying between one thousand and seven thousand dollars. St. Francis Hospital received the largest amount, $7,656.

THE ITALIAN MEDICAL REVIVAL.—An interesting account is given by The Lancet of the present and rapid growth of medical science in Italy. Two new medical journals have just been started, which makes the total number of Italian medical journals fifty-four. Twelve of these are published in Naples, and ten in Milan. Milan is now a great publishing centre. There are 1,200 students at the University at Naples, and the other Universities at Turin, Pavia, and Padua are flourishing. The number of original workers is already considerable, and the names of Bizozero, Semmola, Bottini Bualini, and Crudeli are familiar to American readers. It seems likely that the Italian school will revive the fame of its older days.
PENNSYLVANIA STATE MEDICAL SOCIETY.

Thirty-fifth Annual Session, held at Philadelphia, Pa., May 14, 15, and 16, 1884.

(By telegraph to The Medical Record.)

WEDNESDAY, MAY 14TH—FIRST DAY.

The session opened in the Union League Annex, May 14th, and was well attended.

There were about three hundred and sixty delegates present, representing every county in the State. Henry H. Smith, M.D., of Philadelphia, occupied the chair. After prayer by the Rev. John S. Macintosh, D.D., and an

ADDRESS OF WELCOME

by John B. Roberts, M.D., Chairman of the Reception Committee, Governor Patterson delivered an address, expressing great pleasure at having been selected to open the meeting of the State Medical Society. He had reasons, as Governor of the Commonwealth, to be proud of the progress of medical science in the State. Its schools of medicine were known throughout the length and breadth of the land, and were unequalled anywhere. Its physicians were celebrated for their learning and achievements. It was in Pennsylvania—in this very city—that the first systematic course of study in medicine, from which sprung the University of Pennsylvania, was instituted on this continent. Philadelphia might be termed the Edessa of medical instruction in America, and deserves the reputation, for it is to-day the foremost seat of medical education in the land. This city has been the nursery from which have gone out the men who have given to the science in the United States a distinguished reputation in the most famous schools in Europe. A great loss was suffered lately in the death of that great man to whom more than any other we owe our honorable fame in the field of medical learning, he whom all regarded with so much pride and veneration, to whose masterly mind two continents paid honor, and who held the triple tributes of Oxford, Cambridge, and Edinburgh. In the

DEATH OF PROFESSOR SAMUEL D. GROSS.

the profession of medicine has suffered a "perilous gash, a very limb lopped off." The Governor closed by referring briefly to the progress of the science of medicine and by counselling the Society to conduct its proceedings as to reflect honor and glory upon the State.

At the conclusion of the address Dr. Edward Jackson, of West Chester, presented a list of delegates from other societies and of visitors who were not delegates, and asked that they be admitted to the Convention.

ADMITTING THE FEMALE PHYSICIANS.

Dr. William B. Atkinson, the Secretary, presented a supplementary list of physicians who are not members of the Philadelphia County Medical Society, and who, he thought, were entitled to admission. The list contained the names of Clara Marshall, Francis Emily White, Anna E. Bromall, Hannah T. Crossdale, Rachel L. Bodley, Emilie B. Dubois, Ida E. Richardson, and Emma V. Boone, who had been denied admission to the Philadelphia County Medical Society on account of their sex.

Dr. J. L. Stewart, of Erie, objected to admitting them, but the objection was not sustained, President Smith stating that the women were members of the profession, and therefore entitled to admission. The Convention decided in favor of admitting them. The Society need not, however, admit them as members, but simply as visitors, without the privilege of voting.

Dr. Stewart appeared to be satisfied with the restriction and withdrew his objection, and the physicians were then admitted.

OBJECTING TO FREE ADVERTISING.

A sensation was caused by the reading of the report of the Committee on Publication. The Committee presented a list of the papers which have been prepared for the consideration of the Society, and recommended that they be published.

Dr. O. H. Allis, of Philadelphia, arose at this point and offered a resolution providing that no abstract of any paper read during the session should be published until approved by the Committee on Publication. He said he objected to the course heretofore pursued in this matter. Some members furnished abstracts of their papers to the press and succeeded in having them published, sometimes to the extent of a column or two, while others were cut off with a few lines. This was done not because of any difference in the merits of the papers, but simply because

SOME OF THE MEMBERS WERE SMARTER THAN OTHERS, AND KNEW HOW TO GET THEIR EFFUSIONS INTO PRINT.

This, he thought, was the worst kind of advertising dodge, and ought not to be allowed. It was

WHOLESALE NEWSPAPER ADVERTISING, contrary to the ethics of the medical profession, and to every instinct of fair play. It ought to be checked, and checked immediately.

After further discussion the subject was referred to a committee of five, with instructions to present a report.

VIVISECTION.

Dr. S. Weir-Mitchell, of Philadelphia, read the report of the Committee on the Appeal of the American Anti-vivisection Society. He sketched the history of vivisection, and referred to the opposition to it in this country and in England. He said that many physicians thought there was no harm in experimenting upon animals, and that to check it would place a serious hindrance on physiological research. The restrictive law passed by the British Parliament was very unpopular, and was doing great harm. It had interfered with the research on the subject of

SNAKE-POISONS AND THEIR EFFECTS ON THE HUMAN BODY.

He had made application to physicians in India for snake-poisons, for the purpose of experimenting with them, but he could not get them, owing to the law on the subject. Fortunately for humanity, however, the proposition to abolish vivisection universally was now unpopular, and has little chance of becoming a law. There was no truth in the reports of the cruelties practised upon animals in the attempt to advance science. The New York Legislature has not passed a restricting law. It has been charged that vivisection was carried on in this State to an unwarranted extent. This is untrue. There are only a few medical colleges in the State where vivisection is practised. A few urbane lawyers and ladies think that a curb should be put upon the doctors, but at a meeting held in London recently, twenty-four hundred physicians from all parts of the world, placed the seal of their approval on vivisection.

THE PRACTICE OF VIVISECTION ENDORSED.

The speaker then offered the following resolution, which was adopted without a dissenting voice:

Resolved, That in view of the attempts which have been or may be made to obstruct, by restrictive legislation, the progress in the medical arts, this Society desires to express its earnest conviction that experimenting on animals is a most useful source of knowledge in medical science; that it is the means by which many im-
important discoveries, both practical and scientific, have been accomplished; that its direction and supervision can be properly entrusted only to members of the medical profession, and that its restriction or prohibition by law would inevitably retard the acquisition of knowledge in respect to healthy and morbid actions, the causes and prevention of disease, and the improvement of the medical art.

A STATE BOARD OF HEALTH.

The report of the Committee on the State Board of Health was presented by Dr. Benjamin Lee, of Philadelphia. The report stated that as the Legislature was not in session during the past winter, there was no opportunity for pressing legislation upon this important subject. Long experience shows that nothing can be done in this direction unless the public is awakened to the importance of the work. When the Legislature is convinced that the people want a health bureau, they would be ready to create it. The report was received, and on motion of Dr. E. A. Wood, of Pittsburg, a committee was appointed to prepare a plan for the organization of a State Board of Health.

DENOUNCING THE ADULTERATION OF DRUGS.

Dr. John V. Shoemaker, of Philadelphia, offered the following resolution, which was adopted:

Whereas, The efforts of physicians to treat and overcome disease are in a large measure dependent on the use of pure and properly prepared drugs and remedies; and whereas, Pharmacy is an aid to medicine in preparing, compounding, and dispensing the proper medical agents, and is at present not controlled by any law for efficiency in the art of those practising the same required by any law of the State of Pennsylvania,

Resolved, That the Medical Society of the State of Pennsylvania, assembled at their annual session, endorses the passage of the act to regulate the practice of pharmacy and sale of poisons, and to prevent adulteration in drugs and medicinal preparations in the State of Pennsylvania, as proposed and framed by the Pennsylvania Pharmaceutical Association, and recommends its passage by the Legislature of this State at its next session.

NO TEMPERANCE "IN THEIRS."

Dr. Birdsall, of the Susquehanna County Medical Society, offered a resolution to appoint a committee to consider the propriety of recommending the restriction of the use of intoxicating liquors as beverages.

This met with a storm of opposition, and, at the suggestion of Dr. E. A. Wood, of Pittsburg, who said that such action was unwise and uncalled for on the part of the Society, it was voted down.

A recess was then taken.

Upon reassembling at 2 o'clock, Dr. Benjamin Lee, of Philadelphia, read an address on Hygiene and State Medicine, entitled

THE PRESENT OUTCOME OF SANITARY AGENCIES IN LARGE CITIES OF THE UNITED STATES.

He pointed out the well-recognized dangers of sewers in houses, and inclined to the opinion that in the present state of public feeling there was a strong leaning toward private as against public means of inspection.

After this Dr. E. A. Wood, of Pittsburg, read a paper on A PENNSYLVANIA STATE BOARD OF HEALTH, favoring the establishment of the board.

Dr. Henry Leffmann, of Philadelphia, followed with a paper on PROPER MEDICAL EDUCATION, in which he claimed that the present system of medical education is not the result of efforts to meet the needs of the community, but is largely an irregular develop-

ment. The reforms which medical colleges have adopted have been mostly unwilling concessions to public sentiment. The sevenfold division of branches has nothing to recommend it but antiquity; it is not a convenient nor a scientific division of the subject. Under this arrangement some of the departments of the college course are overcrowded, while others have not sufficient matter to occupy the time assigned. Departments like hygiene, nervous and mental diseases, and medical jurisprudence have developed so of late years that they might properly be taught by separate chairs, and not made merely subsidiary to other chairs or limited to morning or fall lectureships. The extension and success of post-graduate schools indicates the direction in which improvement of the curriculum should be made. Higher specialization is the necessity of the time. The success which has been attained by dentistry shows that other departments, such as otology, laryngology, etc., might with advantage be pursued independently. There would be no reasonable objection to establishing the degrees of Doctor of Otology, Ophthalmology, and so on, commensurate with the degree of Doctor of Dental Surgery.

A preliminary training for the student before entering upon the study of medicine is so obviously necessary that it need not be argued. The final work of medical reform will be accomplished when the legislature, as a matter of public policy, has made merely the instructor, the license to practise being given by an official board of examiners after a public written examination.

Following this, Dr. Thomas H. Fenton read a paper entitled

HYGIENE IN THE PUBLIC SCHOOLS,

in which he said that two hundred and twelve thousand children attended the public schools of Philadelphia in 1880. The value of the school buildings was $6,179,750. The location of many of these was faulty as to light and air. Ventilation especially is defective, no provision being made for the exit of foul air beyond the opening of the windows. Special care has been taken to ascertain the truth of this point by accurate and careful tests, which were described at length by the lecturer. The means for remedying this were referred to, and plans given for securing a free, supply of air at proper temperature without drafts. The next defect noted was that of drainage, and the poor arrangements, especially of water-closets, was considered. Next came the question of the correct position of desks and seats; the bad effect of careless arrangement of these upon the spine, the chest, and the eyes was dwelt on at length. The prevalence of myopia was stated, and the difficulty of managing it without proper arrangements for holding books, etc., before the eyes of the children at proper distances was defined. The plan of allowing the light to fall directly upon the faces of the pupils was condemned, and the lack of proper illumination of black-boards was referred to. The color of walls, ceilings, and the paper of books was stated to be very important. Many valuable suggestions as to the better care of the children attending our schools were made, and the paper was full of interest.

Dr. Alice Bennett then read her address on

THE RELATION OF HEART DISEASE TO INSANITY.

The paper was especially designed to call attention to the coincidence of heart disease with a certain form of chronic mania. Sixteen cases were then related, some of the general features running through which were as follows: They begin generally in middle life; the invasion is usually gradual; ascribed to no cause or to one obviously inadequate. The first symptoms are invariably hallucinations of one or more senses, generally of hearing; and subsequent delusions of persecution. A woman, previously supposed to be in good health, begins to hear voices in the ceiling above her, and this goes on to confirmed delusions. In a large proportion of these cases disease of the heart is found.
The writer does not attempt to draw any inference from these cases, which she offers more as a rather remarkable series of coincidences, that among five hundred patients a certain distinctive form of mania has been found, almost without exception, associated with valvular disease of the heart, generally mitral. Whether the frequency of the coincidence justifies the suspicion of a causal relation she does not attempt to decide.

A paper

ON THE PROTECTIVE RIGHT OF THE INSANE IN PENNSYLVANIA.

by Dr. R. H. Chase, of Montgomery County, was then read.

DR. JOHN B. ROBERTS offered

A RESOLUTION PROVIDING FOR THE ESTABLISHMENT OF A MEDICAL COLLEGE IN THE STATE OF PENNSYLVANIA, to be endorsed by the Legislature. After much discussion his resolution was tabled and the Society adjourned.

The visitors then inspected the Pennsylvania Hospital, one of the oldest institutions in this country, after which the president, Dr. Henry H. Smith, held his address, and the evening was devoted to a banquet by the Philadelphia County Medical Society.

(To be continued.)

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Sixth Annual Congress, held in New York, May 12, 13, and 14, 1884.

MONDAY, MAY 12—FIRST DAY—MORNING SESSION.

The Association met in the hall of the New York Academy of Medicine, and was called to order at 10 A.M. by the President, Dr. Francke H. Bosworth, of New York.

After the calling of the roll the President delivered the Address of Welcome, in which he briefly reviewed the progress made in the Association and the department of medicine which it represents. This was followed by a paper on

THE CLINICAL SIGNIFICANCE OF FIBRINOUS EXUDATIONS UPON THE MUCOUS MEMBRANE OF THE UPPER AIR-PASSAGES,

by the President, in which he first described the characteristics of catarhal inflammation, due, in a majority of cases, to taking cold, and producing an exaggeration of the normal physiological processes.

On the other hand, the affections characterized by fibrinous exudation upon the surface of the mucous membrane indicates a disease entirely distinct from the catarhal process. The essential feature of the morbid process is not hyperemia, or hypersecretion, or cell proliferation, but an element which points to a constitutional affection. The most common of this group is follicular tonsillitis, consisting locally in an exudation into the crypts of the tonsils, the prominent features being marked febrile movement, and marked constitutional disturbance. Here, then, is something more than a disease due to an ordinary cold, and it seemed to him that it should be regarded as akin to an essential fever, not differing materially from an exanthem, the local lesion being evidence of a general affection produced by a micro-organism.

Another class of cases is grouped under follicular pharyngitis, with symptoms the same as those described, the only difference being that which arises from the situation of the eruption. Another group includes follicular inflammation of the pharyngeal tonsil, differing in no essential particular from inflammation of the faucial tonsil.

Another group of cases is included under the term croppus tonsillitis. In young children this means the possibility of the development of a croppus laryngitidis, an exceedingly dangerous disease.

The President regards diphtheria and croup as distinct diseases, but, at the same time, both are due to micro-organisms. He closed his paper with the propositions that fibrinous exudation occurring in the crypts of the tonsils and upon the mucous membrane of the larynx has no tendency to extend, and is self-limited; that the fibrinous exudation which occurs upon the surface of the tonsils runs a course, and presents an appearance by which it can be recognized; that a croppus inflammation of the mucous membrane of the faucies in adults, is a self-limited affection; that when the same disease occurs in children, there is direct danger of a new centre of inflammation developing in the larynx; that diphtheritic membrane developed in the faucies marks a disease dangerous to life with a marked tendency to development of the same process in the larynx.

DR. BEVERLEY ROBINSON, of New York, took exception to the view of the President regarding follicular tonsillitis as an essential fever, and added that the view of many cases lasts for several days. Moreover, the pathological change did not resemble at all that alluded to as belonging to a true croppus membrane, and is not of the nature of a fibrinous exudation. Dr. Robinson also believed that cases are quite numerous in which the physical appearances of the exudation upon the mucous membrane are not alone sufficient to indicate what the diagnosis should be. He also believed that there are certain cases, not so very frequent, in which at the outset the disease is what Da Costa has termed herpetic tonsillitis, and that it should be so termed rather than receive the name designated by the President in the first part of his paper, because it was not presented to the President concerning the germ theory of these diseases, and he also regarded it as wrong to say that diphtheria is essentially the same in all cases, in the sense of its absolute gravity, for there are different grades in the severity of the type which materially affects the question of prognosis.

Dr. W. C. Jarvis, of New York, agreed with the President as to the gross appearances of the different affections of the throat described. He had observed pharyngitis of two kinds: 1, that in which the follicles are affected acutely, and manifest no tendency to the formation of membrane; and 2, that in which the follicles are not so generally affected, but those involved exhibit a tendency to retain the secretion, and when finally distended epithelial covering ruptures, the exudation spreads over the surface and gives an appearance closely resembling that presented by a membrane. He believed that the President placed too much stress on the germ theory, and was of the opinion, as the result of observations made long ago, that the presence of micro-organisms was merely an associated fact, and not a causative factor in the development of this class of diseases.

The President took exception to Dr. Robinson's statement that follicular tonsillitis is characterized by the formation of cheesy masses in the crypts of the tonsils. The point which he wished to emphasize distinctly was that we have within our reach methods of examining by which a great deal of light can be thrown upon the clinical tendencies of local inflammatory diseases of the faucies; and that from the clinical standpoint a careful observation of the gross appearance of the exudation upon the mucous membrane of the faucies had been heretofore insufficiently considered. We already know what the course of acute follicular tonsillitis occurring in adults will be, and if we are able to determine the clinical course will be in the adult, while if it occurs in children the possibility exists of the development of another inflammatory disease in the larynx, causing the greatest danger, due to mechanical obstruction. As to the germ theory, it seemed to him that in absence of any more
satisfactory explanation, it best explained the phenomena of these diseases.

Dr. F. I. Knight, of Boston, directed attention to an important practical point, viz. the increased susceptibility to diphtheritic infection existing in those who have an acute affection of the throat of any kind.

The President said that the point which he wished to make was that the mucous membrane in a state of acute catarhal inflammation is a favorable medium for the lodgement of the germ which produces the diphtheritic process, without there necessarily being any connection between the two processes. He was ready to admit that if one of his children should have catarhal pharyngitis, he would feel very much alarmed, although he did not believe that it was the prodromal stage of the diphtheritic process.

Dr. John N. Mackenzie, of Baltimore, then read a paper entitled

A CONTRIBUTION TO THE STUDY OF CONGENITAL SYphilis,
in which he directed attention to the manifestations of congenital syphilsis in the throat, and their behavior under treatment. The text of the paper was the history of a case, which presented two features worthy of special consideration: 1. the degree of resulting stenosis of the lower pharynx; 2. paralysis of both upper eyelids, with subsequent paralysis of the abducens, and the occurrence of deafness in one ear. The case was one, then, of congenital syphilis affecting the cranial nerves. The two features in the history were considered to direct special attention, that there was no reason for believing in the existence of an ulcerative scrophulitis of the throat; that while congenital syphilis afforded no protection against the occurrence of other diseases, it mitigated the course of certain acute affections accompanied by an exanthem; that the syphilitic ulceration of the throat is more dangerous than that of the ear. He thought that the remarks did not apply to malignant epidemic influences, or to syphilitic cachexia.

The President thought that the question of the identity, or the duality of syphilita and syphilis was an important one for consideration and either rejection or acceptance.

Dr. E. L. Shurley, of Detroit, thought that while there undoubtedly existed an intimate relationship between syphilita and syphilis, the two diseases were, and should be, kept entirely distinct. He was not prepared to say how much difference there was between scrofulous and tubercular ulceration.

He wished to be understood that he said there was no difference between syphilita and syphilis, but simply that ulceration of the throat is an expression of some diathesis, which in the great majority of cases was syphilitic, lupoid, or tubercular, and that there is no distinctive point of difference between scrofulous and syphilitic ulceration of the throat, or between scrofulous and lupoid or tubercular ulceration. He did not mean to say that all syphilis is syphilita.

Dr. J. H. Hartman, of Baltimore, referred to a case of measles occurring in a syphilitic child where the ulcerated condition of the throat was materially aggravated and the child’s condition was very much worse after than before the attack of measles occurred.

Dr. F. Donaldson, of Baltimore, referred to an undoubtedly case of scrofulous ulceration of the pharynx, independent of syphilis.

Dr. F. I. Knight, of Boston, felt very much as did Dr. Mackenzie, that where loss of substance of the mucous membrane of the pharynx occurred it was due to either the syphilitic or tubercular diathesis, and that in dealing with the patients, whether children or adults, should be treated in accordance with this general inference.

The President said he had a growing conviction, based upon observations made in a very large dispensary practice, that, so far as the mucous membrane of the upper air-passages was concerned, there was no difference between ulcerations due to syphilita and those caused by true syphilis. Of late he had depended upon mercurials in the treatment of all these cases, and the use of the remedy had been eminently satisfactory. Perhaps the results of treatment gave some ground for regarding the two affections as identical.

Dr. Mackenzie’s treatment had consisted in the use of mercurials, iodide of potassium, and the local use of iodiform.

The President appointed as Nominating Committee, Drs. F. I. Knight, of Boston, G. M. Lefferts, of New York, and J. Solis-Cohen, of Philadelphia.

For Auditing Committee, Drs. J. N. Mackenzie, of Baltimore, and F. H. Hooper, of Boston.

New Fellows—Dr. S. Solis-Cohen, of Philadelphia, and Dr. Clarence C. Rice, of New York.

The Association then adjourned to meet at 3 P.M.

FIRST DAY—Afternoon Session.

The first paper was read by Dr. J. O. Roe, of Rochester, on RETRO-PHRYNGEAL ABSCESS, in which he referred to the two general classes of the affection: (1) Those which originate in the soft parts, and (2) those which arise from disease of the vertebral. After describing the anatomical peculiarities of the glands and conditions which direct special attention, he mentioned the various causes of injuries of the spine, etc. He then spoke of the differential diagnosis, and passed to the treatment, which consists only of prompt incision and evacuation of the pus, making a small opening at first, and holding the head forward to prevent pus from entering the larynx.

Dr. Roe reported three cases.

Dr. T. A. DeBlois, of Boston, had had three cases, and thought sufficient importance had not been attached to the position of the head, namely, carried markedly backward, as a symptom of diagnostic value.

Dr. S. Johnson, of Baltimore, spoke of the direction of the incision as important in guarding against the danger of pus entering the larynx, namely, horizontal and inverting the child when it is made.

Dr. W. C. Jarvis, of New York, mentioned a case occurring in an adult as a complication of tonsillitis.

Dr. G. M. Lefferts thought it was only necessary to look into the throat, at most to introduce the finger, to make a correct diagnosis. He thought it was a matter of difference whether the incision was made horizontal or otherwise. The indication was to evacuate the abscess, and the sooner the better. He had seen only two cases, and thought that the disease was rare.

Dr. F. Donaldson, of Baltimore, referred to a case in which he emptied the abscess by means of an aspirator and completed the operation by making an incision.

Dr. G. W. Major, of Montreal, had had two cases, also one of sarcoma of the pharynx which had been mistaken for retro-pharyngeal abscess.

Dr. R. P. Lincoln, of New York, cited a case occurring in a child three years old, in which relief was afforded at once by opening the abscess, but it was accompanied by deep suppuration in the neck, which necessitated the use of the aspirator to effect a cure.

Dr. J. N. Mackenzie, of Baltimore, referred to a case of gummy tumor which presented all the usual appearances of retro-pharyngeal abscess, and it was only by incising the mass that the real nature of the case was determined. The case was interesting as evidence that neither look nor touch was a sufficient test as a diagnosis.

Dr. E. F. Inghal, of Chicago, was surprised to hear that the occurrence of this form of abscess was so rare.

Dr. J. Solis-Cohen, of Philadelphia, said that the apprehended danger from pus entering the larynx when the abscess is opened could be obviated by operating with
the head, and the incision was made upward. The chief objection to the horizontal incision was that it left a pocket into which pus might gravitate subsequently.

Dr. C. W. Chamberlain, of Hartford, Conn., cited a case in which the abscess burst and fatal hemorrhage occurred from rupture of the carotid artery.

The discussion was closed by the President and Dr. Rose.

Dr. T. A. DeBlois, of Boston, then read a paper in which he reported

A CASE OF CONGENTINAL WEB OF THE VOCAL BANDS occurring in the dispensary practice of his colleague, Dr. J. W. Fowler. Dr. DeBlois treated the case by introducing a pair of Mackenzie's forceps into the larynx, then opening and withdrawing them, so as to split the web. Several operations were necessary before this was accomplished, and after the desired result was secured, treatment was continued by dilatation with a probe.

Dr. J. H. Hartman, of Baltimore, seriously objected to this method of destroying the web, and thought it could have been accomplished by means of the galvano-cautery.

Dr. M. J. Asch, of New York, referred to a case in which a web formed as a result of acute laryngitis. Dr. F. I. Knight, of Boston, thought there was no danger of doing damage to the larynx with the forceps where the web was as thin as it seemed to be in Dr. DeBlois' case, which he had an opportunity to examine. Certainly he should avoid the use of the galvano-cautery in the larynx.

Dr. DeBlois said that, while the web proved to be a little tougher than he supposed it was, he regarded the case as one which could not have been treated safely with either the knife or galvano-cautery.

Dr. William H. Daly, of Pittsburgh, then read a paper in which he reported a case of

GUNSHOT WOUND OF THE LARYNX, IN WHICH THE VOCAL BANDS WERE INVOLVED.

He first referred to the literature of the subject as found in the "Surgical History of the War," and in the writings of Gross and Cohen. The case was that of H. C. D., eighteen years of age, who was accidentally shot with a pistol, thirty-two calibre, the ball entering the right side of the neck, traversing the larynx, and lodging immediately over the left subclavian artery, from whence it was removed. The boy recovered, and regained the power of vocalization sufficient for all purposes except the voice, and some difficulty in swallowing. Dr. Daly then read several histories which had been sent to him by medical gentlemen with whom he had corresponded with reference to this class of cases.

Dr. J. Solis-Cohen, of Philadelphia, said he had recently had occasion to look up the literature of gunshot wounds of the larynx, and was astonished to find how few cases were on record in military surgery. When he saw Dr. Daly's patient first he was unable to believe that the ball had penetrated the larynx, and it was still strange to him how it could pass through the larynx without producing more symptoms, and more destruction of the thyroid cartilage at the point of exit.

Dr. Lefferts, of New York, referred to a specimen in his collection which proved that a bullet-wound can be made in the larynx without extensive destruction of the thyroid cartilage, and have no place of exit.

Dr. Cohen said there were only four specimens in the Army Medical Museum at Washington of gunshot wounds of the larynx.

Dr. J. Solis-Cohen, of Philadelphia, then reported

A CASE OF COMPLETE UNILATERAL PARALYSIS OF ALL THE ADDUCTORS OF THE VOCAL BANDS, THE ADDUCTORS REMAINING INTACT.

The condition followed a suicidal wound in the neck.

The President thought it was the first authentic case demonstrating the possibility of the occurrence of true adductor paralysis.

The case was discussed by Drs. Knight, of Boston, Lefferts, of New York, and Seiler, of Philadelphia, who made critical remarks bearing upon possible explanations of the phenomenon, and also the rarity of its occurrence.

The Association then adjourned to meet at 11 A.M. on Tuesday, May 13th.

TUESDAY, MAY 13—SECOND DAY—MORNING SESSION.

The Association was called to order by the First Vice-President, Dr. Samuel W. Langmaid, of Boston.

The first paper was read by Dr. F. H. Hooper, of Boston, and was entitled

A RARE FORM OF TUMOR (CAVERNOUS PAPILLOMA) OF THE VOCAL BAND.

The peculiarities of the case reported were the following: (1) it differed from any on record; (2) a bloody cystic growth; (3) the unusual happy termination—there has been no recurrence. It was a nodular sessile growth, situated on the anterior part of the left vocal band. It was removed by avulsion.

Dr. C. Seiler, of Philadelphia, had seen a very similar case, in which the growth was almost entirely angiomatos in character, and situated upon the right vocal band.

Dr. Morris J. Asch, of New York, then reported a

A CASE OF ECCCHONDROSIS OF THE LARYNX,

and said that only two cases had been reported in which the condition had been diagnosed and the patient treated. Dr. Asch removed the growth by the endolaryngeal method, using a Stork guillotine constructed especially for the purpose. The microscopical examination was made by Dr. George L. Peabody.

Dr. W. C. Jarvis, of New York, then read a paper entitled

A NEW METHOD FOR THE REMOVAL OF LARYNGEAL GROWTHS, WITH AN ILLUSTRATIVE CASE.

The paper was intended as a reclamation of the use of chronic acid in the removal of laryngeal papilloma. The method consisted in applying small quantities (one-sixth of a grain) at short intervals, fused upon the point of a probe. The escharotic dissolved immediately when applied to papillomatous tissues, was safe, painless, efficient, and resulted in restitution. Dr. Daly, then, had read several histories which had been sent to him by medical gentlemen with whom he had corresponded with reference to this class of cases.

Dr. J. Solis-Cohen, of Philadelphia, said he had recently had occasion to look up the literature of gunshot wounds of the larynx, and was astonished to find how few cases were on record in military surgery. When he saw Dr. Daly's patient first he was unable to believe that the ball had penetrated the larynx, and it was still strange to him how it could pass through the larynx without producing more symptoms, and more destruction of the thyroid cartilage at the point of exit.

Dr. Lefferts, of New York, referred to a specimen in his collection which proved that a bullet-wound can be made in the larynx without extensive destruction of the thyroid cartilage, and have no place of exit.

Dr. Cohen said there were only four specimens in the Army Medical Museum at Washington of gunshot wounds of the larynx.

Dr. J. Solis-Cohen, of Philadelphia, then reported

A CASE OF COMPLETE UNILATERAL PARALYSIS OF ALL THE ADDUCTORS OF THE VOCAL BANDS, THE ADDUCTORS REMAINING INTACT.

The condition followed a suicidal wound in the neck.
PRESENTATION OF INSTRUMENTS.

Dr. J. H. Douglas, of New York, exhibited a new powder-blower.

Dr. W. C. Jarvis exhibited a new laryngeal stethoscope.

Dr. J. N. Mackenzie, of Baltimore, exhibited a new nasal speculum. He also made a suggestion concerning illumination of the nasal cavities by means of incandescent light.

Dr. Seiler had used this light with decidedly unsatisfactory results.

Dr. Ingals, of Chicago, referred to a device to facilitate the passage of the wire around growths in the posterior nares.

Dr. C. E. Sajous, of Philadelphia, exhibited a new tonsillectomy knife, and also a new uvulotome which leaves an oblique cut surface on the posterior aspect of the uvula.

Dr. D. B. Delavan, of New York, exhibited a new instrument devised to facilitate alimentation in cases of dysphagia from any cause.

The Association then adjourned to meet at 3 P.M.

SECOND DAY—AFTERNOON SESSION.

Dr. Langmaid, Vice-President, in the chair.

On motion, by Dr. Knight, of Boston, the subject of New Nomenclature was referred to the Council for action and report at the next annual congress.

Dr. D. Bayson Delavan, of New York, then read a paper entitled PERMANENT UNILATERAL PARALYSIS OF LARYNGEAL ADHOCRATORS, FOLLOWING CEREBRAL HEMORRHAGE—UNIQUE CASE.

The case reported was interesting not only on account of its rarity, but because it opened for study the whole field of the cause of the paralysis of the adductor paralysis. It was a case of cerebral hemorrhage with paralysis of the region of the pharynx and larynx, and in which all the paralytic symptoms had almost entirely disappeared except with reference to the laryngeal adductors of the right side, the paralysis of which had lasted seven years.

Dr. Knight, of Boston, mentioned a case in which a patient fell, struck upon the top of his head, noticed an alteration of the voice, and on subsequent examination the only lesion which could be found was paralysis of one laryngeal adductor.

Dr. Rufus P. Lincoln, of New York, then read a paper in which he reported a case of STRUCTURE OF THE OESOPHAGUS, occurring in a man, fifty years of age, and due to cancer. The dysphagia and dyspepsia were due to the cancerous material involving the laryngeal and esophageal branches of the pulmonary arteries, and death occurred from changes produced in the cardiac branches by the same disease.

The paper was discussed by Dr. J. O. Roe, of Rochester, Dr. W. H. Daly, of Pittsburgh, Dr. Donaldson, of Baltimore, Dr. Ingals, of Chicago, Dr. Knight, of Boston, and the discussion was closed by Dr. Lincoln.

Dr. E. Fletcher Ingals, of Chicago, read a paper in which he reported three cases of TRACHEAL STENOSIS, syphilitic in character, and in which relief was afforded by twenty large doses of iodide of potassium. The third case was one in which a distinct syphilitic history could not be obtained, but iodide of potassium cured the patient, and the peculiarity was that it yielded only when one hundred and twenty grains were taken four times a day for about ten days, and then after a short interval renewed in doses of sixty grains, and again increased to the largest quantity.

Remarks were made by Dr. DeBlois, of Boston, Dr. Shurley, of Detroit, Dr. Langmaid, of Boston, and Dr. Delavan, of New York, who referred to cases similar in character and which yielded to similar treatment.

The President preferred to use mercurial inunctions, especially as sometimes the iodide of potassium may produce dangerous pharyngeal and laryngeal irritation and oedema.

The Association then adjourned to meet on Wednesday at 10 A.M.

WEDNESDAY, MAY 14—THIRD DAY—MORNING SESSION.

The Association was called to order by the President, Dr. Bosworth, of New York.

The first paper was read by Dr. T. A. DeBlois, of Boston, entitled CASES OF BUCCAL TUBERCULOSIS, in which it was maintained that pulmonary tuberculosis preceded tuberculosis of either the pharynx or the larynx. Two cases were reported in which the lesion manifested itself in the buccal mucous membrane, first in the form of small nodules in the mucous membrane. The second case was one of laryngeal phthisis, in which the tubercular disease extended to the buccal cavity, and manifested itself chiefly in the tonsils, but the microscopic examination after autopsy failed to show the presence of tubercle tissue in this locality, although in abundance in the larynx and several other organs.

Dr. Langmaid, of Boston, said that when he first saw the second patient there was no evidence in her general appearance of pulmonary disease, but examination of the larynx, brought about by her peculiar voice, revealed a condition which led to examination of the lungs, when evidence of pulmonary phthisis was revealed.

The President remarked that, so far as he knew, the microscopic examination given by Dr. DeBlois, was the first that had been reported of buccal tuberculosis. He regarded it as reasonable to believe that tuberculosis of the larynx or the upper air-passages can occur primarily. Besides, it was noticeable that the nearer the tuberculosis occurs to the outer world the more fatal it is, and the more difficult it is to allay the symptoms. From pulmonary phthisis patients may recover; also from laryngeal phthisis, but less frequently; but from buccal tuberculosis never, and the difficulty in allaying the symptoms manifests itself in the same ratio.

A communication from Dr. S. H. Chapman, of New Haven, Conn., was read and referred to the Council for action.

The Secretary read a letter received from Dr. William Porter, of St. Louis, mentioning his great affliction, and the President, on behalf of the Association, extended to Dr. Porter deep sympathy with him in his great bereavement.

Dr. C. E. Sajous, of Philadelphia, then read a paper ON HAY FEVER, AND ITS SUCCESSFUL TREATMENT, in which he stated that the true theory concerning the disease was that it was due to idiosyncrasy becoming affected by certain emanations. Still there are cases in which dust will cause an attack, but if we bear in mind the fact that the nasal mucous membrane is in a state of chronic hyperemia, we can understand how an irritant in these patients can cause a greater degree of discomfort than in others. It was evident to him, also, that malformation of the nasal cavity is not the cause of the affection.

His mode of treatment consists in destroying as much as possible of the mucous membrane covering the turbinate bones. This procedure is not undertaken for the purpose of removing as much as possible of the mucous membrane of the middle and anterior turbinated bones. The operation does not impair the sense of smell.

Hay fever, therefore, according to the reader, is an idiosyncrasy influenced by certain substances; is accom-
panied by hyperesthesia of the nasal passages; organic alteration of these parts annuls the hyperesthesia; and destruction of the sensitive parts of the mucous membrane can be best effected by means of the galvano-cautery. His observations had been conducted without known injury to the patient. His paper is the same subject, and to which he cheerfully accorded the credit of priority.

Dr. Shurley, of Detroit, had no doubt that the theory advanced by Dr. Sajous was correct, but concerning treatment, it had been his aim to merely cut off the peripheral filaments of the nerves, ascertaining with the probe where the hyperesthesia was most marked, and then confine the application to the sensitive part.

Dr. Roe, of Rochester, regarded the affection as a localized disease of the terminal filaments of the nerves supplying the nasal mucous membrane. To destroy the tissue in which these filaments ramified cured the disease.

Dr. J. N. Mackenzie, of Baltimore, thought too much stress had been laid on local conditions of the nose, and believed that the local feature of the disease resides in an exalted excitability of the nasal tissue, especially where the sphenopalatine nerves are distributed, and that the essential nature of the disease consists in an abnormal excitability of the reflex nervous centres. So far as treatment was concerned, he thought that the best plan was to destroy the sensitive areas in the nasal cavities, and if these were destroyed, no matter how sensitive the reflex centres may be, the patient will be cured. The most essential feature of the disease, then, is an abnormal excitability of the reflex nervous centres, which may be inherited or acquired, and set into action by a host of outside influences acting upon a hyperesthetic nasal mucous membrane. It was undoubtedly true that in very many cases the attacks came on in certain months in the year, but this was not by any means a universal fact.

The President thought a better name than hay fever would be vasomotor rhinitis. There are three elements in the affection: (1) the neurotic, as shown by Dr. Beard; (2) structural change in the nasal cavities; and (3) abnormal sensitiveness of the nasal mucous membrane to the action of some irritant, such as pollen, dust, etc. Remove either one of these elements and the patient is cured. To say that all cases are due to either one was wrong. He pointed with pride to the fact that it was in the American Laryngological Association that the best work toward a complete understanding of the affection had been done.

Dr. Sajous said he did not ignore the reflex centres, as without doubt they played the most important part in the development of the disease; but the surface principally exposed to the action of exciting causes was that of the nasal cavities.

Dr. E. L. Shurley then read a paper on the comparative value of the galvano-cautery in diseases of the nasal and pharyngeal cavities, in which he called attention first to the conditions necessitating the employment of the galvano-cautery; second, the comparative value of this agent; and third, its importance and priority. By common consent, the admission of the use of this agent, we should positively discover whether the nasal mucous membrane is temporarily swollen or permanently thickened. In all cases no more of the mucous membrane should be destroyed than is absolutely necessary, for cicatrization tissue does not supply the needs of nature.

Under the second head came mechanical, chemical, and electrical agents. Of the mechanical, Bosworth’s modification of Jarvis’ snare had served him best for the removal of polypi, but he had been unsuccessful—probably from lack of skill—in the use of any snare for the removal of hypertrophied mucous membrane.

Chemical agents failed to destroy sufficient of tissue, unless applied frequently that they were followed by damaging reaction.

The great merit of the galvano-cautery consisted in the precision with which the offending part could be touched. The mucous and submucous tissue must be completely divided.

Dr. Jarvis, of New York, spoke of the special efficiency of the little needle in conjunction with its use in limiting the amount of tissue to be removed, a result which cannot be accomplished so exactly with the galvano-cautery.

Dr. Sajous, of Philadelphia, had used the needle devised by Dr. Jarvis and found it very serviceable in cases in which the desired effect could not be produced by the galvano-cautery without destroying too much tissue.

Dr. Roe had used the galvano-cautery with good results in many cases, but believed that it should be used with great discrimination and care. For obliterating deep vessels it was the best agent that could be employed. In cases of marked hypertrophy of the mucous membrane he always used the snare.

Dr. Mackenzie was a warm advocate of the snare, yet there were cases in which it could not be used. He agreed with Dr. Shurley that the very best treatment for granular pharyngitis was the galvano-cautery.

Dr. Beverley Robinson, of New York, then read a paper entitled A contribution to the study of adenoid vegetation at the vault of the pharynx.

He had met with these growths only infrequently. He had yet to encounter the first case in which the growths had impinged upon the orifices of the Eustachian tube and produced deafness; and believed that the ear disease in these cases was due to extension of inflammation to the middle ear.

He took exception to the view which called chronic follicular pharyngitis adenoid vegetations. Scraping, cutting (Meyer’s method was the best), and the galvano-cautery were the means he had employed for their removal.

Dr. Langmaid had a case in which removal of a large growth was followed by immediate restoration of hearing.

Dr. Mackenzie uses forceps in these cases, and follows with a spray of alcohol. To allow these to remain until puberty was a very fallacious idea.

Dr. Major removes the growths with the finger-nail at the same time he introduces the finger for diagnostic purposes.

Dr. Roe uses forceps, and Dr. Asch has adopted different methods.

Dr. Jarvis protested against the use of forceps, on the ground that it is dangerous to grope around in the dark behind the palate.

Dr. Robinson said that the most important feature of his paper was the claim that, in one-half of the cases at least, mechanical measures are used unnecessarily.

Dr. Louis Elberg, of New York, then read a paper on spasms of the glottis, in which he defined laryngeal spasm to be spasmodic contraction or spasm of the laryngeal muscles; and then presented the subject fully under the heads of classification, etiology, diagnosis, differential diagnosis, etc. In conclusion he answered questions put by several of the members.

The following were elected officers for the ensuing year, after which the Association adjourned, the time and place for the next annual congress to be decided by the Council:

President——E. L. Shurley, M.D., of Detroit; First Vice-President—J. H. Hartman, M.D., of Baltimore; Second Vice-President—William H. Daly, M.D., of Pittsburg; Secretary and Treasurer—D. Bryson Delavan, M.D., of New York; Librarian—Thomas R. Fench, M.D., of Brooklyn; Associate Editors: Dr. Frank H. Bosworth, Morris J. Asch, and Beverley Robinson, of New York, and Dr. Frank Donaldson, of Baltimore.
NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, May 1, 1884.

Horace T. Hanes, M.D., Vice-President, in the Chair.

The Corresponding Secretary, Dr. John G. Adams, announced the death of Major-General William Henry Harner, M.D., of Morristown, N. J., an honorary member.

The Statistical Secretary, Dr. Francis H. White, announced the death of William Parker, M.D., L.L.D., one of the founders of the Academy and an ex-Vice-President. The Chair appointed Dr. John C. Dalton and Dr. Wm. H. Draper a committee to prepare a memoir.

Dr. John G. Adams then read a memoir of the late Edward Langdon Beadle, M.D., one of the founders of the Academy, a steady contributor to its support, and who left it a legacy of $3,000, together with his library. Dr. Beadle resided in Pough-keepsie, and his funeral services took place April 5, 1882. The memorialist set forth the characteristics included in the social excellence, the intense courage, the executive ability, the unassuming usefulness, and the inflexible integrity of the deceased, for whom the paths of duty and happiness ran in parallel lines.

STUDIES IN INTERNAL ENDOMETRITIS.

Dr. Mary Putnam-Jacobi read an elaborate paper on the above subject, in which she spoke first of the anatomy, and directed special attention to the view of Leopold, which gave the inference that the endometrium was regarded as only an immense lymph sac, an inference singularly wide of the mark, as it merely took into account one of the properties which it possessed in common with other organs.

The author of the paper then submitted twelve propositions, of which the following are some of the important points:

1. The essential part of the utero-ovarian system is the endometrium, which may appropriately be called a germinative membrane, because it is the seat of the process of germination of embryonic elements.

2. The utero-ovarian system may be said to have no function.

3. The reproducing tissues generally assume new properties at certain epochs, and continue their manifestations with the single property of growth until the menopause. So with the ovaries: before menstruation is established, the process of growth is continuous; subsequently the process sustains a series of interruptions by means of which is deflected into cyclical movements the changes and processes that occur during their period of activity. There are two cycles: the lesser, menstruation; the greater, pregnancy.

4. The homology between these two cycles is complete.

5. The characteristic disease of the greater cycle is subinvolution of the uterus and its annexes, namely, the ovaries and the venousplexuses contained in the broad ligaments. The characteristic disease of the lesser cycle is subinvolution of the endometrium after menstruation.

6. In both cycles the physiological process of growth is initiated in the endometrium. Menstruation is initiated in the same tissue, and the cause of failure in this regard is to be sought there. Chronic metritis in the multiparse or nulliparse originates in endometritis, which implies subinvolution of the endometrium.

7. A characteristic disease of the uterus depends upon disease of the lining membrane or the membrane covering its surface.

8. Nearly all other utero-ovarian diseases may be similarly traced to disease of this germinal membrane.

Diseases of the ovaries are due in a large proportion of cases to original trouble in the endometrium. Even neoplasms begin in a deviation in the processes of growth taking place first in the endometrium. Disease of the uterine cervix may be primary.

9. Thus, with the exception just named, utero-ovarian affections should be regarded as unique, the real disease being subinvolution of the germinative membrane with its consequent complications.

10. Utero-ovarian disease is a deviation of the process of growth habitually occurring in the utero-ovarian tissues. The most common is called inflammation, and toward the close of the active period of menstrual life the deviation may be exaggerated and terminate in the development of neoplasms.

11. The ultimate object of all treatment of utero-ovarian disease must be restoration of the integrity of the normal processes operating in the endometrium, which may be affected either directly or indirectly, the object remaining essentially the same in either instance.

12. Both for the success and safety of local treatment of endometritis, it is essential to take into account the rhythmic change of which it is the seat.

The author of the paper then elaborated each of these propositions. That the endometrium is the essential part of the utero-ovarian system cannot be disproved from a physiological point of view. Facts have established a continuous inter-menstrual growth of the endometrium. The development of the uterine parenchyma belongs to pregnancy only.

A NEW HYPOTHESIS CONCERNING MENSTRUATION.

The peri-uterine and ovarian plexuses constitute a reservoir of blood to meet the demands of pregnancy. This reservoir is reproductive. Hypothesis: That the accumulation of blood in the plexus is effected by the gradual growth of the veins of which it is composed, and as their lumen enlarges more blood is aspirated into them, and the appearance of engorgement is developed, which really depends upon actual new growth of the vessels, which marches pari passu with the development of the Graafian follicles and the endometrium.

In menstruation the endometrium grows until a certain point is reached, when growth is arrested by pressure and the vitality of the surface is destroyed, and exfoliation takes place. The amount of pressure is according to the measure of growth against the uterine tissues, and the metamorphosis affecting the epithelial layer gives rise to rupture of capillaries and pouring forth of blood upon its surface.

The so-called uterine glands have no function, and are analogous to the depressions in the brain called convolutions. The uterine tissue also has no function. There is no case of subinvolution which does not exhibit at the beginning some form of endometritis, either congestive, catarrhal, or fungous, from formation of granulation tissue. Parenchymatous inflammation further favors growth of the endometrium.

The characteristic symptoms of endometritis are all due to malnutrition of the peripheral extremities of the utero-ovarian nerves from excess of blood.

There is a marked similarity between the symptoms of endometritis and pregnancy, and nausea indicates that the disease, which perhaps began in the cervix, has extended beyond the internal os. The links in the semio-logical chain are in regular order endometritis, disturbances of the spinal cord, disturbances of the medulla, and in aggregation a dash upon the occipital portion of the brain, giving rise during origin, progress, and with destruction, to the multitudinous nervous phenomena developed during the existence of the disease.

There are symptoms which are present in endometritis: the passage of a fine probe through the internal os causes exquisite pain; there is hyperaesthesia attended by hyperemia; the fundus of the uterus is sensitive under abdominal palpation, and the patient suffers from dysmenorrhea.

Pain occurring during the menstrual flow is never ovarian, but due to endometritis, malnutrition, etc.
The pain of ovarian disease is relieved by the flow, and where it exists it will be found that endometritis co-exists.

THE TERMINATIONS OF ENDOMETRITIS
are peri-uterine inflammation, flexions and versions, and, finally, cervical catarrh.

The author of the paper commented on these, and then gave an ingenious

EXPLANATION OF UTERINE DISPLACEMENTS,
based upon the relations of the uterine ligaments to the endometrium. Anterior flexion depends upon irritation of the uterine portion reflected through the round ligaments; if fundal irritation is reflected through the uterosacral ligaments anteversion takes place.

With retroflexion and version there is no irritative mechanism, but it is rather parietic because the ligaments are too short, unless there is relaxation of the round and the uterosacral ligaments. The displacements are only incidental, and radical cure by means of pessaries will be the exception and not the rule.

The ultimate object of treatment is destruction of the subinvolved portion of the endometrium, and the remedies used should contribute to stimulate healthy processes.

The effect of applications should extend from the endometrium to the uterine parenchyma and peri-uterine tissue, and, if possible, to the ovaries.

The principles of treatment are included in the following propositions:

1. Whatever will raise arterial tension tends to establish conditions favorable to involution of the endometrium.

2. By means of local treatment, endocervicitis and a disposition to venous hyperemia may be so overcome as to diminish the venous hyperemia of the internal endometrium, and menstruation may be established and effect a cure.

3. By direct local applications to the internal endometrium the effects to be expected are (a) destruction to a greater or less extent of tissue; (b) reflex excitation of contractions in the uterine wall, as well as of the muscular fibres in the broad and other ligaments; (c) in consequence of these effects temporary acceleration of blood through all the utero-ovarian vessels. By destruction of excess of tissue of the endometrium and blood-vessels, opportunity is afforded to modify the growth of the menstrual cycle, and thus to raise the local arterial tension and increase the menstrual flow.

The author of the paper then pointed out the dangers attending attempts to apply these principles, and followed with rules concerning local applications:

1. The time for local applications should be limited to the post-menstrual week; they should not be begun within the ten days immediately before menstruation.

2. The effect of one local application should completely subside before another is made.

3. In cases involving much parenchymatous metritis the applications should be preceded by the use of tents. The dangers attending the use of tents were then pointed out.

The fundamental principle in the treatment of endometritis is cauterization, the object being to destroy the subinvolved tissue, so that the new growth will proceed in a more healthy manner.

The relative amount of irritation produced by different caustic remedies was then discussed, followed by reference to complications liable to arise from their injurious use.

Dr. B. F. Dawson was asked to open the discussion, and said that as he came to listen and not to speak, he would only refer to one clinical point; and, besides, the paper was so extended and so exhaustive that an attempt to discuss it in detail could not be entertained at that late hour.

With reference to pain, the author of the paper had stated that in ovarian dysmenorrhea it preceded the flow, and was relieved when the flow was established. Physiologically and pathologically this might seem to be correct; but he had seen—perhaps he might stand alone in the opinion—cases in which he was unable to diagnose anything else except ovarian dysmenorrhea, and yet the pain persisted throughout menstruation.

Dr. Paul F. Mundé said he was glad to hear one of the propositions laid down by the author of the paper, namely, that endometritis originates in two conditions, which he thought he had hereafter been insufficiently pointed out. First, endometritis originating in menstrual subinvolution; and second, endometritis originating in purgatorial subinvolution.

He was confident that a large proportion of cases originated in one or both of these causes; because in these cases the uterine canal is patulous, the os gaping so as to admit a large-sized sound up to the fundus without difficulty, and often without pain, and with no other particular symptom except a slight flow of blood, which is, in so patulous a uterine canal, one of the symptoms of chronic endometritis. The importance of carefully appreciating this fact he regarded as evident, because it will lead to earlier treatment of the case than is the general rule, and control of the symptoms of the patients than must otherwise be effected. The longer the catarrh lasts the more difficult it is to cure, or even to effect temporary improvement.

Another point is the dependence of peri-uterine celilitis and peritonitis upon uterine catarrh. He had so doubt that in a large proportion of cases pelvic cellulitis and peritonitis depend upon irritation extending directly to the endometrium to the neighboring organs. Therefore if we wish to cure a case of recurrent pelvic cellulitis or peritonitis, we must remove the inflammation from the surrounding tissues, and also the condition which originated it, namely, the chronic endometritis. But it is not always safe to treat this cause of parametritis, and it is often better to let the endometritis alone than to run the risk of re-exciting its consequence, the peri-uterine inflammation.

The author of the paper had noticed that pelvic peritonitis originates more frequently from the fundus, or is transmitted from the Fallopian tubes, than from irritation brought to bear upon the cervix. Dr. Mundé continued that he had send new patients produced by irritation of the cervical mucous membrane below the internal os than from irritation of the endometrium above it. He believed that the connection between the lymphatics of the cervix and the parametrium is much closer than from the uterine cavity proper to the parametrium.

The same would hold with regard to ovaritis. When there is the slightest sign of enlargement or tenderness of either ovary, he always hesitated to treat the endometritis by local applications, and always followed the plan of reducing the inflammation of the ovary first, before attempting to treat the endometritis, whether corporeal or cervical. There was one symptom of endometritis which had not been mentioned and which he had encountered rather frequently. He had already stated that the uterine canal would be found gaping, but besides that there is erosion of the external os. This he had seen in virgins, in women who had not borne children, and also in parous women, and it is due to the excessive discharge of mucous secretion from the endometrium, and therefore a sign which necessitates the treatment.

With regard to fundal tenderness, he thought it was equally a sign of areolar hyperplasia, or any enlargement of the uterus, as of chronic endometritis.

The statements concerning the etiology of flexions was a very plausible one, and one to which he could hardly subscribe. He was quite sure he had seen cases in which there was decursus of the uterus, where the cervix rested
upon the floor of the pelvis, and where there was nothing pathological in either the ovaries or the ligaments to account for it, but where there had been chronic endometritis extending over a period of seven years, and to that the downward displacement of the uterus was undoubtedly due.

The theory of transmission of irritation through the round and other ligaments, causing them to contract and produce a respective displacement was very ingenious, and seemed quite plausible.

With regard to treatment, which really interested the general practitioner most, it was well to prevent the disease; but when it was present the primary object was to cure it, and yet this is not easily done. In the majority of cases treatment is only temporarily beneficial. So far as general treatment is concerned, measures should be employed which increase pelvic circulation, and tend to remove the hyperemia of the pelvic organs.

But as regards local treatment, he wished to be distinctly understood that corporeal endometritis should be treated from the fundus downward. Cure the fundus first before expecting to cure the cervix, simply because the corporeal discharge will keep up the local infection of the cervix until it is arrested.

With regard to the remedies used the better; the best remedy is the severest remedy, taking into consideration all precautions in its use. In all chronic cases of hyperplasia of the mucous membrane the 'dull' curette is a remedy not at all to be despised. It is a safer remedy, is quite as easily applied, and certainly is as efficient in the beginning as the stronger caustics, like, 'nitrifying.' His usual plan when the catarrh is very chronic and the endometrium is hypertrophic is to remove a portion of the thickened mucous membrane with the curette and then to apply a caustic, and if it was a bad case he did not hesitate to apply strong nitric acid. If not so bad, he used iodized phenol, or compound tincture of iodine, or iodoform, etc.

As a rule he did not first dilate the uterine canal, and did not regard it as safe to attempt to do so when there was evidence ofpara-uterine inflammation.

The length of time treatment will be required will depend upon how long the disease has existed. Certainly it will need to extend over a number of months. With regard to the use of nitric acid he used nitric acid oftener than once in two weeks, perhaps not oftener than once a month. The best time for making the local applications is shortly after the cessation of a menstrual period.

The possible occurrence of pregnancy while the patient is under treatment (as illustrated by a case recently seen by him of pregnancy after three applications, the patient having been sterile during her four years of married life) encourages the use of local measures, as pregnancy is perhaps the best means of curing the endometritis, provided care is taken to examine the patient before her getting up after delivery, and, if necessary, applying local astringents or caustics at this, the most favorable time for a cure. What has been used by others may be expected to be used by him.

Dr. W. GILL WYLIE complimented the author of the paper and then directed attention to a few points which had not been mentioned. The relation which salpingitis, or any disease of the Fallopian tubes, sustained to endometritis he regarded as very important. Many cases were incurable on account of the associated disease of the Fallopian tubes. Many diseases which were innocent while restricted to the uterine cavity might become incurable when they reached the tubes.

Besides this, and it was very frequently overlooked, peri-uterine inflammation occurred much more commonly than was usually supposed.

Again the influence of certain well-known poisons had not been mentioned. He was satisfied that specific disease was by no means an uncommon cause of endometritis, which was intractable and in many cases the cause of a salpingitis which could not be cured, except by removal of the tube.

With reference to treatment, Dr. Wylie thought that in acute endometritis, especially the specific, any local treatment at all was very desirable; and that the best plan was to let the patient very much alone.

He would always lay more stress upon the preparatory treatment, and wait until the subacute stage had been reached, and treat the endometritis by applications to the vagina. He favored the local use of glycerine and alum applied on cotton-balls placed in the vagina.

He agreed with the author of the paper in the statement that local applications are generally very beneficial. He used iodoform upon sponge-tents when they were employed, and also sprinkled all tampons quite freely with the same remedy, because it prevented decomposition. The point regarding applications ten days before menstruation, was new to him, but he was inclined to regard it as an important one.

Dr. PUTNAM JACOBI, in closing the discussion, said that in those cases of endometritis which occur in multiparous women, even with catarrh and exquisite irritability of the uterus, one of the characteristic conditions was the tight contraction of the internal os, and it was in such cases, in which she did not assume there was any enlargement of the uterus, that Dr. Mundé had not quite got her idea. He was not necessarily first to dilate the uterine canal, and did not regard it as safe to attempt to do so when there was evidence of para-uterine inflammation.

The length of time treatment will be required will depend upon how long the disease has existed. Certainly it will need to extend over a number of months. With regard to the use of nitric acid he used nitric acid oftener than once in two weeks, perhaps not oftener than once a month. The best time for making the local applications is shortly after the cessation of a menstrual period.

The possible occurrence of pregnancy while the patient is under treatment (as illustrated by a case recently seen by him of pregnancy after three applications, the patient having been sterile during her four years of married life) encourages the use of local measures, as pregnancy is perhaps the best means of curing the endometritis, provided care is taken to examine the patient before her getting up after delivery, and, if necessary, applying local astringents or caustics at this, the most favorable time for a cure. What has been used by others may be expected to be used by him.

With regard to prognosis, which Dr. Mundé regarded as not very promising at least, Dr. Jacobi thought it depended considerably on the nature of the patients as well as the circumstances by which they were surrounded. Most cases of internal endometritis required more or less constant treatment—with the interruptions defined by the rules—during from one to two years. However, if this was carried out with due attention to all the requirements of the case, might confidently be expected; and even where ovaries were prolapsed and somewhat enlarged, their symptoms might be allayed. Cases of salpingitis, or chronic peri-uterine abscess, were not included among the curable complications of endometritis, and were probably only curable by Tait's operation.

The Academy then adjourned.
Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

London, April 26, 1884.

At the last meeting of the Medico-Chirurgical Society, a paper by Mr. Jessett was read, entitled "An Inquiry into the Cause of the Increase of Cancer in England and Wales." Mr. Jessett contends that the increased death-rate from cancer, as shown in the last yearly report of the Registrar-General, is not merely due to more accurate diagnosis, but actually represents an augmented death-rate from this cause. Mr. Jessett remarked that cancer was more prevalent in low-living, damp localities; but heredity, increased by intermarriages, had probably a good deal to do with the greater mortality from cancer in the "ten" districts which he pointed out. He also thought mention ought to be made of Mr. Jessett's recent paper on cancer.

In the discussion which followed both Dr. H. Snow and Mr. H. Cripps disputed the influence of heredity as a causative agent. Mr. Cripps attempted to show from statistics that cancer in the parent did not have any appreciable influence in predisposing the offspring to suffer from it.

At the same meeting Mr. Macnamara read a paper on epiphysitis, by which term he meant the diffuse ostitis of children or osteo-myelitis during the period of growth. He also used the term as synonymous with the phrases "suppurative periostitis" and "acute necrosis." Mr. Macnamara found himself in the somewhat unenviable position of having no one to support his position. In a rather sharp discussion which ensued on the reading of the paper, all the speakers fell foul of the author and his conclusions. Mr. Holmes led the van by remarking that the term "epiphysitis" was inaccurate, even if we allowed it as meaning an inflammation of the epiphyseal cartilage. If this cartilage had been destroyed it was difficult to understand how the bone was reproduced and the limb grew. Mr. Barwell, Mr. T. Smith, and Mr. Gant also assailed Mr. Macnamara's views.

The Tercentenary Festival of the University of Edinburgh has, on the whole, been a great success. This has been largely due to the number of distinguished men from various countries who attended. The concluding item of the entertainments seems rather droll. This was a students' concert in the drill hall. Smoking was permitted, and as about two thousand were present the atmosphere could have been none of the purest. Fancy two thousand pipes going simultaneously! Could a German university excel this? Songs were sung, speeches made, and stories told by Sir Stafford Northcote, Sir Lyon Playfair, Professor Rutherford, and others. To those who know the last-named professor, and have seen what a martinet he is in the lecture-theatre, the idea of his taking part in such a gathering will be inexpressibly ludicrous. Dr. Rutherford is indeed sui generis. In his lectures (which, by the by, are, from a scientific point of view, very good, or, as one of his pupils told me, "spendid") he persists in pronouncing certain words according to laws of his own. Thus, in speaking of the columns of the spinal cord, he pronounced the word "column" as if it were written "collum" rhyming with "fume." The class made merry, whereupon the lecturer waxed wrath and "ramped" out: "You may think it is column, but I say it is collum." Mr. Royle, the medical attendant of the late Prince Leopold, has been made a C.B.

EXERCISE FOR WOMEN AS ILLUSTRATED IN CIRCUS-RIDERS AND GYMNASTS.

TO THE EDITOR OF THE MEDICAL RECORD.

Six: It has been my good fortune to become acquainted with several of the leading women performers in the circus which has just left the city. My attention was directed toward the influence of their work upon the general health, and upon the menstrual and the child-bearing functions. The riding, the leaping, and the jumping at least do not influence pregnancy unfavorably. Temporary suppression of the menstrual flow sometimes occurs during these exercises, and its duration tends to be prolonged. The loss was not in any case found. The non-existence of uterine disease could not certainly be ascertained; it appeared, however, probable, from the absence of pelvic discomfort, from the absence of leucorrhoea, and from the excellent general health.

I had the women under observation during a number of weeks without finding any evidence of especial fatigue in their faces. They all eat and sleep well.

No. 1 is a bareback rider, doing principally the hurdle act or jumping from the horse to the ground, and from the ground to the horse while in motion. She is about thirty-two years of age, is five feet in height, and weighs one hundred and twenty pounds. Her chest measures thirty-two inches, her hips thirty-four inches, and her joints thirty-four and one-half inches at the end of inspiration. She commenced to menstruate at sixteen years; was married for five years, but never conceived; has always had dysmenorrhoea, and has been told that she possesses a congenital uterine defect. She works when menstruating. While performing she does not feel the pain and glimpses that there is no feeling fifteen minutes that she is in the ring. Her dysmenorrhoea is no less when idle than when employed. She has been in the business for fifteen years.

No. 2 is a bareback rider. She rides standing, and jumps through the hoops while the horse is in motion. She takes fifty jumps in six minutes. She is about thirty-five years of age. She commenced to menstruate at sixteen years, and was married at seventeen years. Previous to her marriage she had pelvic dysmenorrhoea. She now has headache previous to the flow. She flows five and works throughout. The headache is suboccipital and temporal; it is just as bad when she is not employed. Though previously dizzy, her vision was clear when she was in the ring. She does not think that during the performance there is any flow. Her chest measures thirty-two and one-half inches at the end of inspiration and thirty-one inches at the end of expiration. She is five feet in height, and weighs one hundred and twenty pounds. She has been in the business since seven years of age, and has been pregnant four years. The first time she miscarried at three months after a fall; the second time she rode up to the eighth month, and the child was delivered at term. It weighed nine pounds; the third time she miscarried at six months after a fall; and the fourth time she again rode up to the eighth month, and was delivered at term. I saw this child. It is a healthy full-bodied little girl. Her husband died shortly after the birth of this child. She rode at one time four weeks and at another time two weeks after her confinement. Neither of these women has leucorrhoea.

No. 3 is also a rider, she performs all of the feats of the other two. While No. 1 can exhibit only chest and escapular muscles, and No. 2 only muscles of the legs, No. 3 has the muscles both of the trunk and of the upper extremities strongly developed. Her arms are, on the contrary, small and delicate. She is about five feet in height, and weighs one hundred and twenty-four pounds. Her chest measures thirty-three and one-half inches at the end of inspiration, and thirty-six and one-half inches at the end of expiration. She is twenty-four years old. She commenced her training at seven years of age, was married at eighteen years. She commenced her exercise...
ate at sixteen years. She never has had any pain, and has had four children. The first child was born at term. It is now alive and well. She rode to the end of the fourth month. The second child was carried to term. It presented by the shoulder and was born dead. She rode to the end of the fifth month. The third child was born three months after a fall. The fourth is now seven weeks old. She rode up to the sixth month, and has always commenced to ride from four to six weeks after her confinement. At the time of her present engagement her baby was four weeks old, and she still had a serous discharge, which ceased after commencing to work. She has recently menstruated, the flow lasting only three days. In this case the flow does not stop while she is in the ring. She says that its duration varies between three and nine days. This woman, cannot nurse her children, and says that the breast collapses when she commences to work. Another rider whom I have seen, with a baby of three months, has an abundance of milk. She rode up to the eighth month. She is now performing, and has the appearance of perfect health. The mother of No. 3 was also a rider, and had six living children. While carrying her third child she rode up to two weeks of term. None of these women ever heard of any one’s breaking down in the business, except from surgical injury, such as a broken bone, or early miscarriage.

No. 5 was a highly-esteemed gymnast. She performs with rings and ropes twenty-five feet from the floor. She is twenty-seven years of age, with the appearance of twenty-two. She commenced her training when eight years of age. She commenced to menstruate when fourteen years old. The discharge always has been scanty. She has no pelvic pain, but has an acutely-dizzy headache when the flow commences. She says that the headache leaves her when she “comes before the public.” Also that when very much excited the flow stops. She has been married four years. A child was born during the first year of her marriage. She worked through the third month. The child was born healthy, but died later of intestinal disease. Since that time menstruation has been irregular, and she supposes that early miscarriages have occurred. She has no leucorrhoea; is five feet two and a half inches, and weighs one hundred and twenty-eight pounds. Her chest measures thirty-six inches at the end of expiration, and thirty-eight inches at the end of inspiration. She does not think that the work agrees with her. She has no menstruation.

No. 5 is a trapeze performer. She is twenty-five years of age, and has been in the business nine years only; is five feet eleven inches; weighs ninety-five pounds; has been married nine years, and has had a number of miscarriages of from four to six weeks. Otherwise menstruation is regular. She flows from six to seven days, but has no special pain. The flow stops while she is working. She has a constant vertical headache, which she attributes to a fall, and she has a backache during most of the time; but was struck in the back with an iron bar. She has no leucorrhoea. When performing she eats and sleeps well, and at other times is an invalid. She says that the women sometimes break down from climatic exposure, but seldom from the trapeze disease. As a rule the performers marry in the profession, and they marry young.

In the above we have collected the histories of five riders and two gymnasts. These histories differ mainly in the fact that the gymnasts have early abortions without apparent cause, while the riders have never miscarried except as the result of a fall. The gymnast's work has not had this effect. Concerning the routine work of the gymnast this cannot certainly be affirmed. Gynecological traditions allow us to believe that the strain, the actual displacement which is implied by hanging the weight of the body from the hands, distressed and strained the abdominal muscles which they perform, is a sufficient cause for the dilogment and expulsion of the ovum at an early date. It must be taken into consideration, however, that the gymnast does not wear the skirt nor the corset. She has no way to disguise her figure, hence the temptation to provoke abortion must be much greater for her than for the rider, who can exhibit through the eighth month without detection. It is possible that another reason for the prevalence of abortion, as a fact that the gymnast abortions are due to her work, though such a presumption might very properly be made.

The riders’ miscarriages always followed a fall. This is according to ordinary experience; but the fact that they do not more frequently miscarry remains to be accounted for. That the woman who during pregnancy takes fifty leaps in six minutes, who supports herself on tiptoe upon the flying horse, who leaps from the horse and to the horse while it is in motion, and who is so excited by her position as not to be conscious of headache, nor even of uterine cramp, that this woman can be delivered at term of a healthy child, and that she can nurse that child is phenomenal. The explanation is probably to be found in her habit of life. The rider commences her career as a child. The nervous system of the woman exhibiting during pregnancy is not called upon to realize any new shock, while it is but probable that the muscular attachments of the uterus have by her training been rendered more than usually firm.

While this work does not appear to affect pregnancy deleteriously, it is sometimes said to be the cause of menstruation. Dysmenorrhoea of some sort is the rule. Excluding No. 1, who has a congenital defect, all of the performers with whom I have talked either have headache or a prolonged flow, or both. It is suggestive that the three who have headache have suppression during work. Both the suppression and the headache are probably waso-motor in their origin. Women who menstruate scantily are peculiarly subject to this influence. Among the lower classes to bathe or to change the clothing commonly causes the menses to cease, with a coincident fullness in the head; while the menstrual discharge which has been suppressed tends afterward to return, and to be prolonged beyond the usual time. With the circus women the eye of the public, and possibly the effort of performance, appear to be the exciting causes. Whether the temporary suppression from overwork is injurious, I am not prepared to say. In the case of the circus women it appears to do no permanent harm. Excepting No. 1, we have found in them no evidence of uterine diseases.

The influence of the work upon menstruation appears to be good. Three women with whom I have talked have commenced work from four to six weeks after their confinement without injury. One of them recently commenced with a scanty discharge. I have particularly watched this woman, and have seen her vigor of movement and the color of her lips progressively improve. I have already said that the flow ceased very soon after she commenced to work; I have also alluded to my theory that the uterine attachments—the ligaments—are, in these women, more than usually firm. This has been my experience in other cases where the women were actively engaged in varied muscular work.

I have spoken of the fact that the general health was good. The change was very fine, the measurements were taken without clothing, and the tape was tightly drawn. Thirty-four, thirty-six, and thirty-eight inches is an extraordinary measurement for a woman weighing less than one hundred and thirty pounds. With a superb bust curve, in none of them was the breast large. The effect was obtained by the ribbing out of the thorax. The effect was obtained by the ribbing out of the thorax. It is not generally known that a handsome figure may be thus acquired. Women seek after nostrums to develop the breast, and even men ascribe the American flatness to a non-development of the mammary gland.

Exercise as a health-giver and as a beautifier must be world-wide. Wanting does not develop the chest. No. 2, whose performance is confined to standing and jumping upon a level, presents only a chest measurement of
thirty-two and a half inches, while Nos. 1, 3, and 4, who exercise also from the shoulders, present measurements of thirty-four, thirty-six, and thirty-eight inches. It is desirable also that the exercise should be commenced early in life. Nos. 3 and 4 commenced when children of seven and ten years; No. 1, who commenced at sixteen, does not add much, though her exercise is of quite as good a kind. This woman also is the only one who unquestionably has uterine disease.

But little can be done after the woman is grown. With the first attempt the already heavy uterus is displaced, on account of the weakness of its supports. The system must be commenced in the child. Let the girl have the open-air liberty of the boy. Let her play ball, climb, and swim, and skate. Let her give up piano practice and take her musical education in the form of singing, and let her school hours be few. In other words, give the girl a chance.

The question as to what can be done after the woman is grown, requires more thought. As I have said, walking is not enough, and gymnastics as a system are not generally understood, while the caution which is necessary in undertaking unusual work makes one hesitate in regard to advising them. Instruction by a competent authority is needed. We understand that the alumni of Vassar are attempting to supply this want by a chair for physical culture in their college. This effort, if successful, must have an influence for good.

April 19, 1884.

S. E. POST, M.D.

HAS KOCH DISCOVERED THE CHOLERA-BACILLUS?

To the Editor of the Medical Record:

Sir: In an editorial of The Record of April 12th you discuss the sixth report of the German Cholera Commission. Your conclusion is that "Dr. Koch has found a bacillus, but he has not found, for science, the cholera-bacillus." You also intimate that, as far as the report shows, those who would believe are obliged to take for granted the conclusion implied in that document as to the nature of the bacillus in question. You state it thus: "The great confidence felt in the carefulness and skill of the distinguished investigator, however, will lead many to accept his judgment, but such acceptance must as yet be based more on faith (the italics are mine) than sight." For the word sight I will use the broader term demonstration, as I have no time to show what I consider by far the most probable result. Koch's bacillus for the time being has been described, and be an error in your application of the term faith. Since I share in the general confidence in Dr. Koch's carefulness and skill, I am willing to trust him for the truth of the facts he presents; but certainly I cannot be expected to accept his judgments on faith.

Now, in your editorial you deny that Koch has given us a demonstration of the existence of a cholera-bacillus, at least such a demonstration as science requires. Allow me to offer an affirmative rejoinder, and before doing so, to ask, what does Koch claim to have proved? If I have read the report understandingly, what it claims implicitly is that there is a germ peculiar to and constantly present in cholera, and that there is a strong probability that this germ is the cause of the disease. Surely nothing in the report can be construed into meaning that the comma-bacillus has been shown absolutely to be the cause. Now, for everyone—for those opposed to, as well as for those in favor of the germ theory—the question resolves itself into three mutually exclusive propositions: 1. This bacillus is accidentally or intermittently present in cholera; 2, the germ (comma-bacillus) is the cause; 3, being constant, and not accidental, and not being the cause, its presence is accounted for on the theory that its origin and growth are favored by the peculiar conditions of the disease, viz., heat, moisture, and a virus, or what not, peculiar and specific in character. That the comma-bacillus is not accidental, I think few who have read the report will deny. If nothing else has been proved by the commission, I am sure this has. In order to establish the second proposition absolutely, it is obvious that the demonstration requires for its essential element the fact that the cause is antecedent to the disease. Inoculation of the lower animals with the germ, and the germ alone, and production of the disease thereby, is the only means available to investigators; but this has not, and in all probability will never be done. Therefore the highest proof that can be expected is that of probability, greater or less stronger, and this much I think I can show has been thus far achieved. One fact in the report, which you have overlooked in your article, is of great significance, and that is the comma-bacillus are "fourth have multiplied in a most extraordinary manner" in linen soiled with choleraic discharges after having been kept in a moist state for twenty-four hours. Here is an example of germ-development which seems to me to dispose of the hypothesis embodied in my third proposition. But to satisfy those who disagree with me in this last assertion, I can afford to grant, for argument's sake, that my interpretation is unsound.

In such case I am free to appeal to the fact that in pure cultures of the bacillus in question we have an example of development independent of the aid of the before-mentioned conditions. On this latter fact I cannot insist too strongly. For when in a given disease a germ is found in constant association, and at the same time absent in other diseases, even of similar nature, and where the germ can be isolated and cultivated, there, I maintain, is the strongest probable proof that the germ holds a causal relation to the disease—proof next to absolute demonstration. Since these conditions are shown to exist in the disease under discussion, we are, it seems to me, obliged to accept as most highly probable the conclusion contained in my second proposition. Furthermore, Koch's claims are well fortified by the analogical method. In three diseases—malignant pustule, relapsing fever, and tuberculosis—bacteria as a cause have stood the crucial test. From the insusceptibility of the lower animals to many of the diseases that afflict mankind, the utmost the most sanguine investigator can hope to prove is greater or less probability, such proof being based on absolute demonstration in a few cases.

So far we have scarcely crossed the threshold of the mysterious temple of science in our search after facts of etiology. It were too much to expect that even in our time we will reach, as far as the interior. From what has been said, is of considerable importance. It is important to foretell what will be—"a translation of the present system of medicine to a sphere of almost another order. There are many ultra-conservatives, however, who will treat this assertion with incredulity, and perhaps even ridicule. To them the revival of the germ theory means nothing but a repetition of history, having its rise and fall as other historical events have had. It must not be forgotten, however, that the theories of the past had their origin in speculation; now they are being tested by the methods of exact science, and we have the satisfaction of at least knowing that hereafter the question will become settled forever. The theory must stand or fall by the present scientific methods.

Thomas J. Kearney, M.D.

126 Lexington Avenue.
A BULLET THROUGH THE BRAIN—RECOVERY WITHOUT PARALYSIS.—Dr. W. P. Hartford, of Beetown, Wis., sends us the history of a somewhat rare case. A young man, aged thirty, was shot in the face, receiving the full charge of a shot-gun at a distance of fifteen yards. His head was struck with seven No. 4 shot and two bullets. Dr. H. writes: "One bullet penetrated the frontal bone three-fourths of an inch above the right supraorbital ridge, and I think it passed nearly if not quite through the brain; it cut a clean hole through the bone. We probed the wound about an inch and a half; it went straight into the brain, and there was some of the brain substance on the ground where he fell when shot. There was another bullet-wound just under the right eye that penetrated for about an inch. The course of the bullets was from right to left. The patient was unconscious, and then somewhat delirious for a few days. He finally recovered entirely, except for a feeling of numbness in the right hand and leg."

SALICYLATE OF SODA IN INCONTINENCE OF URINE.—Dr. B. J. Bristol, of Webster Groves, Mo., sends us the following very interesting history, illustrating the salutary effects of salicylate of soda in incontinence of urine, a complaint which presents a difficulty in some cases. The patient was a mulatto; aged twenty-one years, of good habits, temperate, does not use tobacco; does not know the time since infancy when he has not been troubled with incontinence of urine, attended with pain in the back, in the region of the kidneys, the pain relieved by micturition. Has always been obliged to get up at night to micturate from one to two times; sometimes, three times, being awakened with pain in the back. Appetite good, general appearance healthy. Examination of urine showed nothing abnormal, examined especially for albumen and sugar. Ergot in full doses three times a day produced no impression. Salicylate of soda, twenty grains every two hours till pain was relieved, then two grains three times a day, has apparently cured both the pain and enuresis. Still bladder very active, and him under observation. C. D., male, aged eighty-two; habits active, always temperate; never had any severe illness; has for some time had incontinence of urine, night and day, with pain presumably about the neck of the bladder; pain constant, somewhat relieved by micturition; no albumen; no sugar; occasionally mucus. Prescribed salicylate of soda ten grains every two hours till pain was relieved, then ten grains three times a day. After sixty grains had been taken the pain in the bladder was relieved and the incontinence was very much better, so much so that when he reported to me he had not taken the medicine for two days."

POISONING BY ACONITIA; SEVERE SYMPTOMS FROM ONE-FOURTH OF A GRAIN.—The following history, sent us by Dr. Leroy F. Brooks, of Norwich, N. Y., is of great importance, in view of the very considerable extent to which the dangerous alkaloid aconitia is now being used. Dr. Brooks writes: "A lady, twenty-two years of age, on the morning of April 2d, took five McKesson & Robbins' pills of aconitia, of which grain each, supposing them to be quinine. Within a few minutes she felt numbness and prickling about her tongue, lips, and face, and passed into half-delirium, and then into delirium, supposing she was dying, yet did not feel power enough to call others to her aid. Within half an hour from the time of taking the dose she commenced vomiting, but could not tell whether she vomited any of the dissolved pills or not. The vomiting, with severe retching, continued, and the numbness and prickling extended over the entire body; then the physician was called to her, considering the symptoms to be due to quinine, had no tears, and did not call medical aid until two hours later. I found her in the following condition: Pulse scarcely perceptible, very irregular, and could not be counted; heart's action intermittent, rapid, and feeble; respiration rapid and weak, and patient complained of a pain in the right side, a sense of great weight on the chest, of dyspnoea; entire body very cold, and face and extremities of a dusky, almost purple hue, and face pre-

DOSING AN ELEPHANT.—One of Barnum's peculiar elephants, "Allah," was attacked with enteritis while in Cincinnati. Dr. George W. Bowler, V.S., was called in, and relates his experience in The Journal of Comparative Medicine. The diagnosis being made he prescribed and administered the following liberal dose: lard, eight pounds; linseed oil, one gallon; tincture of opium, one pint; spirits of nitrous ether, one pint; syrup, one quart. The lard and oil were first mixed, then the other ingredients added. The trunk was raised above the head and the mixture poured down the throat through a large tube. The animal recovered.

REMOVAL OF WARTS.—Dr. El. Guénot reports (Bull. Gén. de Thér.) that he has removed a large crop of warts, occurring on the hands of a patient by giving daily a ten-grain dose of calcined magnesia in the morning before breakfast.

TINCTURE OF BELLADONNA FOR CHLORAL POISONING is highly recommended by Dr. J. Mackenzie Booth in The Lancet.
THE MEDICAL RECORD. [May 17, 1884.

sentemt a pinched expression; slight convulsive move-
ments of left side of face, and a feeling as if face was
costantly drawn toward left side; difficult articula-
tion; pupils widely dilated and did not react; an almost
complete mutism; diffuse reddening and vomiting of
which, the patient says, 'the walls of the stomach strike
together with force.' I at once gave her enemata of
brandy and carbonate of ammonia, and used \( \frac{1}{2} \) grain
of morphia and \( \frac{1}{3} \) grain atropia hypodermatically.
Within five or six hours the pulse became more perceptible
and regular, and pulsations ranged from 140 to 160 per
minute; heart still intermittent, but firmer; voluntary
numbness of extremities diminished, but still existing in
a marked degree in tongue and face; pupils smaller;
vomiting quieted by morphia, but returns at once when
its effects pass off, so that the dose has required repetition
every three hours; surface cold; face dusky; respira-
tions better, but dyspnoea still exists; convulsive move-
ments of face subsided. April 3d: Numbness and
prickling has disappeared; surface still cold and has
marked capillary congestion; pupils normal and react
readily; pulse, 140, feeble but regular, and heart's ac-
tion stronger and without intermission, but increased in
frequency by least move of body; vomiting returns if
morphia is withheld, and has passed four or five
hours; does not retain anything taken into stomach, even
when deeply under the influence of the morphia. April
4th: Pulse, 140, stronger. The patient subsequently con-
tinued gradually to improve; but it was not until April
12th, or ten days after taking the poison, that she could
be considered free from bad symptoms.

FOOT AND MOUTH DISEASE.—Dr. W. Manlius Smith,
of Syracuse, N. Y., writes: "In The Medical Record of
May 10th, p. 511, in a paragraph on 'Foot and Mouth
Diseases in Kansas, you ask, But how does ergot get
in hay?' To this I answer that I have frequently ob-
served ergotized grains on the common quack (or
quick) grass, triticeum repens. I remember also, several
years ago, noticing and collecting ergot from some of
the coarse grasses on the banks of the muddy stream
that winds through Jersey City flats. It is further well
known that some of the ergot of commerce is furnished
by the wheat-plant, the ergotized grains of this plant
being of a much larger size than the common ergot.
The size and shape of the ergot varies in the different grains
on which it occurs, but its general appearance and in-
ternal structure is so nearly alike in all that it is readily
recognized as ergot. There is no improbability in the
statement that Kansas hay contains ergot."

A CASE OF EXTRA-UTERINE PREGNANCY—OPERATION
—RELIEF—REMARKS UPON ETIOLOGY.—Dr. Charles E.
Davis, of Eureka Springs, Ark., writes: "A married
woman, aged thirty-five years, had two children, the last one
nine years ago. In 1877 had a uterine polypus, which
was removed; in June, 1882, partial insolation; in Au-
gust, dysentery; in October, menses ceased. During
the next seven months she suffered from severe pains in
the pelvis, and irregular bloody and watery discharges.
A tumor was felt in the left inguinal region. A return of
the polypus was suspected." Dr. Davis was called in
April 11th, and found the tumor present, the uterus en-
larged and empty. A second examination detected foetal
movements, and the diagnosis was established. Two days
later, the patient had a severe chill and several rigor
with a great deal of pain. A gangrenous odor was de-
tected. "On examination," continues Dr. Davis, "it
was found that the foetal tumor had been forced at least
one and a half inch outside the vulva, carrying the vaginal
wall on the left side, and so very tense was it that it was
black and evidently rapidly becoming gangrenous. Know-
ing that it was absolutely necessary to act at once to
operate. Having no precedent, I was obliged to ad-

vance on general surgical principles, keeping in mind (1)
cleanliness and disinfection, (2) hemorrhage, (3) protect-
ing peritoneal cavity. After thoroughly cleansing and
disinfecting with a five per cent. solution of carbolic acid,
I carefully pointed and sharpened a fore-finger nail, be-
lieving that the vaginal wall so tense could best be di-
vided with it. The tumor was soon succeeded in being cut
through and enlarging the opening almost bloodlessly. I
soon delivered, in a partially decomposed state, a small, poorly
nourished four and a half or five months' fetus, and
that without the admission of any air into the cavity.
I instituted careful and steady traction upon the cord
for some time, but finding it impossible to deliver the
placenta by this method, I gave it in its compatible with safety from internal
hemorrhage or inflammation, I decided to secure the cord,
dissect the cavity, provide for drainage, and rest matters
for the time. This I did. The next day the placenta
was removed. The wound healed rapidly and the pa-
tient made a good recovery." Dr. Davis concludes with
the following queries: "What were the etiological bear-
ings of the succession of conditions—eight weeks' inac-
nation of uterus; 2, relaxation from overheat, furthered
by overtax and anxiety localized by the dysentery—upon
the nervous power of the pelvic organs, notably the Fal-
lopian tubes and their extremities, disabling them from
properly passing the ovum on the one hand, or regulating
the menstrual period on the other—producing conception from the highest expression of nervous
rhythm and vital power to that of a sort of passive acci-
dent, as shown by its unnatural location? Whence comes
the expansive force sufficient to stop circulation so rapidly
in so vascular and mobile tissue as the vaginal wall?"

DEATH FROM CHLOROFORM.—Dr. G. E. Goodfellow,
of Tombstone, A. T., sends us the following: "In April,
1880, while temporarily in Tucson, I was asked by Dr.
Handy of that place to assist him in an amputation by
administering the anesthetic. The case was one of severe
compound dislocation of the ankle-joint in a man aged
about fifty, who had been on a prolonged spree. The
injury had been received three or four days previously
on the 21st of March, while the patient was drunk. Nitrous
oxide and ammonia in conjunction with artificial respiration
were used imperfectly. I am not a lover of chloroform, and
in this, as in other cases when I exhibit it, used every
precaution. The fatal result could have been avoided
in only one way, by not using chloroform. I have rarely
seen a case of favorable symptoms follow the injurious
use of ether and chloroform was used, and the A. C. E.
mixture is the anesthetic I have always preferred, and most
frequently use."

TWENTY-ONE MAJOR OPERATIONS WITHOUT A DEATH.
—Dr. Theodore R. Varick, of Jersey City, writes: "In
the Telegraphic report, in the last issue of The Medical
Record, of a paper read by me before the Surgical Sec-
tion of the American Medical Association at its meeting
in Washington, on the 7th inst., I am credited with hav-
ing performed twenty-one major amputations without a
death. This is an error. The correct record is, twenty-
one major amputations performed in St. Francis' Hospital,
Jersey City, without a death; five in the City Hospital,
with one death, and three in private practice, all of which
were successful. This makes a record of twenty-nine
cases, and one death. Since the paper was written, I
have had two cases, viz., a thigh and forearm, which are
still in the hospital, but are convalescing rapidly. The
points of operation were as follows: Thighs, 16; legs,
5; amputations without a death, Total, 21. This makes
the twenty-one seventy. Total, 31. All these amputations were performed since
August 12, 1879. By giving this a place in your valu-
able journal you will oblige."

THE MEDICINAL, MAINLY MERCURIAL, TREATMENT OF PSEUDO-MEMBRANOUS CROUP.†

BY A. JACOBI, M.D.,

CLINICAL PROFESSOR OF DISEASES OF CHILDREN IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

I.x 1868 I formulated the indication for the performance of tracheotomy in pseudo-membranous croup as follows: "There ought to be no contra-indication when the prominent symptoms are dyspnea and suffocation. I cannot imagine any complication of croup that would prevent me from opening the trachea when the child is dying of suffocation. This is so plain to my understanding that I should consider it even a cruelty, in many cases, to refuse tracheotomy, when I knew beforehand that the child was surely going to die from other causes. Whoever has seen children die of croup, fully conscious, gasping, raving for air until they are slowly strangled in your arms, under your eyes, will bless a proceeding the consequence of which will at least be an easier death in most cases. Nor do I acknowledge that tender age, that under two years, ought to be held up as contra-indication to the performance of the operation." (Journal of Obstetrics, vol. i., May, 1868, p. 49.) And on page 57: "While I admit that with symptoms of general diphtheritic complication a case of laryngeal diphtheritis, called membranous croup, the prognosis of the operation becomes more doubtful, I lay stress on the fact that even in such cases only the indication for the operation rests in the local obstruction. For it is easily understood that while general diphtheritic poisoning with insufficient obstruction does not indicate tracheotomy, it is just as plain common sense that sufficient obstruction of the larynx complicated with a constitutional affection requires the only possible relief just as urgently as suffocation from obstruction of the larynx without such a complication. Seeing a person suspended by the neck and being strangled, we should hardly investigate into the propriety of cutting the rope from the point of view that the sufferer might be, or is, affected at the same time with tuberculosis, carcinoma, or diabetes. Such are the principles which have guided most of those who have operated. The result has been that Monti could collect 12,736 cases of croup with general diphtheria, 3,409 of which (26.7 per cent.) were saved by tracheotomy. Those indications for tracheotomy in croup are still valid. I did not discover them, but I understood them and acted in accordance with them almost ten years previous to my writing. At that time I was not at all in the fashion, just as little as those who frequently operated before me, viz., Drs. von Roth, Krackowizer, and Voss. On the contrary, the question was seriously asked if Dr. Jacobi did not cut altogether too many throats. I refer to that fact because it is always instructive to turn to the history of theories and facts in our science and art. Now, since that time the drift of public opinion has entirely changed. What I insisted upon as a necessity, viz., that amongst the few operations every general practitioner ought to know, and be prepared to perform any time, tracheotomy was the foremost, has been appreciated since to its full extent. I feel certain that hundreds of practitioners in this city have performed tracheotomy, or are capable, willing, and anxious to perform it. The extent of this change is very great indeed. One of the proofs is certainly the fact that renowned gentlemen, who are identified in the respectful opinion of the professional public with what has been called internal medicine, commenced and carried on an instructive and valuable discussion on the surgical treatment of croup, in this very hall. The unity of medicine cannot be better proven than by that fact, and in order to prove my appreciation of the same, and of the necessity of keeping together the disjointed members of the body medical, which threatens to be dissolved into soulless and spiritless specialities, I may be permitted, after having performed four hundred or more tracheotomies myself, and witnessed several hundred besides, to claim a little attention for the consideration of some points concerning the medical treatment of pseudo-membranous processes in the respiratory organs, which has been given up by very many as well-nigh hopeless.

Two cases of pseudo-membranous croup were treated in my service in Mount Sinai Hospital in the following manner: The patients, one less, the other more than two years old, were kept in a thermometer of 70° F., under a tent which was filled with steam and the vapor of turpentine, as I shall detail afterward. They were given besides 75 grain of pilocarpinum muriate, according to the method of Guttmann. Neither of the cases was or became severe, neither of them was septic. I make that statement because I believe it to be important in regard to the value to be placed upon the recommendations of Guttmann in general. Altogether I have not modified my opinion on the efficiency of the drug expressed during the sessions of the American Medical Association of 1881, about eight months after the first article of Guttmann, on the efficacy of pilocarpinum in croup and diphtheria made its appearance. It appeared exaggerated as a specific, no case ever so severe or septic was said to be inaccessible to its healing influence. My first experiments were therefore made with septic cases, both pharyngeal and laryngeal. In every one of them I fully believe I accelerated the fatal termination by hastening cardiac failure. But in a number of cases I do not hesitate to state that the softening, macerating, disintegrating effect of the copious secretion brought about by the jaborandi preparation was quite marked. One of the cases in the Mount Sinai Hospital got well. The other got better, but the pulse became frequent and small, the general strength failed, and the treatment had to be given up after three days. The same results I have obtained in private practice. A child of but a little over a year did not tolerate the debilitating effect of the pilocarpinum more than two days, in spite of careful alcoholic stimulation. The final recovery I was always inclined to attribute to two factors, viz.: 1, the macerating effect of the drug; 2, the timely withdrawal of the treatment with the symptom, while the rest of the treatment was continued. One case, three years old, I have seen recover with a fair amount of strength after having been imprisoned in a tent four days. A few more had to be discharged from it for fear of fatal exhaustion. My final opinion is, therefore, that the effect of pilocarpinum is certainly a powerful one, inasmuch as it increases the secre-
tion of the mucous membranes of the respiratory tract and thereby facilitates the maceration of the pseudo-membranes, but that its debilitating effect must be watched and counteracted constantly and necessitates the interruption of its use in a great many cases.

These two hypotheses must have been a powerful adjuvant in the treatment of croup. My opinions, as expressed in my "Treatment of Diphtheria," p. 178, have not changed these four years. I then said, in regard to their administration:

"Quite remarkable effects have been expected of, and claimed for, them. It is true that pseudo-membranes, like everything else, become softened by the warm vapors. It is also probable that steam increases the secretion of the mucous glands, and thereby possibly loosens the overlying membranes and favors their removal, but it must not be forgotten that it also softens the healthy tissues, and that this change in character enables the poison, whatever be its nature, to penetrate more deeply into them. These two hypotheses must be kept in mind when, in any case, the question of the employment of steam arises.

"Steam for the purpose of softening the tissues and of provoking the secretion of mucus and suppuration has been used to a considerable extent; in fact, in England and America it constitutes an important part of the treatment of diphtheria of the larynx. The patient inhales it directly from a vessel, or in a tent which is more or less closed, or breathe the atmosphere of the room after it has been saturated therewith. For the latter purpose, water is kept constantly boiling, or lime slaked, or red-hot stones put in water from time to time. The results from this procedure in diphtheria of the larynx have not always been pleasant. I have repeatedly had the joy of seeing children with croup become less cyanotic after their removal from an atmosphere of vapor, and I can readily see that pure atmospheric air would be more agreeable and wholesome to a child with stenosis of the larynx than an atmosphere laden with steam.

"I have seen cases of fibrous bronchitis getting well, when I had every reason to attribute the recovery to the persistent use of steam. I have known a baby locked up in a small bath-room, with one window, the hot water running persistently for days, filling the room so as to produce a constant fog, and make every person in the room dizzy; the baby, however, greatly gratifying; the fever went down, and so did another with which I had the good fortune by my experience in that case. Again I insist, steam will improve, steam will impair. Individualizing is a great art. In regard to the steam, it is, however, not so difficult. Its object is to soften, but principally to increase the secretion from the mucous membrane, and thereby throw off the superjacent membrane. This can be done to advantage only where there is a natural tendency to it, that is, where there are a great many muciparous follicles under a cylindrical or fimbriated epithelium. This is the condition on part of the pharynx, but not on the tonsils; in a small portion of the larynx, in the trachea and bronchi, not on the others. Wherever there is pigment or vaginal epithelium on the normal surface, and where the membrane is imbedded into the tissue, steam can hardly be expected to do good. In the other cases it will. Thus the locality of the diphtheric process determines to a great extent whether steam is indicated or not. If it be used, the necessity of a full supply of atmospheric air must not be overlooked. Steam, with an overheated room and without pure air, is liable to be as injurious as steam in pure air is beneficial in a number of cases." I may say in most cases; for though the number of muciparous glands may be small in some places, the macerating effect of vapor is always observed to a certain extent.

I may be permitted here to remark, in regard to the inhalations of turpentine, to what I published on page 186 of the work alluded to.

"For years I was in the habit of using turpentine, either the oil or the rectified spirits, as an inhalation in bad cases of pneumonia, where hepatisation was very extensive, and expectoration and resolution did not commence, with very good results in children and adults. The vapors of turpentine are so volatile and penetrating (and certainly the procedure of Taube so disagreeable to the patient, if it be permitted at all by children) that the usual method of inhaling from an apparatus appeared to me to be very superfluous. I allow the patient to remain in his bed, and keep water boiling constantly on an alcohol lamp, or on the stove, or over the gas. A tablespoonful of spirit, rect. or ol. terebinth., more or less, is poured on the water, care being taken that nothing is spilled in the fire. Thus the room is constantly filled with a penetrating odor of turpentine, which is not at all disagreeable, even when in great concentration. The effects are very satisfactory indeed. When circumstances allowed or required it, I raised a tent over the bed, large enough to give inconvenience to the patient, and to admit either the whole apparatus or the tube containing the mixed vapor of water and turpentine. This plan I followed in many cases, also in the case of laryngeal diphtheria of a girl of two years, in the children's service of the Mount Sinai Hospital. The apparatus was her own. A tent was raised over the bed. Three days and nights was she exposed to the water and turpentine treatment, awake or asleep; not only she, but also the nurse, whose presence under the tent was insisted upon by the patient whenever she was awake. It ought to be stated that the case was not, or was not allowed to become a very serious one. It was serious enough to be dangerous, to produce hoarseness, aphonia, dyspnoea, and to render the perception of pulmonary murmurs impossible; but there never was cyanosis, with the exception of a slight hue on the upper lip. She got well with no other treatment but by iron and pot. chlor. solution. As a practical addition, I may say that the nurse did not suffer much more than she would have done after the same time passed in a close room, and in constant attendance upon an exacting and whimsical patient."

Now, Mr. Chairman, I take it for granted that when a number of practitioners give up part of an evening to listen to a fellow-member, they expect that it will tell them what to copy, and not to borrow books for his benefit. I therefore abstain from enumerating the remedies in and out of the Pharmacopoeia which have been recommended in the treatment of croup. With my permission I select one now for discussion, which is not new, but which the historical view I deem necessary will prove that the consideration of mercury in its application to cases of pseudo-membranous croup is still advisable.

Samuel Bard administered calomel in doses of three or five grains daily. Rush also recommended calomel in his "Medical Inquiries." Bretonneau employed the same, and also inunctions of blue ointment. After their use he observed the cough get moist, the pseudo-membranes softer, the sputum less copious and mucusy. In his opinion the result of tracheotomy after mercurial treatment is rather more favorable. But Trouseau opposed it, and his authority was sufficient to suppress its use almost entirely. Autenrieth, in Germany (1807), gave from one to four grains of calomel every hour, never less than fifteen grains altogether. Joseph Franz, Stieglitz, Billard, J. C. Werner, Ruppitz (1838), Bonnet, G. B. Wood (1847), in their "Treatise on the Practice of Medicine," Hein (1849), Bourgeois (1850), Brown (1850), Löwenhardt (1848), Burow (1864, Journal f. Kinder.), Steppuhn (1844, Journal f. Kinder.), Bartels (1867, D. Arch. f. Klin. Med.), are in favor of mercurial treatment. Burgus limits it to gr. 1.; white of one egg; distilled water, § iv.; a teaspoonful every hour, until three or four grains were taken altogether. Eighteen undoubted cases of
croup are reported by him, eleven of which recovered; of these eleven three only were tracheotomized.

Miquel (1848) administered one-sixth of a grain of calomel, and two and one-half grains of alum, either alternatively or together. By the administration of alum he hoped to prevent salivation. His method has been extensively adopted by Guerassim, Blache, and Trousseau, also by Millet, who had five successes in seventeen cases of croup.

Oppolzer (1868) gave calomel and iodide of potassium, gr. j. of each every hour, after an emetic had been administered before.

Bohn and Mouth have opposed the use of mercury in croup. However, Bohn, in his latest book, gave calomel, twenty to forty grains in twenty-four or forty-eight hours, and up to an ounce and a half of blue ointment besides. He never saw any injury done by it except once, a mild exfoliation from the upper jaw, and of twenty cases thus treated eight recovered. Though he says that but two of these were very severe, the result is so favorable that Rauchfuss is correct in asking why, after all, Bohn should object to the use of a remedy which has rendered him such good services (Gerhardt's Handbuch, vol. iii., 2, 1875, p. 210).

Guerassim (art. "Croup" in "Dictionnaire de Medicine," third volume, 1833-1845) expresses himself as follows: "A cure is sometimes obtained in neglected croup, when one is called in the beginning, and the symptoms are not too pressing and the patient too feeble already, are mercurials. Certainly they fail sometimes, but a great many successes are due to them. I have seen three cases of croup getting well under the treatment, and in one of them the symptoms ceased as by magic when salivation commenced. Seven recoveries are mentioned by Bretonneau. Inunctions into the neck, the gums, the inner side of the arm and the axilie must be made simultaneously, together with calomel internally. The latter must be given as an alterant, and not with a purgative effect. To avoid this, it must be given in refracted doses, one-fourth or one-half grain every half hour or every hour, with gum powder, or sugar, or candy, and not swallowed. When no laxative effect at all is produced, the doses must be larger, but always given in the same manner. But we must not overlook the fact that mercurials, particularly when they produce salivation, throw the patient sometimes into such a state of convulsions that a change of medication, or a visit of Bretonneau quite often becomes necessary. Thus it is prudent not to try this mode of medication on subjects with a feeble constitution, or such as are debilitated by previous sickness, and to suspend the use of mercurials where injurious effects become visible, and give tonics instead. For this reason it is best to resort to that kind of medication in the summer only, and perhaps not to employ it at all in the cold or moist seasons."

Barrier ("Traite pratique des Mal. de l'Enfance," 3 ed., tome i., p. 394, 1861): "Mercurials have enjoyed, and are still enjoying, a great reputation in the treatment of croup. The preparations most in use are calomel and the blue ointment. Small doses would not obtain an effect in due time, and in croup a rapid result must be looked after. Thus, according to the age of the child, 02 or 0.5 grains of calomel (gr. ½ to ¾) must be given every half hour, with the addition of a small dose of opium to avoid the purgative effect, and three or four times daily one or two grammes of the blue ointment (in older children to be doubled) are used on different parts of the body in inunction. This method is praised by Guersant.

Of forty-one cases of croup, observed by Bartels, and not treated with tracheotomy, five recovered with mercurial inunctions. They were all serious cases, laryngeal stenosis and constitutional diptheria were fully developed in all. Within three days the main symptoms improved, the croup membranes disintegrating. According to Friche, who advises to introduce large amounts of mercury into the system within a short time, he rubbed into the surface, in different places, 1.25 grammes (¾ juss.) of the blue ointment every hour. Several times he used as much as 75 grammes (3 juss.). Anemia and hemorrhages were observed in two cases, but still the patients recovered. The same treatment was used by him for the fibrinous tracheo-bronchitis succeeding tracheotomy.

Dr. C. Rauchfuss, in his elaborate paper on "Fibrinous Laryngotracheitis," printed in the third volume of C. Gerhardt's Handb. der Kinderk., expresses himself in the following manner: When Burrow published his remarkable cases, his curious treatment, the results induced me to try the croup treatment with corrosive sublimate. Its results were so satisfactory, compared with other methods of treatment, that I have remained true to it since and joined to it the inunctions with blue ointment; or, if the condition of the gastro-intestinal mucous membrane forbade the internal administration, I limited the treatment to inunctions extensively. The remarkably satisfactory results of a very energetic mercurial treatment has been appreciated as well by many colleagues, both in and out of the hospital, as by myself. When tracheotomies were performed, or autopsies made, it was almost always noticed that the pseudo-membranes were in a condition of muco-purulent disintegration and that the growths were in the cases of catarhhal laryngitis, with considerable sub-thoroidal tumefaction and stenosis without pseudo-membranes, have I noticed that tumefaction disappeared soon and a copious muco-purulent secretion followed. Thus I look upon the diminution of the phlegmonous process in the mucous membrane and the copious secretion from the muciparous glands as the most results of the mercurial treatment. I have a large experience, but am not aware of a single case in which an energetic but brief mercurial treatment was attended with evil consequences, with one exception. This is a very intense and diffuse erythema, of the surface, resembling scarlatina, which may give rise to increased temperature. It is met with after inunctions, when the skin is perspiring. When it occurs the external treatment must be stopped, the child bathed, and the medication restricted to the use of the bicloride. Some of my mercurialized patients are at the present time ten or twelve years old, and in good health. Constitutional diptheria, in its intense form, I do not consider as a contraindication to a croupicidal fact in Bretonneau's cases, and to an urgent indication. Thus the treatment is to be continued after tracheotomy has been performed. But it is self-evident that no astonishing results can be obtained in either form, and when I eulogize the mercurial treatment, if compared with other modes of treatment, I do so hoping that it may soon be replaced by a more successful one."

And in regard to inunctions in particular, he adds: "I never saw bad results of the inunctions with forty or fifty grammes (¾ juss.). Sometimes I have, without fear, however, used seventy-five or one hundred grammes. In but one of the latter cases the medicinal results were bad; never since have I employed more than fifty grammes, but never less than forty." My own experience in regard to mercury, up to the summer of 1880, when I finished my "Treatise on Diptheria," is condensed on pages 188-190 in the following sentences:

"In regard to the action of mercurial remedies, I am no longer so sceptical as I was a quarter of a century ago. For a dozen years I have considered it wrong, supposing that the harm it might do could be avoided by substituting other medicines, and that its effect, except in syphilis, could be obtained by other means. I admit that the experience of many subsequent years has changed my views to a certain extent. I know that in chronic inflammatory troubles, which I considered incurable in former times, a good many favorable results have
been due, at my hands, to the protracted influence of mercurials; thus, for instance, in chronic inflammations of the nervous system, the particular constitution of which is descripted as constitutional, I also know that when the constitutional effect of mercury could be obtained speedily, cases of fibrinous tracheobronchitis got well in an unexpected manner. To accomplish that it is necessary to give small doses very frequently. Calomel, 0.5 to 0.75 (grs. viij. to xij.), divided into thirty or forty doses, of which one is taken every half-hour, is apt to yield a constitutional effect very soon. Such doses, with minute ones, a milligramme or more (gr. xvi.), of tartar emetic, or ten or twenty times that amount of oxy sulphuret of antimony, have served me well in fibrinous tracheobronchitis. But the mucous membrane of the trachea and bronchi is more apt to submit to such liquefying and macerating treatment than the nervous cords. The latter has no epithelial film like the former, in which they are very copious. And while the tracheal membrane is apt to be thrown out of a tracheal incision at once, though of more recent date, the pseudo-membrane of the vocal cords, if not interfered with, takes from six days to sixteen or more for complete removal. Still, a certain effect may even here be observable in cases of calomel ingestion, whether on the normal mucus of the mucousar glands, but on the total secretion of the surface, which will be in constant contact with the whole respiratory tract. Thus, either on theoretical principles, or on the ground of actual experience, men of learning and judgment have used mercury in such cases as I detailed above, with a certain degree of authority as to its benefit. But experience has not not have been great, for the mortality from croup has nowhere been encouraging. Nor is it an enjoyable proof of its efficacy that Bartels is known to have lost confidence in it in his ripest old age, either for its general unsatisfactoriness, or for the reason that the general character of all the cases in the epidemics of his later years can be contrasted with the character of his cases from the inflammatory to the septic type.

"If ever mercury is expected to do any good in these cases of suffocation by membrane, it must be made to act promptly. That is what the blue ointment does not. In its place I recommend the oleate, of which ten or twelve minims may be rubbed into the skin, along the inside of the forearm or elsewhere, when their surface becomes irritated, every hour or two hours. Or refracted doses will be useful, such as given above; or hypodermic injections of corrosive bichloride in one-half (or one per cent. solution in distilled water, four or five doses from four to six times a day, or more, either by mouth or inunction with the oleate or calomel internally. The hypodermic injections act very promptly and favorably, as I repeatedly convinced myself; for instance, in those cases of hereditary syphilis, which, from the presence of volar or palmar pemphigus and general cutaneous eruptions at birth, yield, as a rule, an almost fatal prognosis under ordinary circumstances, and with the ordinary treatment."

Henoch ("Vorletz. är. Kinderkrs., 1881, page 306) is opposed to mercurial treatment: "It cannot be denied that the vigorous antiaphlogistic treatment employed against this dangerous malady, particularly formerly (such as leeches, frequent emetics, and mercurials), together with the lack of appetite and repugnance to food, produced debility and anæmia." And (page 642), "A few times I believe to have seen a favorable effect of blue ointment applied every two hours in doses of 1 gramme each; and thus felt induced to try it in a large number of cases. These trials, however, terminated so unfortunately as to make me despair of a favorable result. A boy, aged eighteen months, was undergoing inunctions for syphilitic rashes, with little benefit. Of one hundred cases treated in this manner but one terminated favorably; of the rest thirty-three died without an operation, and sixty-six were tracheotomized."

E. Charon ("Contrib. à la Pathologie de l'Enfance,"

1881, 2 ed., page 49) takes the same stand: "Is there a medicinal treatment of croup? None in my opinion..."

On the other hand, H. C. Wood, in his "Treatise on Therapeutics," 1876, 2 ed., page 369, expresses himself as follows: "Calomel is useful in severe laryngitis, and especially in the pseudo-membranous variety where the type is sthenic; and no time should be lost in bringing the system under its influence."

In Reynolds' "Synopsis of Medicine," vol. i., however, mercurials are hardly mentioned amongst the remedies to be employed, and J. Lewis Smith is of the opinion that mercurial treatment in croup "has been properly discarded."

Barthelow ("A Practical Treatise on Materia Medica and Therapeutics," 1884, 4th ed., page 235): "Large doses of calomel in the form of red fumes are to be very efficacious in true croup or membranous laryngitis. It is claimed that it allays spasm and checks the formation of the false membrane. The author is sceptical in regard to the utility of calomel in this affection. There is, however, no doubt as to the value of the subphosphate as an emetic in this disease. If given early, so high an average does not occur. Barker, of New York, claims that a fatal result will most certainly be averted."

The first to recommend cyanide of mercury in diphtheria was A. Erichsen ("St. Petersburg Woch.," 1877, vol. ii., p. 14). He objects to the employment of the blue ointment, because of the uncertainty of the dose absorbed, and of other preparations, because of their actual or alleged disagreeable properties. He recommends potassium cyanide and cyanic acid. The patients were from seven months to thirty years of age. The pseudo-membranes became thinner and loosened within a short time, not only in pharyngeal, but also in laryngeal affections. Three cases, seven months, two and a half, and three years of age, were treated exclusively with the drug, and a hot sponge externally. No adverse reactions were observed. The use of tincture of iodine was made for the purpose of circumscribing the morbid process. The dose was .006 gramme up to the age of three years (1/64 gr.) every hour, and twice that amount for older children. Of twenty-five patients Erichsen lost one of cardiac paralysis, another of inanition, and a third of a complication with meningitis; in all, however, even in the last mentioned, the diphtheritic process became extinct.

Annsucasch also recommends ("Berliner Klin. Woch.," 1880, No. 43) the cyanide of mercury in diphtheria. Of one hundred and twenty patients fourteen died. They were from one to fifteen years of age. The dose was a teaspoonful of a mixture of cyanide of mercury 0.1 to 0.2 in 100 water every hour. Benzoate of sodium was blown into nose and pharynx. Stimulants were given besides. Some cases recovered after three or four days, some after six or eight. The more unfavorable or septic cases, or the more the larynx was affected, the less favorable was the result of the medication.

H. Schulz ("Centr. f. Klin. Med.") recommends the subcutaneous administration of mercury, mainly the cyanide, as recommended by C. G. Rothe. The latter ("Die Diphtherie," etc., Leipzig, 1884) reports the following: "A girl of three years, whose brother, four years old, had just died of diphtheria, appeared nearly moribund after an illness of a fortnight. Complete apnoea, stenotic respiration, and a high temperature. The prognosis very bad indeed. I then gave every hour a drachm of the following mixture: Hydarg. bicyan., o.o1; sq. dest., 60; tr. aconiti, 1. When five or six doses had been taken respiration became moister, the cough looser, viscid mucus
was expelled, and the night was less restless. The child finally recovered with several perforations of the soft palate, otitis media, and perforation of the drum membrane.

Since that time (September, 1880), I have employed the drug in ninety-eight cases, some of which were complicated with scarlatin a, and the result was favorable, inasmuch as the duration of the cases appeared to be shorter, and the local process exhibited unmistakable modifications (Allg. Central., 1880, No. 89; Deutsche Med. Woch., 1881, No. 34). Of these ninety-eight cases, the first seventy-one terminated in recovery. In the seventy-second, a girl, seven years old, the pharynx being nearly clear of membranes, the larynx was suddenly affected after an inhalation of lime-water, and the patient died within a short time, even before the completion of laryngeal stenosis. This was the first case in which the larynx became affected during the treatment. Two more cases in children of from two to three years terminated fatally. The treatment was not commenced before the fourth day; at that time group had already commenced. These three cases, as also that of a boy of five years with genuine croup, whom I was called to see a few hours before his death for the purpose of performing tracheotomy, have convinced me that no effect must be expected from the remedy when the larynx is already affected; that, however, when it is early enough to prevent the affection of the larynx and the fatal termination. By an affection of the larynx, however, I do not mean mere hoarseness and barking cough, or aphony, all of which may last for days and still terminate favorably, but real stenosis.

In place of the cyanide I sometimes give the bicarbonate: hydrarg. chlor. corros., 0.01-0.015; sodii chloridii, pepasin, & 0.5; &q. distill. 60.; tr. acon., r—2—a drachm every hour, with the same result. The tincture of aconite was added for its effect on the temperature, the pulse, and the pharyngeal irritation.

With these quotations and reports the historical review of our subject is almost exhausted, if I mean to confine myself to the most important literary publications only. Still, a very few must still find places to prove the discrepancy of opinions. I copy the following from J. Forth Asa Meigs and William Pepper ("A Practical Treatise on the Diseases of Children," 7th ed., 1885, p. 906):

Recently Dr. G. A. Lynn ("Trans. Pennsylvania State Medical Society, p. 886, 1879) reported remarkable results from the use of large doses of bichloride of mercury in grave cases of diphtheria. He found that even so large a dose as gr. 3 every three hours was well borne by children one year old, and asserts that from his experience it prevents the spread of the membrane or the development of blood-poisoning, and acts as much as a specific in diphtheria as quinia does in intermittent fever. These bold assertions have been corroborated by several good observers. We have not used this remedy sufficiently to authorize an expression of opinion, but a truly remarkable case, occurring in the practice of Dr. T. T. Yarrow, in Philadelphia, and seen by us in consultation ("Address on the Use and Abuse of Mercury," M. D. "Trans. Am. Med. Assoc.," 1881), where this remedy was used in the above manner with excellent results, convinces us that further cautious trials should be made in this direction. The same may be said for the treatment by enormous doses of calomel, which has been advocated by some good observers as producing specific curative effects. It is difficult to take the cases in question, and I am not able to try either of these modes of treatment, but it seems to us that it would chiefly be in cases where a continued tendency to pseudo-membrane showed itself, while as yet no extreme degree of blood-poisoning had occurred.

In the latest French text-book, however (A. Descroizilles, "Manuel de Path. et de Clinique Infantiles," 1884, p. 326) the following sentences are found:

"Mercurials have been eulogized in America, and are still fashionable in England. In France they are not believed in at all. Mercury has been used in the form of calomel in repeated doses, or the blue ointment has been employed round the neck. In spite of what has been said in England to the contrary, they debilitate, purge, and salivate, impoverish the blood, and facilitate hemorrhages. Therefore they have been almost given up."

Finally, in F. Bouchut's "Clinique de l'Hôpital des Enfants Malades" (1884) mercury is not mentioned at all amongst the remedies employed in Europe. Thus it is evident that the diffusion of opinions in regard to the availability of mercury, in croup, is very great indeed. But, there is a peculiar feature in the controversy which cannot escape your attention. It is this, that those who speak of the subject in a text-book, and in brief text-book fashion, are apt to trifle with it because of their tendency to teach accepted facts only, while some of those who have personal observations to relate in full, appear as the friends of the mercurial treatment.

My own experience is not a very extensive one, but by what I have since seen my opinions of 1880 are somewhat modified in favor of accepting the beneficial results of mercury in croup. Particularly was I struck with, and encouraged by, the force of the statements made by Pfeffer, case a little before the American Medical Association at Richmond, in 1881, and alluded to before. Since that time I have employed, or recommended, mercury in many cases, and believe with fair result. I am not, however, of those who never lose a case. But what I have seen is at your service. Allow me, therefore, to detail a few cases as instances only, and finally to draw some conclusions.

Case of Dr. G. Mourraillé.—F. M., female, aged three years and eight months. The doctor was called March 28th, 4 P.M. The little girl had slept well the previous night and took her breakfast as usual; complained of headache and refused to go out at 2 P.M. Took tinct. ferr. mur., gtt. iij. every hour, and was ordered for the evening a dose of pulv. dover. and hydrarg. c. ret., & gr. j. At that time, temperature 101.5, gray extensive, but thin deposits on tonsils; no cough. Was called again at 8 P.M. Powder had been taken. Cough frequent and croupy, voice hoarse, great dyspnoea, face congested, but not cyanotic. 11 P.M.: Same condition, child has not slept. Cough very dry, at first velar, later giving way to an actual whoop, and c. ret., & gr. 1. Child falls asleep about midnight. Respiration less disturbed, cough less frequent, but of the same character; sleep restless. Солг-сulation on the 29th, 9 A.M.: Temperature, 101°; voice feeble and hoarse; cough hoarse; pharyngeal membranes less extensive; respiration croupy; moderate precordial and supraclavicular recession.

Bichloride of mercury, gr. 1/2 every hour in water. Night restless; voice and cough not changed, but respiration rather easier.

March 30th.—No change in the general symptoms, but more diaphoretic deposits in the throat. Twenty-four doses of the bichloride of mercury had been taken by 3 P.M. It was ordered to be replaced by hyoscine and several loose passages, with griping pain. The remedy was discontinued and pulv. dox. spdt. hyd. c. ret., & gr. j., given instead. Night fair; voice hoarse; cough rather looser; respiration rather easier.

March 31st.—The bichloride resumed in the morning, followed by loose passages. About noon one drop of the calomel of opium was ordered with each hourly dose. In this way the remedy was well tolerated. The night was rather satisfactory; three doses only of the medicine were given.

April 1st.—Cough, loose; respiration, pretty easy; no membranes in the pharynx; the medicine is continued until 2 P.M. In the evening pulv. dox. and hyd. c. ret. April 2d.—Voice hoarse, but cough more catarhal. Treatment discontinued. Child very nervous. Pulse in-
THE MEDICAL RECORD.

578

termittent. Doses of bromide potass., gr. vj., in the evening. Night good. Temperature from March 28th to April 6th, 99° to 101° (rectum), the latter in the afternoon's mostly. Cough lasted until April 12th, hoarseness to April 16th. The total amount of bichlor. hydro- drag. was gr. ij.

CASE OF DR. T. N. BURCHARD.—Fibrinous bronchi- tis in a child five months old, treated with corrosive sublimate; recovery.—Called March 30th, 6 A.M., to see Leila H., aged five months. Found her suffering with dyspnea, croaky respiration, and painful cough. The child had been perfectly well the day previous, and had been on a ride. Two months before had had a severe capillary bronchitis which lasted eight days. Examination revealed hyperemia of funes, no swelling or membrane visible. Physical examination of lungs negative. Ordered mustard cloth to throat, to be followed with hot fomentations, two grains of quinine and a diaphoretic mixture of ipecac, niter, and spirits of minde- reraus. The room to be kept filled with steam, 9 P.M.; had passed a comfortable day, and vomited consider- able phlegm at 7 P.M. Pulse, 120; temperature, 99 4°; respiration, 38. Fauces red, no membrane; physical examination of lungs negative; respiration croumpy; cough painful; voice absent. Ordered whiskey, grt. viij., q. h.; paraligic, grt. iiij., q. h.; diaphoretic mixture to drink; cod-liver oil, 1 drachm., 1 P.M.; respiration, 152; respiration, 34. Ordered carb. ammon., gr. ij., and tinct. digital., grt. ij. Whiskey, grt. xxv., to be repeated at end of half an hour.

March 31st.—3 A.M.: Child sleeping, breathing more easily. Pulse, 148; temperature, 101 4°; respiration, 32. 11 A.M.: Pulse, 132; temperature, 103 3°; respiration, 36; nurse says she is better, but still absent. Diaphoretic mixture discontinued. Whisky, grt. x., q. h.; quinine, gr. ij. 1 P.M.: Seen by Dr. Jacoby in consultation. Pulse, 132; temperature, 101 1°; respiration, 68. Physical examination of throat and lungs negative. Percussion over lungs posteriorly and apices anteriorly, extra-sonorous; a few faint sonorous rales heard posteriorly. Diagnosis of acute laryngitis confirmed. Since last visit, however, respirations have doubled in frequency, with falling temperature. Dr. Jacoby suspects the exudative process is invading the bronchi. Pneumonia, pleurisy, and capillary bronchitis can be positively excluded. Ordered hydarg. bi-chlorid., grt. x., q. h.; stimulants, poultices, and cod-liver oil to follow. Pulse, 132; temperature, 101 5°; respiration, 70. Condition about the same; voice absent. 7:50 P.M.: Vomited after taking corrosive sublimate. 12 P.M.: Again seen by Dr. Jacoby. Pulse, 132; temperature, 101 5°; respiration, 62. Has taken 3/4 gr. bi-chloride of mercury each hour since 2 P.M.

April 1st.—8 A.M.: Passed comfortable night; vomited corrosive sublimate at 4:45 A.M. Pulse, 128; temperature, 102 2°; respiration, 64. Ordered whiskey, grt. xv. q. 2 h.; bi-chloride to be continued. 1 P.M.: Seen by Dr. Jacoby. Pulse, 132; temperature, 101 5°; respiration, 66. Fauces slightly red; no swelling or membrane; examination of lungs negative, save few sonorous rales heard posteriorly. Has taken and retained twenty-two 1/2 gr. doses of corrosive sublimate. Ordered treatment continued. 6 P.M.: Pulse, 132; temperature, 101 5°; respiration, 64. Noticed slight puffiness on left side of neck; lymphatic glands not enlarged; no swelling of tonsils. 10 P.M.: Pulse, 120; temperature, 100 4°; respiration, 48. Has had normal movement at 8 o'clock, followed by a loosen one at 8:45. Ordered paragogic, grt. iiij., and to omit one dose hydarg. bi-chlorid. 11:30 P.M.: Seen by Dr. Jacoby. Pulse, 132; temperature, 100 5°; respiration, 53. Mother's milk having failed, ordered barley-water and milk. Whiskey, grt. xv. q. 2 h. The hydarg. bi-chloride to be continued, unless diar- rheea or vomiting should supervene. Physical examination of throat and lungs as before.

April 2d.—2:45 A.M.: Vomited considerable phlegm; swallowing with difficulty; child's appearance worse. Ordered brandy to be substituted for whiskey, grt. xv. q. 2 h.; tinct. digital., grt. iiij. q. 2 h. Poultices and steam to be kept up. 9 A.M.: Child complained of being dying; marked dyspnea with cyanosis. Pulse indistinguish- able; respiration, 72. Found above conditions to be dependent upon accumulation of mucus in the throat. Inverted the child, wiped out mucus from throat with friction, brandy, carb. ammon., and tinct. digital. 9:50 A.M.: Color and breathing greatly improved; child not complaining of being dying in bronchi; caused vomiting by finger in throat. After vomiting, pulse about 160; respiration, 48; temperature, 101°. Neck more swollen; hyperemia of throat increased. 1 P.M.: Dr. Jacoby in consultation. Child has taken twenty-two doses of hydarg. bi-chlorid during past twenty-four hours, all except one dose having been retained. Dr. Jacoby detected a swelling on left side pharyngeal-wall, low down, of phlegmonous character. Child's general appearance improved. Ordered brandy, grt. xii., q. 2 h.; milk and barley-water to be continued; other treatment as before. 11 P.M.: Seen by Dr. Jacoby in consultation. Pulse, 144; temperature, 100 5°; respiration, 60. 12 P.M.: Temperature, 100 4°.

April 3d.—9 A.M.: Child passed comfortable night, coughing less, and sleeping more. Two small, green movements during the night. Pulse, 140; temperature, 101 5°; respiration, 66. Swallows better; cough less painful; hyperemia of throat less; swelling about the same. Examination of the lungs gave numerous moist rales posteriorly. Child appeared quite respiratorily resonant. Treatment continued. 1 P.M.: Seen by Dr. Jacoby in consultation. Has taken and retained twenty-one doses hydarg. bi-chlorid. Pulse, 150; temperature, 100 4°; respiration, 60. Ordered brandy, grt. xv. q. 2 h.; tinct. digital., grt. iiij., q. 4 h.; hydarg. bi-chlorid., grt. x., q. 1 h. 3:35 P.M.: Had large consipitated movement. 4:35 P.M.: Vomited considerable phlegm. Pulse, 150; temperature, 101 4°; respiration, 68. 11 P.M.: Breathing much better. Takes and retains nourishment and medicine. Nostrils considerably occluded with mucus. Pulse, 144; temperature, 100 4°; respiration, 52. Has vomited some curdled milk during the evening. Swelling in throat about the same. Condition of lungs unchanged.

April 4th.—3 P.M.: Pulse, 132; temperature, 101 5°; respiration, 132. Feet and legs very cold; hot-water bag applied to them. Brandy and carb. ammon. given freely. 5:30 A.M.: Small consipitated movement followed by loose movement at seven o'clock. Vomited sour milk several times during the night. Child very restless, but general condition improved. 1 P.M.: Seen by Dr. Jacoby. Pulse, 160; temperature, 102 3°; respiration, 54. Has taken nineteen 3/4 gr. doses of bi-chloride since yesterday. 6 P.M.: Nursed ten minutes freely this afternoon. Treatment continued.

April 5th.—9 A.M.: Has passed a comfortable night. Has vomited phlegm a number of times. Stomach quite irritable; substituted inunctions of the olesate of mercury in place of the bi-chlorides. 1 P.M.: Seen by Dr. Jacoby in consultation. Pulse, 132; temperature, 100 5°; respiration, 28. Asleep. Has nursed twice during the morning; swallowing in throat less; poultice discontinued. Ordered brandy, grt. xv. q. 3 h.; tinct. digital, grt. iiij. q. 4 h.; hydarg. bi-chlorid., grt. x., q. 8 h. Steam to be continued as before.

April 6th.—9 A.M.: Passed comfortable night. Vomited phlegm twice or three times during night. Pulse, 128; temperature, 100 5°; respiration, 32. Voice returning; cough stronger and less frequent. Ordered whiskey, grt. x. q. 4 h.; fr. digitalis, grt. iiij. q. 8 h. Child nursing.

April 10th.—Steam discontinued. Thoroughly convalescent.

April 15th.—Child taken to Lakewood, N. J., to-day.
CASE OF DR. E. J. HOGAN. - Group; trachotomy; bronchial croup; recovery. - I was called to see Milton EVANS, aged two years, on March 9th. Two persons living in the house had suffered from pharyngeal diphtheria about a month previously. The child seemed to have a mild laryngeal catarrh with moderate dyspnoea. A careful examination failed to reveal more than congestion of the pharyngeal and tonsillar mucous membrane. His temperature was normal. General condition excellent.

On the evening of March 10th he was breathing easily, pulse good, temperature normal; so much better, indeed, that I did not think it would be necessary for me to call again.

An alarming dyspnoea developed at about 3 A.M., March 11th. A physician, called in the emergency, administered therpeth mineral, which was followed by emesis and partial relief of the dyspnoea. A profuse diarrhoea, lasting over twenty-four hours, also resulted from it.

During the morning of the 11th, the symptoms became steadily more threatening. (There were occasional remissions of short duration.) Pulse, 140 to 150; respiration, 50 to 60; cyanosis, at times very marked; semicoma; considerable epigastric and suprarectal dilatation. On the trachea, passive expiratory signs masked by the noisy laryngeal breathing. Neither Dr. McMahon (who had been called to see the case) nor myself could detect any membrane in the throat or nose. We both agreed as to the necessity of an early tracheotomy. Meanwhile the child was taking carbonate of ammonia internally and lime vapor inhalations.

Laryngo-tracheotomy was done by Dr. F. Lange, at 2.30 P.M. No anaesthetic used, patient being insensible. Two bleeding veins were ligated. A portion of the first tracheal ring was removed after the windpipe had been opened. A thin, soft, easily detached membrane was removed from the trachea. A tube was inserted, covered with a sponge, wrung out of hot water. The wound was treated with corrosive sublimate solution (HCl) and iodiform; no spray used; no internal treatment except small doses of Dover's powder (p. r. n.) for cough.

On the evening after the operation the child was breathing easily through the tube and took nourishment (milk) freely. The pulse had fallen to 120. Temperature (rectal), 102.4°.

March 12th. - In the afternoon the patient began to suffer from increasing obstruction below the tracheal wound. Loud tracheal râles. Respirations very rapid. Both tubes removed in the evening by Dr. Lange, who, by the aid of a catether and aspiration, freed some pieces of thick, very dense, adherent membrane. Later seen also by Dr. Jacobi (2 P.M.). Breathing still much obstructed. Examination of chest negative. On the suggestion of Dr. Jacobi the bichloride of mercury was administered in doses of 1/8 of a grain hourly, with the expectation of its favoring the disintegration and separation of the membranes.

From this time on it never became necessary to remove the outer tube for the sake of cleaning the trachea. The use of the feather with occasional instillations of a solution of common salt sufficed to remove any material causing obstruction. The bichloride was suspended on the third day, on account of intestinal irritation. The gums were not affected. On March 14th, the temperature reached 102.8° on March 21st, 104.8°. On these two occasions, quinine was given, eight grains morning and evening in divided doses. On about the ninth day the patient was put on the elixir of gentian and iron (Wyeth's). The tube was removed on March 22d; after its removal the wound did nicely. During the course of the disease albumen in small amounts and some blood were found in the urine.

In connection with the report of his case, Dr. Hogan says: "My experience with the bichloride in this case, it is fair to state, has been such that I would feel it an injustice to withhold it from a patient in the future, under similar circumstances. Previous to its administration, as the history shows, there was a rapid formation of very dense, thick, membrane, with every prospect of death from tracheal occlusion. Afterward, the case went on steadily to a favorable termination. Even granting the possibility of a coincidence, it would seem that a resort to this means is both rational and expedient."

These three cases are but specimens of what I have frequently seen in my own practice, and in that of colleagues, some of whom may be present. Not only have I seen a certain number of cases of pseudo-membranous croup, mostly complicated with pharyngeal diphtheria, getting well without tracheotomy with mercurial treatment, but the percentage of recoveries after tracheotomy in the last three years, in my experience, has been greater than through ten years previously when no mercury was employed.

Now, I am not so enthusiastic as to generalize on the strength of my cases—even dozens of cases count but little when we recall the fact that statistics without great numbers are deceptive—but I know that for years past, when tracheotomy was the only remedy applied to authenticated cases of membranous croup, not tracheotomized, the mortality amounted to ninety or ninety-five per cent., has been happily shaken in its foundations.

In regard to the preparations of mercury to be used I agree with Voit and Hartnack in this, that it is best to agree upon a very small of the preparations of mercury in medical practice. The bichloride may be used in a dilution of more or less than 1 to 15,000, that is, a grain in a quart, or Baerensprung's albuminate, or Bamberger's peptonate may be employed. The latter's patients who used either, subcutaneously, were not salivated, though nothing was done to prevent salivation, and increased in weight during the treatment. Albuminate taken internally disturbed the stomach in no way; its favorable effect on the appetite has been observed occasionally. Soluble preparations in large dilutions are easily absorbed by the mucous membranes (or by ulcerated surfaces), thus they act in baths. In somewhat concentrated form it may give rise to inflammation, in stronger concentration to catarrh. Intramuscular and intestinal disturbances may reach the degree obtained by arsenic or cholera, and prove fatal. Pills with larger doses of mercury lose their dangerousness by meeting with plenty of albumen to form albuminates, particularly when given after meals. The corrosive sublimate is a strong antifertamentive. Bacteria are killed by it in dilutions of one to twenty thousand (Buchholtz), or according to others, one to three hundred thousand. At all events it is ten times as powerful as thymol and benzoate of sodium; twenty times more than cresot or benzoic acid, or oil of thyme; thirty times than salicylic acid, or eucalyptol; one hundred times than carbonic acid or quinia. The deductions of Dr. Wm. H. Findlay, of Brooklyn, as published in the New York Medical Journal of April 12th and 19th, prove not only that the bichloride of mercury is a proper antifertamentive to be given, but also that the doses must be large when compared with those prescribed or permitted by the books.

Hydargyrum bichloride combines in the stomach with chloride of sodium, is absorbed as such, and changes into an albuminate with the albumen of the blood. Dissolved albumen, it is true, is coagulated by hydargyrum bichloride, and antagonized and rendered not absorbable; but both a surplus of albumen and the addition of chloride of sodium restore its solubility. These conditions are mostly found in the stomach, and, always in the blood, salt solution of albumen, hydargyrum bichloride produces no coagulation.

1 Reported by Dr. Hogan.

when sodium chloride was added. Thus, subcutaneous injections meeting with the alkaline tissue fluid are best tolerated when sodium chloride is added to the mercurial solution. The contents of the stomach and its fluids are mostly acid, however. Marl found that acid solutions of albumen are not coagulated at all by hydrargyrum chlorid, but absorption of the latter is reduced, however, by the addition of sodium chloride, so that the latter may better be dispensed with in internal medication, unless the dose of the hydrargyrnum chlorid be large. Marl expresses even the opinion that large quantities of the sodium chloride may disturb digestion by its shrinking influence upon the hydrargyrum chloride. He contains that the digestible fluid hydrargyrum chloride does not coagulate peptone in a solution of one to three thousand, nor does it throw out the pepsin in a solution of one to one hundred, or less (Arch. f. Ezpér. Pathol. u. Pharm., vol. iii.).

In regard to the treatment of croup after the performance of tracheotomy, I finally make the following fragmentary suggestions:

The temperature of the room must not be too high, not much over 70° F. The air must be kept moist. A kettle with boiling water on an open fireplace, works quite well, provided the steam enters the room, and not the chimney. To obturate the latter, a tin cylinder, of the shape of a funnel, may be placed over the mouth of the kettle, which is generally too short. The old-fashioned cooking oven in the room, or a stove of former patterns will do as well. The self-acting stoves are bad, they give out a great deal of coal-gas, and have no place where to put a kettle. Gas-stoves of any shape or pattern are injurious, gas consumes so much more oxygen than alcohol that a large alcohol lamp, to boil water on constantly, serves the purpose better. When the room is large, or cold, part of it may be easily changed into a closet by means of a few nails driven into opposite walls near the ceiling, ropes, and bed-sheets. Into such a closet, or tent, the steam may be introduced by a tin tube, the alcohol lamp remaining outside the sheets. A tablespoonful of spirits of turpentine may be poured on the boiling water every half hour, or hour. The steam or vapor, however, must not be too thick. Oxygen must not be excluded. Many years ago I demonstrated the necessity of allowing a full supply of oxygen by the case of a baby who suffered from descending respiratory paralysis. Oxygen was supplied in convulsions from carbolic acid gas poisoning. Whenever I introduced oxygen from a standing cylinder into the tube, the convulsions would cease, and the cyanosis decrease; when I stopped the supply, cyanosis and convulsions would return. Thus it may frequently be necessary to open a window, more or less. Here, as in everything else, the judgment of the physician will decide upon the indications of the individual case.

The nutrition of the patient has generally suffered much. Before the operation but little food was taken, still less was digested, and the operation itself and the anesthetic have added to the previous weakness or exhaustion. Moderate feeding and stimulation are therefore to be commended soon. Yomiting after chloroform I have seldom seen to last long or to be embarrassing under these circumstances. Feeding and stimulation is the more necessary the more the hungry lymph-vessels are liable to absorb injurious material when not supplied with healthy food.

Is internal treatment required? The general treatment must be continued. If it consisted in the administration of hydrargyrum, either internally or externally, it must be continued. If its effect was not sufficient to clear the larynx and to render the operation unnecessary, it will or may be sufficient to complete its effect in the next day or two, to prevent the process from descending or the membranes becoming too many or too thick. No changes ought to be made in the treatment unless there be changes in the symptoms. Not infrequently the first symptoms of broncho-pneumonia come on within a few hours after the operation, recognizable by frequent pulse, respiration frequent beyond proportion, and physical symptoms. The stomach is not very reliable. Quinine answers best hypodermically. From six to ten grains may be injected at bed-time. The proposition that has served me best in the last few years is a solution of the carbamid in five parts of water. If an additional remedy is required, from twenty to thirty grains of sodium salicylate may be given in the course of three or four hours, in hourly doses, to reduce the temperature. Tincture of digitalis will prove advisable at the time when the child in artificial digestion will act as a powerful nerve; a twenty-fifth of a grain may be given to a child, two years of age, every two hours, until four doses, or five, will have been taken. The rest of the treatment of the complications depends on their nature and character. It is not the name of the disease which has to be treated, here as in every case, but the individual patient.

In regard to stimulants I have but little to say. I use alcohol in the most pleasant shape, preferring brandy or whiskey. I use a great deal of camphor, ten to forty grains daily, or in cases of urgency, Siberian musk, from two to five grains, every half hour or hour, until from fifteen to twenty grains have been taken, in cases of colic or for the purpose of prostration.

In this connection I have nothing to say about local applications to the trachea, or the handling or removal of the tube. My subject was a limited one. Besides, I meant to suggest rather than to teach. My object was to impress upon the minds of my colleagues, and particularly those younger than myself, the necessity of not dispensing with any one of the most serious problems of medical practice. This one fact I will urge upon you, trite though it may be, and ridiculous though its expression may appear, viz.: that the name of a disease is not the object of treatment, that the name of a drug is not the requirement in a morbid process, but its intelligent and appropriate use. Scores of times have I been told, for instance, that my method of treating diphtheria with tincture of iron was carried out in an individual case, when I found that three or four drops of tinct. ferr. mur. had been administered three or four times a day. This may serve as an instance, but also as a warning. It is not enough to administer hydrargyrum bichloride; to be effective, enough must be given and well diluted. The doses must be large and regularly diluted. Both local and constitutional effects must not be feared. They will seldom be met with. If they are they amount to little in comparison with the mortal enemy you are going to fight. Mercurial stoma-
titias in infants is very rare indeed, and will readily heal. In larger children, of from two to five years, it appears but late, if at all; as a rule, the administration of mer-
cury is the less objectionable the younger the patient. My doses have varied from 1/30 to 1/3 of a grain (1 to 24 milligrammes) every hour, and the treatment has been continued from one to six days.

To conclude, however, I shall here suggest again, what has been the gist of the remarks of the evening, in brief words:

First.—The mercurial treatment of pseudo-membranous affections of the respiratory organs is promising of great results.

Second.—The corrosive sublimate is the preparation best adapted for internal medication.

Third.—The system must be brought under its influence slowly, by frequent doses.

Fourth.—It must be given in dilutions of 1 to at least 3,000 to 5,000.

Fifth.—Babies of tender age bear one-half grain and more a day, and many days in succession.

Sixth.—Salivation and stomatitis are rarely observed, and appear to heal kindly. Gastro-intestinal disturbances are not frequent; they are moderate, can be avoided by
the administration of mucilaginous and farinaceous food, or of mild doses of opium.

Seventh.—If not well tolerated, the injunction of sufficient and frequent doses of hydargyrum oleate takes the place of the corrosive chloride, either together, or alternately with the internal administration.

Eighth.—The treatment of croup may be preventive to a great extent. Most of the cases are caused by cold, either direct or by exposure to the cold from other causes. The simplest preventive treatment of croup must begin. Without desiring to encourage mere local treatment, which in unwilling patients has to resort to force or violence, and thereby does great harm, I point to the peculiar local effect of mercury on the pharynx, both in the healthy and sick, as a means to influence the threatened invasion of the larynx.

THE SUBCUTANEOUS INJECTION OF HUMAN SCARLATINAL BLOOD.

By J. W. STICKLER, M.S., M.D.,

ORANGE, N. J.

My own experience in the subcutaneous use of human scarlatinal blood does not fully confirm the results given by Coze, Feltz, and Reiss. In my first article (Medical Record, March 24, 1883) I quoted the results they obtained by injecting under the skin of sixty-six rabbits blood taken from a patient sick with scarlet fever. Of the sixty-six, two died, and the remaining four had an intense fever which nearly destroyed them. I have taken blood from patients who had well-marked scarlatina, and have introduced it under the skin of rabbits and dogs without destroying life, or producing such symptoms as would justify the belief that the animals experimented upon had scarlet fever. It is true that a slight constitutional disturbance resulted, but nothing characteristic.

As is well known, white rabbits are very susceptible to the action of almost any morbid product introduced into their bodies. The inference, then, would be natural, that if a specimen of scarlatinal blood were introduced into the system of several small animals, such as rabbits and dogs, without reproducing the disease, the same result would follow the introduction of blood from the same source into the human system. Of course, some allowance must be made for the difference of susceptibility of the lower animals and man. I therefore think that the virulence of any given specimen of scarlatinal blood should be tested before injecting it under the skin of a person who is supposed to have been protected against the disease, otherwise it cannot be relied upon as a test.

I draw attention to this point because, in my first series of experiments in the use of equine scarlatinal virus, I endeavored to ascertain whether the inoculated patients had secured immunity from the natural variety of scarlatina, by injecting subcutaneously blood taken from well-marked cases, patients who had both angina and eruption as pronounced as they could be. If I remember correctly, some of this same blood failed to produce characteristic symptoms in rabbits. However, as I employed different specimens, and all taken from severe cases, it is possible that some of them might have produced in the lower (small) animals the symptoms spoken of by Coze, Feltz, and Reiss. At all events I feel satisfied that the introduction of human scarlatinal blood under the skin of my first twelve cases was, in the light of my own experience, an unreliable way of ascertaining whether the equine virus had secured to them safety from an attack of scarlet fever. The most satisfactory method as it exists in the air of the sick-room. In this way the poison is brought into contact with the mucous membrane of the eyes, nose, pharynx, larynx, and lungs, and is much more liable to be absorbed and produce a specific effect than is the blood when introduced under the skin. I make this statement in order that absolute truth may be made prominent in all the details pertaining to these investigations. Some of the children inoculated have been exposed to air which has been contaminated by scarlet fever patients who have had the disease in the locality where they live, others have been exposed directly to the poison in the sick-room, but they have, with a few exceptions, escaped without a trace of the disease. The" exceptions" were children who, red without or descend from, diphtheria of the fauces. Here the preventive treatment of croup must begin. Without desiring to encourage mere local treatment, which in unwilling patients has to resort to force or violence, and thereby does great harm, I point to the peculiar local effect of mercury on the pharynx, both in the healthy and sick, as a means to influence the threatened invasion of the larynx.

Progress of Medical Science.

INTERMITTENT PARAPLEGIA.—Dr. Shakhnoivitch describes a case of this kind in a patient, aged forty-four, of a strong build, with a powerfully developed muscular system, of splendid general health, who for twenty-five years has suffered from intermittent paraplegia. The patient's father had the same curious affection, and, as the author alleges, succumbed in his fifty-fourth year exclusively from increase in the frequency of the paralytic attacks. The patient's brother is reported to suffer from the same condition, and the first paralytic attack appeared a few hours after exposure to cold. The attacks come in intervals varying from a few hours to two months; they commence invariably during sleep. He awakes, already struck by complete paralysis in all four extremities, consciousness being perfectly retained, and no pain or any unpleasant sensations long felt. Speech, sight, hearing, smelling, and taste; tactile, painful, and thermic sensibilities, and the bladder and rectum remain thoroughly normal. Reflexes are abolished; the muscles of the body and extremities are stiff and hard to the touch. By the end of from three to twelve hours the patient falls asleep, and on awaking feels only numbness in the extremities, which passes away in a few hours, or—when he begins to make energetic movements, or undergoes shampooing—in half an hour. The patient is intelligent and cheerful, and leads a very active life. He never suffered from malarial fever, therefore his case cannot be placed in the same category with the cases of intermittent paraplegia published by Hartwig, Macario, Romberg, and Gibney. Dr. Shakhnoivitch thinks that he has discovered a new form of neurosis, which he proposes to call "paraplegia spinalis intermittens nervosa."—London Medical Record, March 15, 1884.

HUMANE BLISTERING.—Mr. S. Stretton, in the British Medical Journal, recommends the following method of blistering. The surface requiring such counter-irritation is to be well covered with annular blisters about the size of the human iris, cut from vesicating tissue with an ordinary gun-punch, the centre being extracted with a punch of small size. Once secure to the surface, and covered with cotton-wool and bandage, these blisters require no further attention. The discomfort created is so slight that there is never any resistance to their application.

RAPID STAINING OF KOCH'S BACILLI.—Dr. Law, writing in the British Medical Journal, recommends the following plan: A thin and even film of spumrum is first dried upon the cover-glass in the usual way, and then floated upon the surface of a small quantity of the magenta and aniline solution previously filtered into a watch-glass. Gentle heat is now applied by means of a spirit-lamp, until vapor rises from the liquid. The cover-glass is now removed and carefully washed in methylated spirit, until as much as possible of the stain is dissolved out, and finally dried. A drop of Tarrant's solution, on a glass slide, forms a suitable mount for the specimen. The whole process need not last longer than five minutes; and it will be seen that the use of chrysoine and nitric acid is entirely dispensed with, a gain that all must appreciate.
THE MEDICAL RECORD. [May 24, 1884.

THE TREATMENT OF HYPERTROPHY OF THE NASAL MUCOUS MEMBRANE.—Dr. Morell Mackenzie, in a paper on hypertrophy of the mucous membrane of the nose (Annales de l'Academie de l'Oeil, du Larynx, etc., vol. ix., No. 6), says that when catarrh of the nose has existed for some years, and, indeed, in scrophulous children, when it has lasted but a few months, great thickening of the mucous membrane sometimes takes place. The symptoms are the same as those of ordinary chronic catarrh, but intensified, the patient being often quite unable to blow his nose, and being compelled to breathe entirely through the mouth. The voice is persistently nasal, and the patient, if a child, always keeps the mouth open, presenting the well-known stupid appearance so often observed in cases of enlarged tonsils. It has recently been noticed by several physicians that obstruction of the nostrils in such cases is apt to give rise to very troublesome reflex phenomena, such as asthma, cough, and even epilepsy. These phenomena, however, are not nearly so frequent in cases of simple hypertrophy as in polypus, the probable reason being, as suggested by Hack, that the morbid alteration of structure destroys the cavernous tissue, diminishes sensibility, and thereby lessens reflex action. In the diagnosis of hypertrophy, for a careful examination with the speculum and rhinoscope will, as a rule, reveal the nature of the case. The author then points out the connection between such thickening and genuine polypus, remarking that the two conditions are frequently found associated. He regards the prognosis as favorable. With respect to treatment he says that it frequently needs to be of a vigorous character, but at an early stage the mildest measures are sometimes sufficient, the daily use of gum-elastic bougies often effecting a cure. The smallest size of instrument should, as a rule, be employed at first, and at the beginning of the treatment the bougie should be left in the nose for no longer than five minutes at a time; after a few days, however, it may remain in the nostril for fifteen minutes, and after a week of it can be easily tolerated for half an hour. Larger bougies should afterward be employed, but force must always be carefully avoided. Mild alkaline sprays or hand-washes are often of great service if perseveringly employed. Sneezing must be checked by the inhalation of strong ammonia or acetic ether.

The following measures are active steps must be taken; but a word of caution is perhaps necessary in connection with this point. For, though the introduction of the electric cautery and the wire écraseur permits some relaxation of the rule under which surgeons were taught “to cut through everything soft, to saw through everything hard, and to tie everything that bleeds,” the spirit of this maxim is still retained. For years, sometimes influenced the young practitioner, and the nasal passages have occasionally been “cleared” with a zeal and energy worthy of the industrious backwoodsman. In several cases that have come under his own care, in which severe measures had previously been urgently advised by others, he succeeded in effecting a cure by the simple removal of all causes of irritation and the persevering use of gentle dilatation. He would also warn some of his jeunes confères that as the appearance of the interior of the nose varies in healthy persons just as much as its outward configuration, it is unnecessary, when no inconvenience is felt, to restore geometrical symmetry to the turbinate bodies, or to invest the lining membrane of the nose with artistic merit. While but deprecating unnecessary aggression in this tender region, he does not deny that there are many cases which can only be cured by active treatment. Should the hypertrophy resist the measures already recommended, the redundant tissue must be destroyed or removed, and this should be done with care and precision, as the most simple and efficacious method. Instead of destroying the hypertrophied tissue, however, it may be removed by a cutting operation. For this purpose either a snare or sharp forceps may be employed. When the anterior part of one of the turbinate bodies is enlarged, it should first be transfixed with a needle mounted in a light handle, the loop of the écraseur being then passed over the needle and gradually drawn round the hypertrophied membrane. If the posterior extremity of the turbinate body be the part affected, such a bend should be given to the loop before it is pushed through the nose that it will pass over the mass in the naso-apharynx. A little manipulation will suffice to secure the growth, which, if hemorrhage is anticipated, should be attended to very slowly. The operation being interrupted every few minutes, and not completed for half an hour or even an hour. In these cases, it will be found much more easy to remove the swollen tissue with the écraseur passed through the nose than to destroy it through the naso-apharynx. Dr. Beverley Robinson has successfully removed hypertrophied tissue from the turbinate bodies by means of strongly toothed forceps, but this treatment appears to the author to be much more severe than either the electric cautery or the wire écraseur.

VANILLISM.—Dr. Laget has made an examination relative to the accidents caused by the manipulation of vanilla. In the Bordeaux warehouses the pods are unpacked, brushed, and put in boxes; in the distilleries they are cut in small pieces for the fabrication of various liqueurs. It has been found that the workmen exposed to the dust and emanations of vanilla are liable to suffer from sensations of the face and eyes accompanied by much itching and swelling, and followed by desquamation. Coryza and conjunctivitis are frequent. In other cases the chief symptoms are anæmia, headache, giddiness, irritability of the bladder, nervousness, and sexual excitement.—London Medical Record, April 15, 1884.

ALBUMINURIA IN NERVOUSNESS.—In the recent interesting discussion on albuminuria by the Glasgow Pathological and Clinical Society (British Medical Journal, regionary 23, 1884), and at the American Medical Association, two not generally recognized classes or groups of cases in which albumen frequently occurred in the urine without organic disease. First, there were cases of young men in which the genito-splanic centre had been debilitated and rendered preternaturally excitable, not necessarily by sexual excess, but by the struggle to repress and restrain the passions. General nerves excitement which might be so wrought up as to prove as noxious in its effects as excess or abuse. In these cases, he said, albuminuria frequently occurred, and was either overlooked or wrongly regarded as evidence of kidney disease; the latter mistake being the more likely to be made, because there were often no symptoms of kidney disease generally the right, and, as often happened when neuralgia of visera was accompanied by vasomotor disturbances, “pain on pressure.” The second class of cases to which he directed attention, consisted of studious or sedentary men of middle age, who suffered from mental depression and “nervousness,” with, perhaps, aphagia or claustrophobia, or both. In these cases the albumen was often found in the urine, and in some instances its appearance alternated with that of sugar in small quantities, pointing significantly to the location of the excitement, or the glance of the reflex, and suggesting the fact of nerve-centre disturbance as the cause of the malady. He pleaded for the recognition of these varieties of albuminuria without kidney disease, and, insisting strongly on the scientific error of placing the albuminuria in the first of these cases, with the result of creating needless alarm, and in too many instances producing grave mental depression, urged a wiser and better use of the urinary test-box, recommending that the urine of all patients should be examined before treatment is begun, for will be found that the examination is a more extended practical and more precise method of research, he believed it would be found that albuminuria without kidney disease was by no means uncommon.
PARALYSIS FROM PERIPHERAL IRRITATION.

When a mixed nerve-filament receives an injury, it is not unusual to observe a complete loss of sensibility and movement in the parts supplied by the nerve of which this filament is a branch. But it is more rarely that one observes notable disorders of sensibility and mobility in regions more or less removed from the seat of the injury, and thus far no very satisfactory explanation of this phenomenon has been given. Several cases of this character were seen during the War of the Rebellion, and Keen, Mitchell, and Morehouse have published seven cases in which paralysis supervened immediately upon the receipt of the injury. Mitchell has recorded two very interesting cases: one of a wound of the thigh probably involving the sciatic nerve, in which, besides the natural result of paralysis of the right leg, there was also reflex paralysis of the right arm; in the other, in which the right crural nerve appeared to be injured, the right leg and arm were paralyzed.

Interesting cases of this kind were also seen in the Franco-Prussian war, but differing as to the date at which the paralysis began after the injury. In these the paralytic troubles commenced some time after the traumatism, and hence it would at first seem that they should not receive the same interpretation as the first-mentioned cases.

Bumke reports a case of gunshot wound of the chest, in which, fifty-four days afterward, there was great weakness of the right upper extremity, with partial atrophy of the forearm and hand and contractures of two fingers. Leyden reports a case in which paralysis commenced a year after the traumatism, and another in which it suddenly appeared three years afterward. Schwahn reports a similar case.

Bidon reports (Revue de Médecine, April, 1884) a most interesting case. The patient was quite severely wounded, by the breaking of a porcelain pôt-de-chambre upon which he was sitting, in two places, the one just in front of the coccyx in the median line, the other immediately behind the anus, and formed by the junction of two incisions. Ten days afterward small pustules appeared about the coccyx, in the genito-crural folds, and on the internal aspect of each thigh. They attained their maximum development in twenty-four hours, but were succeeded by others, and did not entirely disappear for about two months. About one month after the injury the patient began to complain of pains in the right knee and along the crest of the ilium, erythematous spots making their appearance in these places at the same time; subsequently ulcers developed at these points. Just as the patient seemed on the point of recovery a new set of very interesting symptoms appeared. He began to feel weak in the legs and complained of formications; the upper limbs became weak and delicate movements were impossible; and when the paresis became more generalized anesthesia set in. These symptoms attained their maximum in about a month, and three months after the injury the man was scarcely more than what might be called a thinking vegetable. The muscles of the neck and face and of respiration were unaffected, the limbs and trunk were paralyzed and anesthetic, and the tendon reflexes were abolished. This state lasted about fifteen days, when, under the influence of strychnine, the patient began to improve, and was practically well in another month. Professor Lépine reported, in 1875, two very interesting cases of this character, in which the paralysis was caused by thoracentesis. The paralysis in one case lasted for one hour and then gradually ceased. The patient was subsequently aspirated several times, and each time the same phenomena occurred.

Seeing, then, that paralysis may supervene at a time more or less remote from the time of the injury, it is proper to inquire: Are these phenomena simple coincidences or are they due to the traumatism? And how are they produced? With regard to paralyses coming on immediately after the traumatism, it would seem that they must necessarily be the result of that traumatism; for there is no other cause by which they can be explained. Just why an injury should cause these symptoms cannot be very satisfactorily explained. Certainly the explanations thus far offered by Vulpian, Brown-Séguard, Jacquot, and Weir Mitchell are somewhat contradictory and not entirely satisfactory. Bidon considers paralysis coming on immediately after traumatism as the result of the injury, and thinks that it is sometimes caused by reflex vascular constriction acting on various parts of the cord (Brown-Séguard), sometimes from an abolition of the medullary functions by shock (Weir Mitchell), and made more persistent by the continuity of the excitation due to the wound (Jacquot).

The paralytic accidents coming on some time after an injury are also due to the traumatism. In the nine cases cited by Bumke, Leyden, Schwahn, Lépine, and Bidon, there was no other paralyticogenic cause. The pathogenesis of these paralytic accidents is easily understood if the cases now on record are compared with typical examples, notably the one recorded by Trouseau, in his Clinique, 1., 492, of diphtheritic paralysis. From a symptomatic point of view there is a very great resemblance between the two.

Traumatism, then, may cause paralysis due to lesions of nerve-filaments (ascending neuritis) and of the cord; and the best name for this paralysis is that proposed by Weir Mitchell, paralysis from peripheral irritation. It may be added that Landouzy has arrived at almost exactly the same conclusions as regards paralyses following acute diseases.

COUNTERFEITING FISH.

The tricks of trade are quite frequently divulged in court when the partners in the deception fall out with each other. Sugar has its glucose, butter its oleomar-
Prepared, and the results were in all cases valuable contributions to medicine.

Few papers, but good ones, would be an excellent motto for medical societies and conventions everywhere to adopt.

News of the Week.

A Dispensary Willing to Divide Some of Its Pecuniary Profits with Its Medical Staff.—The North Eastern Dispensary of this city has recently divided several hundred dollars among its medical staff in acknowledgment of valuable services rendered the institution. The sum was given for that purpose by one of the managers, at the instance of Dr. Alex. Hadden, the founder of this dispensary, instead of appropriating the same for an enlargement of the building. This is an example worthy of imitation by sister institutions. Most of the dispensaries of the city have surplus funds every year, which are invested by the managers for what are called current expenses, and some of them are actually growing rich. It is otherwise with the medical men who are doing the work in these dispensaries. Every dispensary patient treated by a doctor is so much actually out of the doctor’s pocket, for very few patients are too poor to pay something. It is gratifying, however, to learn that one institution at least is willing to recognize the value of its working staff in more ways than one. It would be interesting to know how much could be done in this direction as borne out by an examination of the balance-sheets of the out-patient department of the New York Hospital, the Demit, North Western, and New York dispensaries? But the managers may say in extenuation of apparent neglect, “Why should we pay men who are willing to work for nothing?”

The Late Dr. A. Randolph Mott.—At a special meeting of the Manhattan Medical and Surgical Society, called May 17th, the following preamble and resolutions were adopted:

Whereas, We have learned with profound sorrow and deep regret of the untimely death of our esteemed fellow-member and dear friend, Dr. Armstead Randolph Mott, Jr., who fell a victim to typhus fever, contracted in the discharge of his duties as Chief Physician to the Riverside Hospital, May 6, 1884; be it therefore Resolved, That in his death this Society deplores the loss of an earnest and valued member, and one who by consecrating his best years to faithful work in a dangerous field has honored his profession. Resolved, That his associates mourn the death of one whose noble character had won their warmest affection, and whose devotion to his profession offers an example worthy of the highest emulation. Resolved, That these proceedings be recorded in the minutes of this meeting, and that a page of the records of this Society be inscribed with his name and the dates of his birth and death; that a copy of these resolutions be forwarded to his bereaved family, and that we tender to them the sorrow and sympathy which we so deeply feel. Resolved, That the editors of The Medical Record and The Virginia Medical Monthly be respectfully requested to publish these resolutions.
THE SIMS MEMORIAL FUND.

To the Medical Profession and Others throughout the World:

The great achievements of Dr. J. Marion Sims call for some more lasting testimonial than obituaries and eulogies. Dr. Sims was the father of gynecological surgery. Those who have been benefited by his teachings and new operations, and such as have had the direct advantage of his personal skill are among the first to recognize and acknowledge this debt.

To him is due the honor of giving the first strong impulse to the study of gynecological surgery in America.

It is believed that the medical profession everywhere, the vast number of women who owe their relief from suffering directly to him, and those who realize the benefits he first made possible, will gladly unite thus to honor the man through whose original and inventive genius such blessings have been conferred upon humanity.

At the suggestion of many friends, therefore, the subjoined committee has been organized, and it is proposed that a suitable monument be erected to his memory in the city of New York.

To this end the active co-operation of the medical profession and the many other friends of Dr. Sims throughout the world is respectfully solicited. Contributions are desired and are to be forwarded to the journal which has been constituted the treasury of this fund—THE MEDICAL RECORD, New York.

WEST VIRGINIA MEDICAL SOCIETY.

Seventeenth Annual Session held at Clarksburg, Va., May 21, 22, and 23, 1884.

(By Telegraph to THE MEDICAL RECORD.)

WEDNESDAY, MAY 21ST—FIRST DAY.

The seventeenth annual session of the West Virginia Medical Society convened at half-past three o'clock in the City hall of Clarksburg.

Prayer was offered by the Rev. J. F. Book De Agerrstel, of Keyser.

The President being absent, on account of sickness, the chair was occupied by Dr. A. F. Steifel, of Wheeling.

Dr. D. P. Morgan, of Clarksburg, Chairman of the Committee of Arrangements, delivered

THE ADDRESS OF WELCOME

to the delegates.

His Honor, the Mayor of Clarksburg, then spoke a few words, offering the visiting doctors the courtesies of the town.

Dr. J. E. Reeves, of Wheeling, Chairman of the Committee of Publication, reported that three hundred copies of the sixteenth annual report had been issued at a cost of eighty-seven dollars.

Dr. W. F. Vankirk, Treasurer, reported one hundred and forty-eight dollars balance in the treasury.

The report of the Committee on Climatology and Epidemics was read by Dr. R. W. Hall, of Moundsville.

The following is an abstract of that part

ON EPIDEMICS.

West Virginia had been unusually fortunate this year, having had no very severe epidemics, so far as the committee had been able to ascertain. Nearly all, or perhaps all, the diseases indigenous to the State have been represented, epidemic as well as endemic in character. The diseases most prevalent have been diseases of the respiratory organs. First of these in frequency is bronchitis. This disease among small children was frequently of the capillary variety and attended with a high rate of mortality. Next in point of frequency is pneumonia, usually very fatal, especially where the disease occurred bilaterally.

LARYNGITIS

comes next, occurring in most parts of the State, notably in the eastern and northwestern parts.

Dr. R. S. Donohoe, of Fairview, Hancock County, says that many a doctor, with either an itch for notoriety or an itching palm, denominates this disease diptheria. The disease usually commenced like an ordinary cold, running a definite course, and usually ending in recovery.

PHARYNGITIS

also occupied a prominent position in the list, but the average duration was usually short and the disease mild and manageable.

Whooping-cough occurred in Harrison County, frequently complicating other diseases. When it complicated or accompanied with measles it became formidable and exceedingly difficult to control. Phthisis had its full measure of representation, sending an increased number of its victims to the grave.

From advices they were led to believe that diphtheria prevailed over nearly two-thirds at least of the State, but frankly confessed that they had not seen a case within the year. Dr. R. S. Donohoe, of Fairview, and Dr. W. H. Sharp, of Volcan, think there is

GREAT LAXITY AMONG THE PROFESSION IN THE USE OF THE TERM DIPHTHERIA,

some physicians having a great number of cases, with marvellous success, frequently curing their patients in from two to five days. It seemed to the Committee that probably there should be some allowance made for errors of diagnosis in this disease, that the number of cases of pharyngitis should be greater, and that the general term of diphtheria should be less. Diphtheria has not been attended by as high a rate of mortality as is the usual habit of the disease, and the foregoing may be the explanation. The causation has been variously stated as decaying vegetation, foul emanations from stables and cesspools, decaying animal matter, bad water, unfavorable hygienic conditions, insufficient clothing, scanty and poorly cooked food, contagion, etc. It may be of interest to quote from Dr. Carpenter's report to us. He says:

"Diphtheria has been rare during the past year. However, my own family, consisting of eleven persons, has just emerged from a visitation of the disease. The cases graded from the severest to the mildest in form, no one in the household escaping. As the outbreak of the disease was confined to my own family, there was of course a local cause, and this I assign to foul emanations from the cellar, which had been flooded in January. I had stowed away in the cellar all the vegetables and fruits intended for winter consumption. On account of dampness there had been unusual decay of some, emitting pungent gases, which found access to the general family-room, situated immediately over the cellar and separated by the floor only." Now it would seem from this statement by Dr. Carpenter that this outbreak was due to decomposing vegetables and fruit. So far as they were aware this condition does not always maintain. The history, together with the alleged causes, of different outbreaks of this disease are various. About three years ago an outbreak was observed in a family living on the top of a hill. The water drained from the house in almost every direction; there was no cellar; the house was high enough on the ground to allow free ventilation under it. The house-yard and adjoining grounds were kept scrupulously clean; the stable was about one hundred and fifty yards from the house and below the water supply. Two children were simultaneously attacked by the disease, which was severe in its character, ending with paralysis of the vocal cords in one case and paralysis of the lower extremities in the other. Both cases finally recovered. It was a remarkable fact that no cause as to the disease was known. This time was known within a radius of ten miles. The cause of this outbreak had always been a mystery.

What the materies morbi is, with regard to this disease, they were persuaded, remains in the future to be determined. Whether it be bacillus, microcosm, or a fermentation principle we know not, although investi-
The report of the Committee on New Remedies was read by Dr. R. M. Baird, of Wheeling, in which particular reference was made to convallaria majalis jequirity, kairin, and paraldehyde.

Dr. J. P. Miller, of Buckhannon, read a paper on the Successful Treatment of Phtisis.

He used picrotine and atropia for night-sweats only when the temperature is normal or subnormal, and depended on fluid extract of yerba santa; as a solvent of tubercular or fibrinous deposits in lungs on iodide and carbonate of ammonia.

Dr. F. L. Howel, of Clarksburg, read a paper describing the removal of a silver dollar impacted in the cricoid cartilage by cesophagotomy.

Dr. W. H. Sharp, of Volcano, read a paper on the Prevention of Puerperal Fever in Labor Cases. He presented an historical review of the subject, and reached the conclusion that no other precaution than strict cleanliness is needed. The use of antiseptics in private practice is not necessary.

Dr. George H. Rohe, Delegate from the Medical and Chirurgical Faculty of Maryland, read a paper on the Treatment of the Later Syphilitic Lesions of the Skin and Subcutaneous Connective Tissue.

The writer of the paper expressed the opinion that the view of Hutchinson, that the so-called tertiary manifestations of syphilis are merely sequelae and not symptoms of the syphilis, could not be accepted without more definite evidence in its favor than had as yet been furnished. The tubercular syphilide and the subcutaneous gumma were regarded as anatomically identical. The author said the prognosis of syphilis was generally favorable. He regarded it as curable, and deprecated the hopeless prognosis given by so many authorities. In the treatment of tertiary syphilitic lesions potassium holds the first place. It should be given in free doses—twenty grains four to six times daily are sometimes necessary to produce the effect desired. Mercury is of much less value in this than in the secondary period, but should not be entirely omitted. Tonics are of importance in all, to counteract the specific effect of the disease upon the red corpuscles. Good food, fresh air, cleanliness, and moderate exercise should be insisted upon. Cod-liver oil, and iron, in the form of tincture of the chloride, or part of the preparation often indicated. Locally, the application of mercurial plaster to the lesion, before ulceration, assists in promoting free absorption; after ulceration the syphilitic infiltration should be scooped out with the curette and iodoform applied.

Pennsylvania State Medical Society.

Thirty-fifth Annual Session, held at Philadelphia, Pa., May 14, 15, and 16, 1884.

(The Special Report for The Medical Record.)

Thursday, May 15th—Second Day.

The Association was called to order promptly at 10 A.M., the attendance not being as large as on the first day. The report of the Treasurer, Dr. Benjamin Lee, of Philadelphia, was read, and showed a balance on hand of $2,451.65, with several counties in arrears for dues.

Dr. W. H. Daly, of Alleghany, delivered the address in medicine, and gave a sketch of the advance made in the science for the past year as to investigation and practical knowledge. The work of Koch, Pasteur, and Pivon in the field of physiological pathology was noted, but he questioned the utility of their germ theory discoveries in a practical way. The germicides were in constant use, but their value was unfixed. The lack of government aid was noted and the great aid of clinical inquiry was generously praised. He thought the bedside was the place to gain useful knowledge for use, for it re-
quires no help from the government and it brings the surgeon and physician directly to a knowledge of disease and its effect, forms not laid down in the books. While we are looking for the bacillus tuberculosis, we must not cease to give prompt relief to suffering patients, and add to our therapeutics for immediate benefit and to assist our brethren. By patient work we can only hope to advance. It was an obscure country doctor, Jenner, who discovered vaccination; and it was his clinical observations in the dairies that showed him that cow-pox of the maids gave them immunity from small-pox. He had no doubt that Koch's germ theory would be worked out, but in the meantime we should go on with our minor studies. He believed that to study true science would bridge over our diseases faster with the homoeopaths. Men are now living who will see the medical dogma rendered ridiculous. It will not do to be arbitrary, we must be pure, honest, and just, large and observant in our labors, without resorting to dogma.

Dr. Charles W. Dulles, of Philadelphia, read a paper on Disorders Mistaken for Hydrophobia.

He alluded to the literature of the disease, and said it was enormous and apparently beyond all reason, and he related his experience during two years of close investigation. He asserted that no less than thirty complaints have been mistaken for hydrophobia. The disease is known mainly by convulsions, and the inability to take liquids; yet there are other very important phenomena, and the revolting at liquids is known in other affections. Some of these disorders similar to hydrophobia will deceive the most experienced physicians at times. They are disorders of the alimentary canal, of the nerves, and of the respiratory and circulatory systems. Symptoms are sometimes presented in mania-a-potu, angina pectoris, of rabies humana, and cases were cited to show how errors may be avoided. He noted that uraemia is frequently mistaken for hydrophobia because of the nephritic convulsions.

Prof. Traill Green, of Lafayette College, declared that there were more rabies from rum than from mad dogs. If a man dies of hydrophobia it is known all over the world, but if a hundred die from alcoholic convulsions, almost like those of rabies humana, no note is made of it. The disease of hydrophobia is very rare, even in dogs, and if doctors will read "Hewitt on the Dog," they will learn more about canines than from any other source. Dr. Green then challenged the members of the Society to say whether they had ever seen a case of hydrophobia. Several members arose at once and answered affirmatively, Dr. H. C. Wood saying that he had seen four cases.

Dr. Van Harlingen then read a paper entitled The Principles of External Treatment in Diseases of the Skin.

He sketched out a scheme by which the various outward applications commonly employed were arranged according to their effect, as protective, sedatives, astrigents, anesthetics, stimulants, caustics, and mechanical means of treatment, giving under each head the effects of each class of applications so far as known, together with a list of individual medicaments belonging to the class.

Dr. J. V. Shoremaker read a paper on Jeurity (Abras Precatorius Linne.), Its Use in Diseases of the Skin.

The use of jeurious in affections of the eyes, first empirically developed by the natives of Brazil, has been closely studied by eminent ophthalmologists, and pronounced by them as of marked value in granulomatous affections of the lids, though so powerful as to require great caution in its application. Its result, when so applied, is to produce a specific ophthalmia of a croupous nature, which destroys the granulations and leaves them in a favorable condition to heal. This had led the writer to the deduction that it might be applicable to other morbid processes consisting in exudant granulations, alternating cell-growth, and with a tendency to remain in a slowly degenerative condition, where caustics, escharotics, and superficially destructive measures seem indicated.

Selecting lipoid conditions, epitelomias, sloughing ulcers, etc., as tests of his theory, he found that a weak infusion, such as is used in ophthalmic practice, was of little avail, and obtained as a more serviceable application an emulsion-infusion from Dr. L. Wolff. This, when first applied, produced no pain, but soon set up a specific inflammation, which at times assumed quite alarming proportions, oedematous swelling, with erysipelatous appearance of the surroundings, accompanied by feverish symptoms, though this occurred only in applying it to extensive surfaces, and in highly sensitive and irritable patients. The products of this inflammation cast an immense crust on the surfaces, under the protecting influences of which the constructive process rapidly developed, so that after either forcible detachment, or better, spontaneous casting off of the cutaneous-like crusts, the healthy surfaces of the ulcers and repeated applications cures were speedily effected by it.

Dr. Joseph B. Potsdamper followed with a paper entitled Bronchitis and Pneumonia of Rheumatic Origin, in which he discussed the pathology, diagnosis, and treatment of the disease, salicylic acid and its salts or phosphate of ammonia being given when uric acid and urates are found in the urine, lemon-juice when phosphates were present.

A Plea for Chemistry.

Dr. Traill Green, of Easton, read a most practical and valuable paper with this title. As a result of very many years of observation and experience, he has come to the conclusion that very few physicians know as much about chemistry as they ought to, and even some druggists are very deficient in this knowledge. To illustrate the latter point, he related the experience of a friend of his, who went into a drug store and asked for chlorate of sodium. The druggist told him, and persisted, that that was table-salt, not seeming to understand, as Dr. Green said, that there is a difference between a chlorate and a chlorid. He considers it essential that physicians should know more about chemistry, in order that they might avoid prescribing explosive mixtures, as has frequently happened. He said, that they are not to use potassium chlorate, glycine, and tincture ferri chlor. will make an explosive mixture. Potassic chlorate and catechu have been used as a dentifrice; if there is much friction in cleaning the teeth this mixture will explode. The following formula was ordered by a physician for a woman:

B. Argenti oxi. gr. viii.
Morph. muriat. gr. j.
Ext. gentiane. q. s. 4.
Pt. pil. No. xxiv, a sicutem.

The woman placed these pills in her bosom for safe keeping, and in a short time an explosion took place. Some nitric acid was put into a presumably clean vial; very soon an explosion, with a loud report, occurred, when it was ascertained that an almost unappreciable quantity of glycereine was in the vial.

In view of the fact that permanganate of potassium has been highly recommended of late in amenorrhea, Dr. Green advises us not to use an excipient for it that is very readily oxidized, as glycine; t alc or kaolin will be safe. Fluid extract of uva ursi and certain samples of spirits of nitre will form an explosive mixture, as will also, sometimes, chronic acid and glycine.

The view of the fact that permanganate of potassium has been highly recommended of late in amenorrhea, Dr. Green advises us not to use an excipient for it that is very readily oxidized, as glycine; t alc or kaolin will be safe. Fluid extract of uva ursi and certain samples of spirits of nitre will form an explosive mixture, as will also, sometimes, chronic acid and glycine.
Dr. Benjamin Lee read a paper on

MAGNATE, THE LATEST HANDMAID OF MEDICINE,

in which he considered the influences of the method in modifying the processes of nutrition, removing effete material from the system, stimulating assimilation and invigoration digestion, soothing nervous irritability and relieving nerve pain, removing morbid deposits from the neighborhood of inflamed joints, and thus restoring them to their normal mobility, equalizing the circulation and sending the blood from the hot head, congested spine, or laboring heart, into the cold extremities.

DIPHTHERIA.

Dr. L. B. Klein, of Catawissa, read a paper on this subject, in which he stated his belief that the disease was primarily local, from the fact that it was usually sudden in its onset, and affected only mucous membranes that are so situated as to be specially exposed to poisonous particles floating in the atmosphere, and that the disease was largely spread by contagion. He considered topical applications to the affected parts of great importance, caustic applications should, however, be discarded, as their utility is doubtful, and injurious effects are likely to ensue from the mechanical irritation produced. The local applications which he relied upon were external means of the tincture of chlorid of iron and glycerine applied with ruber, also carbolic acid and glycine, applied in the same way. Where the patient is old enough to gargle, the following is one of the most valuable combinations that can be employed:

\[\text{Acid. lactic} \quad \text{gtt. xx.-xxx.}
\[\text{Spts. rectif.} \quad \text{§ ijs.}
\[\text{Glycerine} \quad \text{§ ijs.}

M. S.—Gargle frequently.

The lactic acid had a solvent effect upon the false membrae. One of the most valuable and indispensable local remedies was hot medicated vapor. Its manner of using it was in the form of hop-tea, to a pint of which twenty or thirty drops of carbolic acid is added. In malignant cases this should be used every half hour, and continued from ten to fifteen minutes at a time.

The speaker also highly recommended, from his own experience, the vapor of slacking lime. As constitutional remedies, he recommended tincture of chlorid of iron, quinine, chlorate of potash, and permanganate of potash. Alcoholic liquors are recommended as valuable to prevent systemic infection and for their stimulating and supporting qualities. They should be employed early and continued throughout.

ADDRESS IN OBSTETRICS.

In making this address Dr. Jacob Price, of West Chester, gave a very interesting history of obstetrics in this country. A hundred years ago it was not recognized in the curriculum of the medical college. The first medical school in this country, established in Philadelphia in 1765, contained no provision for the study of obstetrics. After some time it was attached to the chair of anatomy. In 1810 it was made a distinct chair in the University of Pennsylvania, and in 1812 that attendance upon lectures in this branch was made a requisite for graduation.

Dr. Price then spoke about the pernicious vomiting of pregnancy, which he considers due to congestion or inflammation of the uterine cervix, and which he has succeeded in relieving by the use of iodine, crystallized carbolic acid, and tannin. He did not use two drachms dissolved by heat in an ounce of pure glycerine, and applied on tampons to the cervix, tri-weekly.

In discussing the treatment of abortion, the speaker took strong grounds against immediate instrumental interference to remove the secundines, and reprobated the teaching of some of the younger writers, who would make every miscarriage an excuse for scooping out the cavity of the uterus. Such active interference was uncalled for and mischievous in a vast majority of cases. The use of the vaginal, or cervical tampon (disinfected) will, in most cases, be followed by the almost painless, and usually safe expulsion of all the contents of the uterus, and thus the dangerous element of traumatism be avoided. Yet when operative means really become necessary Dr. Price considers that the smooth wire curette of Thomas, or the larger one described by Mundé, is the safest instrument that can be used. It is far less painful than the finger, more efficient, and if used carefully is less liable to produce injury.

He strongly repudiated any manipulation of the os uteri during the first stage of labor, and especially any effort at its rapid and forcible dilatation. To the care of the perineum, during its extreme distention as the head descends, so as to prevent laceration at the moment of delivery, the speaker devoted considerable attention. The descent of the head must be prevented by firm pressure directly upon it, until the perineal tissues have had time to yield slowly, yet sufficiently to allow the head to pass safely.

Placenta previa claimed considerable attention in the address. Shall the pregnancy be allowed to continue? is a question that in every case has to be met at the onset. After careful study of the whole subject, one cannot avoid the conclusion so well stated by Lusk, that the result depends in a large measure upon the personal qualities of the physician in charge. A self-possessed man, cool, resolute, and with clear ideas of the anatomical conditions to be dealt with, will, if summoned in season, deprive even placenta previa of a good share of its terrors. The pathology and treatment of puerperal convulsions received careful attention in the address.

In treatment, the delterious influence of mental excitement, exposure to cold, and indigestion are to be kept in mind. When an attack threatens, full doses of bromides, of hydrate of chloral, and of morphia (the latter hypodermatically) are indicated; when the action of the kidneys is deficient the muriate of pilocarpine (hypodermatically), aided by hot foot-baths to bring on diaphoresis, are very beneficial. But perhaps the most efficient of all remedies at this time is the free abstraction of blood. No other means can be so safely relied upon to lower arterial tension, diminish irritation of the vaso-motor and convulsive centres, and restore to the kidneys their normal functions. The question of puerperal fever was discussed, and the more recent views on the subject stated, and Dr. Price closed by discussing the question of women in medicine, leaning to the view that the profession was not within their sphere.

OBSTETRICAL FORCEPS JOINED AT THE JUNCTION OF THE BLADES AND SHANKS

was the title of a paper by Dr. J. A. McFerran, of Philadelphia.

After describing the detailed uses of the instrument, he claimed that it had all the advantages of the ordinary forceps, as a tractor, as a lever, and in the independent application of the blades, while the disadvantages were dropped by simply placing a joint so that the motions of the fetal head shall not be interfered with.

Dr. Mary H. Stinson, of Norristown, then read a paper on the

WORK OF WOMEN PHYSICIANS IN ASIA,

which gave an excellent history of the labors of missionary physicians. It was stated that the large sum of $44,000 had been collected during the year 1883, by four Women's Foreign Missionary Societies, which gives some idea of the magnitude of their work. The necessity for educated women physicians in oriental countries was dwelt upon, and it was stated that thirty-six women medical missionaries had been graduated during the past year. Of these, fourteen had been sent
to India, fifteen to China, and two to Japan; one is under appointment for Damascus, and five for China. There are now eight undergraduate missionaries in the class in the Women's Medical College, of Pennsylvania. The Society then adjourned for the day.

FRIDAY, MAY 16TH—THIRD DAY.

The attendance at the last day's session was not so large as that of the day before; and when President Smith's gavel fell there were not more than one hundred members in the room.

The first business transacted was the passage of a resolution offered by Dr. Richard J. Lewis, of this city, regretting the absence of W. L. Atlee, of Lancaster, who is confined to his home by illness.

BODIES FOR THE DISSECTING-TABLE.

The subject of the distribution of dead bodies to medical institutions was brought up by Dr. Joseph Leidy, the Professor of Anatomy in the University of Pennsylvania, and President of the Anatomical Board of the State. The subject, he said, was one of great importance, and merited the earnest attention of every surgeon in the State. The time had come when it was important that something should be done, looking to an equal distribution of dead bodies among surgeons.

He offered a resolution requesting the members of the profession to aid the Anatomical Board in carrying out the acts of Assembly in relation to the distribution of cadavers for dissection.

Dr. W. H. Daly, of Pittsburg, said that he was in hearty accord with the resolution. There was need, he thought, of about seven hundred bodies yearly for the surgical classes throughout the State. There were enough bodies in some counties, but not in others. The trouble was that the bodies were not equally distributed. The law placed an effectual check on grave-robbing. All bodies must now be received for, and superintendents of public institutions are thus protected against fraud. No fault could be found with the law. It was the very best in the country, and under the Anatomical Board it was sure to be carried out, thus insuring to cemeteries full immunity from ghoul.

Dr. Trail Green, of Lafayette College, said that he also favored the resolution, and it was then unanimously adopted.

Dr. Henry Leffman, of Philadelphia, offered a motion which was adopted, directing the Secretary to send copies of the resolution to the County Medical Societies.

Dr. William S. Little, of Philadelphia, delivered the Address in Ophthalmology, selecting for his subject the value of pupillary symptoms in general disease—an analysis of one thousand cases.

He said that after the hospitals for chronic diseases had admitted ophthalmic surgeons to their wards, opthalmic medicine rapidly developed, and soon hospitals for acute diseases claimed their services. The past twenty years has been the era for developing ocular symptoms in general disease. Medical education has felt the same impulse, and post-graduate instruction is the outgrowth of the success of instruction in ophthalmic hospitals abroad and at home.

Medical ophthalmology has been the special factor in developing ophthalmic medicine.

At Elwyn, Pa., at the Institution for Feeble-Minded Children, he found lesions of the eye-ground in thirteen per cent. of the inmates. The study of the visual field for perception of light and color is another means of help in studying general disease. Ophthalmoplegia externa and interna have received the greatest attention of late. Pupillary symptoms belong under the head of ophthalmoplegia interna. The statistics of many observers vary largely as to their presence in disease, especially of a nervous type. He had believed the variation to be due to non-recognition of the symptoms being produced by intraocular and extraocular conditions; only the latter are of any value in general disease, and the former must be excluded, unless both conditions are recognized.

After giving the physiology of pupillary movements and describing how to study the normal and abnormal pupil, the results of a personal examination of three hundred and fifty cases at the institution already referred to were given. The examination was thorough, and intraocular and extraocular conditions, as factors, studied. Ophthalmoplegia externa was noted in only two cases. Ophthalmoplegia interna, from central causes or associated with the diseases exhibited, was present in seventeen per cent.

One thousand cases have been studied with the following results: 602 males, 224 per cent. pupil symptoms; 398 females, 248 per cent. pupil symptoms. Total, 1,000 cases, 235 per cent. pupil symptoms.

A paper on a form of epithelial mycosis was read by Dr. Albert G. Heyl, of Philadelphia.

The disease described in this paper has long been known to ophthalmologists, and has been principally studied by them. In its graded forms the general symptoms are of far more importance than those observed in the eye, as the disease is frequently fatal. Leber, within a few months, has given a full description of a parasite found intra vitam in the conjunctival debris, and post mortem in the epithelium of the renal pelvis and in the small intestine. This parasite attacks the epithelial cell, inducing fatty degeneration of its structure. The dead cells accumulate in lamina, giving rise to a characteristic dry parchment-like appearance, the so-called conjunctival xerose. The disease is usually ushered in by hemeralopia. This symptom, which is associated with the conjunctival xerose, may last a month or two, when cornal ulceration commences.

About this time general symptoms appear. There is a rise in body temperature, frequency of pulse, a dry, harsh condition of the skin, the hair on the head becomes dry and lustreless. Along with this a peculiar state of apathy is developed. Persistent purging and vomiting occur, and finally broncho-pneumonia, to which the patient succumbs. All cases do not run precisely this course. Some do not proceed beyond the stage in which there is no in others the corneal ulceration appears after the inception of the general symptoms. In some the apathic state is the most striking symptom. In some constitution exists instead of the purging. The existence of a parasite in the conjunctiva in this disease was known before Leber's researches. But Leber has not given a clear account of it, but also shown that it attacks the epithelial cell, and that it is found in other localities besides that of the conjunctiva. Probably the symptoms of the disease are traceable to this epithelial mycosis. Dr. Heyl gave added reasons for considering the epithelial cells as the receptive organ of centripetal nerves. In the treatment, the careful administration of food is important, and as the application of moist heat to the eye has been found very serviceable, possibly it would also be if applied to the surface of the skin.

ALARMING AND DANGEROUS DOSES OF THE MYDRILICS was the title of a paper by Dr. Edward Jackson, of West Chester, who said that it is intended to call the attention to the limits which are imposed upon the dose of atropia and other mydriatic alkaloids by danger of fatal poisoning. This paper has been prepared to remind practitioners that these limits are not really so narrow as many seem to think.

The paper contained quotations and abstractions of such cases as bore directly on the subject under discus-
sion, among them twelve in which the amount of atropia taken was known to exceed one-half grain, yet the patient recovered. Allusion was also made to the report of Dr. Fuller, of London, on the extreme tolerance of belladonna shown in choreic children, one taking as much as seventy grains of the officinal extract daily, and another taking thirty-seven grains of atropia in eighteen days. In the case of acute mania reported by Dr. Sydney Ringer, one-grain doses of the crystallized alkaloids, atropia, datura, and hyoscyamus, were repeatedly given with benefit to the patient.

Dr. Carl Seiler read a paper on

AN ELECTRIC LARYNGOSCOPE,
in which he described an apparatus for the illumination of the laryngeal, nasal, and other cavities of the body by means of an electric incandescent lamp.

DOES A CHRONIC DISCHARGE FROM THE EAR MAKE LIFE INSURANCE HAZARDOUS?

Dr. Charles S. Turnbull, of Philadelphia, called attention to a point of vital interest to Life Insurance Companies and their medical officers. He described the frequent error of regarding applicants making application for life insurance, holding that some of these, while passing a first-class physical examination, may at the same time be suffering from fatal discharge from the ear. He maintained, that whatsoever the plan may be, whether mutual, life, or endowment, the risk incurred and the liabilities assumed by Life Insurance Companies, through their medical examiners, is in no small way compromised by the existence of a chronic ear disease of the applicant. Deaf persons are not insured by the leading companies, at least, not at ordinary rates, because of the self-evident fact of their being in imminent peril, hence such are not accepted, or are considered as "extra hazardous." An otorrhea may exist a long time without being noticed by the patient, and this is, in his opinion, in many cases, a much greater source of danger to life than that arising from the mere physical defect of not hearing. Deafness of a dangerous or hazardous degree cannot be concealed, and is only an element of risk in so far as accident is concerned; while a chronic purulent inflammation of the middle ear, whether purulent or necrotic, or some particular condition, can be intentionally or unintentionally concealed, or, on the other hand be overlooked, while it threatens life within a year. One remaining sound ear may do all the work, and the examiner, as well as intimate friends, may never suspect the defect. Total deafness, like total blindness, on one side, may exist for years, even for a quarter of a century, and the individual, being aware of the fact, and a purulent discharge continue from childhood without causing annoyance, or even a thought.

He suggested an ocular inspection of the ears, and at times, when of sufficient importance, the employment of an expert, because, in his experience, he has known of liabilities incurred where even a hasty examination of the ear would have saved the insurance companies thousands of dollars. The same may be said with reference to the organs of sight. He concluded by urging the profession to exercise more care in the treatment of the ear-symptoms and complications in the exanthemata, and likewise called especial attention to the importance of the insurance companies making the examination of the ears compulsory in every case.

As an easy and yet complete method of examination of the ears, he suggested the following, which places the examiner in a secure position, and makes him entirely independent of the statements of the examined, as well as of instruments of precision, or reflected light: 1, test each ear separately with the watch, the eyes being covered; 2, inspect, by good daylight, the auricular region, especially noting condition of mastoid or cicatrizes thereabouts; 3, inspect (nearly, as do the gas-fitters) each auritory meatus, and, to sum up, what the impaired hearing does not suggest, cicatrizes from loss of bone or fistulous orifices over temporal bone will point out, while the presence of pus on, what is more significant, of fotor, will settle the question. A purulent discharge from the ear should always raise a question with insurance companies, and its character and ultimate course as to the future health of an individual can only be settled by an acknowledged expert, i.e., a man of experience must say whether it be curable or not.

Dr. John B. Roberts read the address in the Section of Surgery entitled

SURGICAL DELUSIONS,

referring to the dangers of chloroform as an anesthetic compared with ether, the inutility of styptics in hemorrhage as compared with ligation and pressure; the advisability of trephining in cases of doubt as to brain injury; the delusion of delay in operating for strangulated hernia, acute phlegmonous inflammation, and malignant tumors; the mistaken ideas regarding the fatality of traumatic tetanus, of pericardial and cardiac wounds, of the symmetry of normal limbs, and of the uselessness of treating vicious union of fractures.

Dr. P. D. Kryzer read a continuation of his paper entitled

OPHTHALMOLOGICAL OBSERVATIONS DURING TEN YEARS' SERVICE IN THE WILLS EYE HOSPITAL.

He described a cystotome of his design for rupturing and drawing up of the anterior capsule, for the removal of a piece of it in the operation for extraction of cataract. He gave his modification of Pagenstecher's operation for the removal of pterygium; and also the history of an interesting case of complete paralysis of the sixth pair of nerves from injury to the head, causing extreme double convergent strabismus, which was relieved by operation of shortening and bringing forward the external recti muscles.

Four cases of gloma of the retina were narrated, two of which were operated upon by enucleation, and the macroscopic and microscopic account of the balls given.

OFFICERS ELECT.

The Nominating Committee reported as follows:

President—E. P. Allen, Bradford; Vice-Presidents—Jacob Price, Chester; D. M. Bland, Columbus; S. Brandis, S. R. Rutledge, Indiana; Permanent Secretary—William B. Atkinson, Philadelphia; Recording Secretary—A. T. Cornell, Lackawanna; Corresponding Secretary—John G. Lee, Philadelphia; Treasurer—Benjamin L. Lee, Philadephia, Pennsylvania; Auditor—John B. Roberts, Henry Leffman, E. Jackson; Judicial Council—Traill Green, Northampton; J. A. Ellier, Lackawanna.

Next meeting will be held on the second Wednesday of May, 1885, at Scranton, Lackawanna County, Pa.

Chairman of Committee of Arrangements, J. F. Everhart.

Dr. J. William White, of Philadelphia, followed with a paper by himself and Dr. Edward T. Bruen, of Philadelphia, on

THE OPERATIVE TREATMENT OF PURULENT PLURAL EFFUSIONS,

defining the causes, diagnostic features, indications of treatment, and recent operative methods, and giving a summary of thirteen cases. He said, regarding the method of treatment, that pleural effusions should be thrown off by the insertion of a tube. If the patient was over ten years of age the walls of the chest would be similar in formation to those of an adult, and the insertion of a tube would then be unnecessary. It was important to drain the suppurating region. If the drainage tube was of no avail, as was sometimes the case, the resection of the ribs could be resorted to. This could
not be done except in cases where the diseased lung fell somewhat from its normal position in the pleural cavity.

Dr. C. B. Nelson, of this city, read a paper on the bichloride of mercury as a surgical dressing.

DENOUNCING UNPROFESSIONAL ADVERTISING.

A sensation was caused just before the close of the morning session by the following report and resolution from the committee appointed to consider the report of the Committee on Publication. "All the papers read or appointed to be read before this Society become thereby the exclusive property of the Society, and the author has no right to publish or cause to be published the paper or any part of the same without the consent of this Society. The Committee on Publication shall not be at liberty to publish any paper that has been published in violation of the above requirement.

Resolved, That the Medical Society of the State of Pennsylvania look with great disfavor upon the making use of this organization as an advertising medium, and hold such practice as contemptible, as a flagrant violation of the spirit of the Code of Medical Ethics."

The report was strenuously opposed by Dr. John B. Roberts, of this city. He said that if it was adopted it would prevent the writing of good reports. His duty compelled him to sit on the platform during the session of the Society, and he was forced to say that half the papers that were read were very poor. They would not have been accepted by the editors of the reputable medical journals throughout the country, and yet the members of the Society were compelled to listen to them. The authors did not prepare the papers with the greatest possible care, because they probably thought that they would not be published.

Dr. E. A. Wood, of Allegheny County, said there was no disposition on the part of the Society to interfere with the press. The idea was to let the newspapers do as they pleased, but that the papers were the property of the Society.

After further discussion the resolution was laid on the table.

CHRONIC ARTICULAR OSTETIS OF THE KNEE-JOINT.

Dr. A. Sydney Roberts, of Philadelphia, read a paper on this subject, in which he said that he had chosen the chronic articular osteitis as the one best expressing the pathological condition found in those lesions of epiphysis of the knee-joint, that have usually been described by the old Roman writers, Celsus and Albuj; the reason for so doing has been by proper classification to refer directly to inflammation of the cancellous structure of bone, thereby avoiding the confusion that usually exists if the more general terms, arthritis, or knee-joint disease be employed, before considering the main feature of the paper, viz., to bring before the Society a new mechanical agency designed for the treatment of the chronic osteitis of the knee-joint. Dr. Roberts hastily reviewed the etiology and pathology of the affection. To meet the universally recognized principles of treatment, i.e., fixation of the joint and extension, he has designed the splint that he most feels justified, from the success that has attended its use, in presenting to the profession. It consists of two light steel paddles troikas that are firmly secured to the limb by encircling bands of surgical netting, affording absolute fixation to the joint when the extending rods are locked after adjustment. Three ratchet extension bars, arranged in the form of a triangle, are placed posteriorly, corresponding to the long axis of the limb, placing within the control of the surgeon a power to stretch and overcome the flexor and extensor to the production of deformity, and at the same time produce extension. The extension rod acts directly upon the head of the tibia and parallel with the line of contraction of the flexor group of muscles, obviating thereby the error in the mechanical arrangement of the popular

splat, or in all where the power is applied on the tibia to overcome the flexion.

In the evening the Society was entertained by Dr. P. D. Keyser and John B. Roberts.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, May 15, 1884.

Horace T. Hanks, M.D., Vice-President, in the Chair.

PRACTICAL SUGGESTIONS ON THE ALIMENTATION OF PATIENTS SUFFERING FROM DYSPHAGIA.

Dr. D. Bryson Delavan read a paper on the above subject, in which he first directed attention to the immediate relation between dysphagia and the general well-being of the patient, and then to the urgent necessity which always existed for its relief. The object of the paper was to recall the morbid conditions with which dysphagia might be associated, also to refer to its influence upon these conditions, to discuss some of the methods that have been heretofore used, and urge their employment. The author of the paper then enumerated the indications to be met, and mentioned the following diseases which might give rise to the indications, namely, tuberculosis, cancer, syphilis, acute tonsillitis, parotitis, retro-pharyngeal abscess, surgical conditions and operations upon and injury of the soft palate, tonsils, pharynx, and larynx. The injuries to these parts might be due to the action of mechanical or chemical agents.

The indications to be met were, first, securing rest, and avoiding all causes which excite pain; second, protection of the parts from mechanical injury; third, maintenance of nutrition. The main proposition was to abolish the act of deglutition, and, in all cases where the stomach is good, the indication was to either remove the obstacle to deglutition or overcome it. The basis of the method consisted in the use of the stomach-tube, and according to the following principles: First, the employment of a tube of the smallest possible calibre; and, second, the introduction of the tube, not into the stomach, but merely into the osophagus, beyond the point of obstruction, or the pharyngeal constrictors. When used in this way pain and injury of the parts is avoided, and nutrition is easily maintained.

Dr. Delavan then exhibited a simple apparatus which he had devised for accomplishing this purpose. It consisted of a soda-water bottle with a conical bottom, which diminished the probability of air getting into the tube during use. Into the bottle was inserted a glass tube to which could be attached the bulb of a Davidson syringe; into the other hole was inserted a glass tube to which could be attached an india-rubber tube, which was connected with the tube to be introduced into the osophagus. That which was ordinarily employed was the catheter, instead of the ordinary osophageal tube; from No. 9 to 13, English scale, was a convenient size. After carefully introducing the tube into the osophagus, guiding the point with the finger to prevent it from entering the larynx, the plan was to allow first about half an ounce of the fluid to enter the osophagus at once, and then wait for a few moments. If more than that quantity was introduced it was apt to provoke fits of coughing. The size of the tube should be regulated according to the age of the patient and the kind of fluid used, and instead of using the catheter with an opening in the side, one with an opening in the end was preferable. As a general rule the irritation caused by the catheter was increased in proportion to the size of the instrument. In many cases the patient could be taught to use the tube, and could do so better than any one else. If the pharynx proves to be too irritable to the presence of the tube it may be introduced through the nostril.
Dr. Delavan then referred to the class of cases to which the method which he proposed was especially applicable—Tubercular laryngitis, which in many cases exists for a long time before the lungs are in such a condition as to place the life of the patient in immediate jeopardy; cancer, syphilis, diphtheria, all acute inflammatory affections of the tonsils, parotiditis, retro-pharyngeal abscess, functional derangements of the larynx, spasm of the pharyngeal constrictors, faucial paralysis, whether from cerebral hemorrhage, embolism, or diphtheria, and certain surgical diseases and conditions. He urged a fair trial of the method in cases in which it can be properly employed.

Dr. J. C. Peters thought that alimentation and stimulation in acute throat diseases was not as important immediately as had previously been considered.

Dr. E. C. Harwood had heretofore succeeded in sustaining nutrition by the use of the stomach-tube introduced in the ordinary way, or by the use of a tube introduced through the nasal passages, and had found the means a most important adjunct in the treatment of certain cases. He could commend the apparatus exhibited by Dr. Delavan, although he had not had an opportunity to use it.

Dr. R. C. Brandeis thought that but few patients could be trusted with the introduction of the catheter in cases of dysphagia, and that the plan of treatment suggested by Dr. Delavan, while it might probably prove effectual, would give rise to the necessity of making so many modifications as to render it impracticable. He then referred to a plan of treatment introduced by Krishaber—namely, the introduction of the tube through the nose, and allowing it to remain for days in succession. Krishaber had reported one case in which the tube had remained in position one hundred and fifty consecutive days without any special inconvenience. Brandeis had had a case similar to that reported by Wigglesworth, of Boston, and still another case had been related to him by his late colleague, Dr. Burnstead. The author of the paper then gave the history of cases which had been reported in foreign literature, and afterward described the peculiarities of the case as it appears upon the tonsil. It is first noticed that the tonsil is red and swollen, with a more or less indurated point, to be followed by an indurated point at which ulceration occurs, to be covered with a whitish exudation. The prominence of the tonsil will depend upon its previous condition; that is, if hypertrophied it will be more prominent than if the initial lesion occurs upon the nearly normal tonsil.

Dr. Taylor then gave the points in differential diagnosis between chancre of the tonsil, mucous patches, and syphilitic sclerosis. The diagnosis would be based, first, upon the details and the mode of infection; second, the slow unilateral development of the chancre with corresponding glandular enlargement; third, limited ulceration of the oral and nasal mucous membrane; fourth, difficulty in feeding and swallowing; fifth, duration of the ulceration much as he can, and then through fluid this can be forced in such quantities as might be desirable without serious inconvenience to the patient.

Dr. W. C. Jarvis thought that Dr. Delavan’s apparatus fulfilled all the indications in cases in which it was possible to employ this method of alimentation. But there is a method which he thought was original with himself, and perhaps was worthy of mention. There were some cases in which it was impossible to use any kind of a tube, however small—for example, certain cases of tubercular laryngitis. For these cases he had used with considerable success the elastic gelatine capsules, such as used by Parke, Davis & Co. for administering castor oil, etc. These capsules can be filled with fluid of any kind by means of a hypodermic syringe, the little opening sealed, and they are so easily swallowed that nutrition can be sustained in this way without pain accompanying efforts at deglutition. With reference to acute tonsillitis becoming so severe as to threaten the necessity of tracheotomy, as had been suggested by Dr. Harris, he thought that excision of a portion of the tonsil should be resorted to rather than tracheotomy, as it could be done without any danger whatever.

Dr. Harwood remarked that in that class of cases he fully agreed with Dr. Jarvis concerning the propriety of excising the tonsil rather than performing tracheotomy.

Dr. Delavan, in closing the discussion, said that he would not, of course, advocate the use of the tube by the patient unless the patient possessed sufficient intelligence to introduce it without doing himself damage, and he thought that not infrequently an intelligent patient could introduce it more successfully and comfortably than could be done by the physician. Krishaber’s method was certainly ingenious and useful, but he thought it would be found unnecessary except in extreme cases; for example, of cancer, in which the introduction of the tube might be very difficult. But if the oesophagus is patent he did not see the propriety of leaving the oesophageal tube in position. Doubtless there were cases in which it was impossible to use any tube, and in that event, he thought the method suggested by Dr. Jarvis would be an admirable one.

CHANCE OF THE TONSIL.

Dr. R. W. Taylor then read a paper on chancre of the tonsil, by which he meant the initial lesion of syphilis. He thought that this form of chancre was not so rare as was once supposed, and that it possessed considerable interest. It was the first of its kind, although he had not had an opportunity to use it.

Dr. D. R. Taylor then read a paper on chancre of the tonsil, by which he meant the initial lesion of syphilis. He thought that this form of chancre was not so rare as was once supposed, and that it possessed considerable interest. It was the first of its kind, although he had not had an opportunity to use it.
seen the inflammatory attack had been pretty well pronounced. The infiltration of the tonsil had been well marked, throwing the tonsil well out into the cavity of the throat, making deglutition, and sometimes respiration, difficult and painful. In one of the cases the tonsil was not nearly so much indurated as in the other, and the ulceration was superficial, so much so as to render the diagnosis quite difficult. Dr. Sturgis regarded the condition of the glands as important, especially the pre-auricular, as, in the cases which he had seen, they had always been enlarged by induration and not inflammatory infiltration. He thought that chance of the tonsil was not a common affection. The point of differential diagnosis was chiefly between the initial lesion and gummatous infiltration of the tonsil, between which, when the gummatous infiltration has begun to break down, there is a very great similarity. But the main point of differential diagnosis was with regard to the condition of the glands, which in the late lesion of syphilis are, so far as he had seen, never indurated.

Dr. L. D. Bulkley thought that an important part of the subject was the fact that the paper had brought to the attention of the profession another place in the body through which the poison of syphilis can effect an entrance. Years ago it was supposed that syphilis was exclusively a venereal disease, and that the poison was obtained by sexual contact. At the present time, however, that syphilis occurs very frequently from inoculation during operations, from innocent exposure of the lips to the poison by kissing, and other methods equally consistent with the good character of the person afflicted.

He had seen four cases, and in one the secondary and latent manifestations of syphilis were exceedingly severe. Dr. Bulkley then recited briefly the history of one case, and closed by saying that the paper would teach us to look for the entrance of syphilis where we would not have thought of looking for the disease twenty years ago.

Dr. W. C. Jarvis thought that the steady flow of saliva with the secretions from the mucous membrane of the mouth gave rise to a condition which was very unfavorable for infection from syphilis, and that from this cause it was very seldom that syphilis was seen within the buccal cavity, because the virus was swept beyond the point and carried into the stomach. He then referred to the occurrence of mucous patches upon tonsils in the cases excited in which a certain fibrous change that gave rise to a condition that was exceedingly important in connection with excision; for, if such tonsils were excised there was a very great liability to the occurrence of severe hemorrhage; but they could be removed by means of the wire snare without danger.

Dr. Taylor, in closing the discussion, said that there was no variation in the appearance of chancres as seen in mucous membrane or the skin; that chance of the tonsil did occur as an established fact; that the necessity for the mere recognition of the lesion was not so very great, because not much harm would come from failure to recognize it, as it was not until the appearance of symptoms that there was specific treatment for the cure of syphilis was necessary. With regard to the intensity of the suffering of these patients, in some of his cases it had been very severe. With regard to gummatous infiltration of the tonsils, it was well recognized that it offered one of the difficulties in differential diagnosis; but the cardinal point in diagnosis, namely, glandular enlargement always helped to solve the enigma when taken in connection with the history. Dr. Bulkley's case was one indeed of great interest. As to washing out the mouth with saliva to prevent infection of syphilis from finding a lodging-place, that was all very well, but here were four cases of undoubted chance of the tonsil, which he regarded as sufficient evidence that the lesion might exist.

The Academy then adjourned.
May 24, 1884] THE MEDICAL RECORD. 595

THE THIRTEENTH CONGRESS OF THE GERMAN SURGICAL SOCIETY.

Held in Berlin, April 16, 17, 18, and 19, 1884.

PROFESSOR V. LANGENBECK, PRESIDENT, IN THE CHAIR.

(Special Report for The Medical Record.)

The attendance at the opening session of the Congress was large, numbers of German surgeons not only from the Fatherland, but also from the neighboring countries of Europe being present. The former President, Dr. VON LANGENBECK, was re-elected by acclamation, and Dr. VOLLKAMM was chosen Vice-President.

The Association voted to admit a certain number of surgeons, not exceeding twelve, as honorary members. The candidates are to be presented by the Executive committee, a unanimous vote of the committee being required for nomination, and shall then be voted upon by the members of the Congress, a two-thirds vote of those present being necessary to elect. The first election of honorary members is to take place at the next session.

The scientific labors of the Congress were commenced by Dr. F. NIELSEN, of Rostock, the title of whose paper was "HOW CAN WE RECONCILE OUR CLINICAL NOTIONS OF SEPSEIS, SYPHILITIC, AND PSEUDOMYSEUCLATHESIS, AND THE LATEST TEACHINGS OF PATHOLOGY?"

The diseases arising from infection through open wounds were, except where their specific nature has already been determined, as in the case of erysipelas, to be regarded as the combined result of three processes—septic poisoning, local inflammation from the multiplication of bacteria in the blood. The experiments of v. Bergmann, Panum, and others, have shown that it is not to the micro-organisms themselves, but to the chemical changes caused by them, that the symptoms of fever—vomiting, somnolence, and diarrhoea—are to be referred. The typical septicemia, due to a combination of these three causes, may become modified by an extension of the inflammation to distant regions of the body through the lymph- and blood-channels. With the development of these metastatic abscesses we have a condition simulating very closely pyemia, but it is not pyemia. For this latter is a disease sui generis, like small-pox or glanders, and does not arise by infection through a wound. We may, nevertheless, see a combination of septicemia and pyemia in the same individual.

Dr. KÜSTNER, of Berlin, then presented a paper on THE USE OF SUNKEN SUTURES, ESPECIALLY IN PLASTIC OPERATIONS.

The author pointed out the disadvantages of the ordinary method of approximating the edges of large wounds by sutures passing through both the integument and deeper tissues. It afforded little or no protection against the accumulation of secretions at the bottom of the wound, and furthermore was often injurious by reason of interference with the circulation in the constricted tissues. These evil results were obviated by the method described by Werth in 1879, of inserting a row of catgut sutures along the sides of the wound, and below which in this way the surfaces are approximated along their whole extent, the necessity of drainage-tubes is in many cases done away with, there is practically no constriction of the tissues, and the chances of union by first intention are greatly bettered.

Dr. König, of Göttingen, followed with an argument on the question:

IS THE DANGER OF GENERAL INFECTION AN INDICATION FOR THE RESECTION OF TUBERCULOUS JOINTS?

He did not regard resection as being protective against general tuberculosis, since he could never be certain that there were no other foci of disease in other parts. Sometimes the disturbance of the parts in an operation seemed to scatter the bacilli, and so actually to provoke a general infection, which might never have occurred had the local process not been interfered with. The number of such cases, however, seemed to have decreased since the general use of iodine after operations.

Dr. CLAUSER, of Wiesbaden, related a case of BLOOD-POISONING CAUSED BY THE PRESENCE OF A SANGUINEOUS CYST.

The symptoms of poisoning ceased immediately upon the removal of the cyst, and were due, the speaker thought, to the continuous giving forth of fibrin ferment from the coagulated blood within the cyst.

A paper by Dr. J. WOLFF, of Berlin, upon THE LAW OF OSSOUS TRANSFORMATION was next read, in which the author sought to prove that when pathological changes occurred in the outer layers of bony tissue, certain compensatory transformations took place in the cancellous layers. His views were opposed by a number of his hearers and a somewhat heated discussion ensued.

A case of EXTRACTION AND REPOSITION OF AN INCISOR TOOTH was related by Dr. A. BIDDER, of Berlin, in which he had replaced a tooth loosened by an alveolar abscess. It remained firm for three years and then fell out, when it was found that the root had almost entirely disappeared.

Dr. Wagner, of Königsbrücke, then followed with an interesting paper on DISLOCATIONS OF THE CERVICAL VERTEBRAE.

He related a number of cases that had been observed by him in the past few years which differed in several respects from the cases usually met with. The first was that of a man who fell from a railroad car, striking the nape of the neck against the buffer. There was complete paralysis of the legs while the arms were only partially affected. The head was strongly extended and the cervical muscles spasmodically contracted. Nothing abnormal could be discovered on palpation of the processes. Even after death no displacement could be found until the muscles had been dissected away. It was then seen that an anterior dislocation of the sixth cervical vertebra with rupture of the intervertebral cartilage had occurred. The second case was that of a young girl. The head was extended to such a degree that the face was turned almost directly upward. The autor revealed posterior dislocation of the sixth cervical vertebra. In another case with a similar position of the head recovery ensued. The next was a typical case of left rotary dislocation caused by a blow on the back of the head. Reduction was effected by the method described by Richet and Huetter. Another patient was totally paralyzed and presented the opposite case of a very severe injury of the cord. The head was flexed toward the right shoulder and rotated in the same direction. The diagnosis was made of left rotary luxation of the fifth vertebra. Reduction was effected by rotating the head first to the right side, flexing it at the same time to the left, and then turning it in the opposite direction. An im- pressed and presented the opposite case of a very severe injury of the cord. The head was flexed toward the right shoulder and rotated in the same direction. The diagnosis was made of left rotary luxation of the fifth vertebra. Reduction was effected by rotating the head first to the right side, flexing it at the same time to the left, and then turning it in the opposite direction. An im-
amination showed a deviation of the spinous process of the fifth vertebra to the left, while the body of the same vertebra could be felt projecting in the pharynx and turned to the right. By strong flexion to the left, rotation to the right, and traction Dr. Wagner succeeded, after three attempts, in effecting a reduction.

In concluding, the author said that in forward dislocations no attempts at reduction should be made unless the diagnosis could be established with certainty. This was not always easy, even to the most skilled diagnostician, since the position of the head in these cases was so variable. In rotary luxations it is of therapeutic import to determine whether the processus obliquus is impacted or not, as in the latter case traction and rotation alone are required, while in the event of impaction further manipulations are required in order to free the engaged process.

Dr. Schede, of Hamburg, had seen two cases where rotary luxation was produced by very slight causes. In one it was caused by the energetic efforts of a man to wash the back of his neck; in the other the luxation followed a fall from a horizontal bar. In both cases reposi- tion was effected without difficulty.

Dr. Czerny, of Heidelberg, asked whether, in such cases, any very great efforts at reduction should be made, and whether there were any special symptoms to be relied upon in the differential diagnosis between contusion and compression of the cord. He himself had the impression that in simple compression the reflexes were less feeble, while in contusion they were continually abolished. When there is evident injury of the cord, the efforts at reduction would be of little avail and might even be productive of harm.

Dr. Wagner relied also on the reflex phenomena, but thought that even with these evidences of a wound- ing of the cord greater efforts at reposi- tion should be made that had hitherto been the rule. This is now the practice of American surgeons. In certain cases he had seen great improvement follow upon traction made after the head had been restored to its normal position.

Dr. Volkmann, of Halle, stated that he always made attempts to reduce the dislocation when the paralysis was not complete or when a certain asymmetry in the symptoms indicated only a partial contusion of the cord.

Dr. Küster, of Berlin, related a case of fracture of the axis with compression of the cord.

The patient was a girl, eighteen years of age, whose mistress one day seized her by the hair and knocked her head several times against the wall. After this had happened the girl was seen by several persons walking in the street, but in the evening she complained of pain in the neck, and retired early to bed. The next day, on attempting to rise, she fell over and struck her head against the cowmode. She was found in convulsions and unconscious. After removal to her own home she was seen by several physicians, who agreed that she had an injury of the spinal column in the cervical region, but were unable to determine the exact nature of the injury. She remained in this condition without any noticeable change for six months, suffering from paralysis, with difficulty in speaking, and every now and then having convulsions. At the end of this time the patient, was found lying motionless in bed, but when urged could move the leg very slightly. The intelligence was un- affected, she gave correct answers to questions, but articulated with difficulty. Examination of the neck showed a slight prominence of the spinous process of the second cervical vertebra. The nervous symptoms pointed to a myelitis from compression, which did not however affect the entire thickness of the cord. Accordingly it was determined to try the effect of traction upon the head, and the result was most gratifying. Within five weeks the patient was able to move the extremities and even to write, while a marked improvement was noticeable in the speech. A leather cravat was now applied and the patient allowed to go about.

The speaker had recently heard from the patient, six months after her discharge, and she was able to dispense entirely with the support.

Dr. Wagner was forcibly reminded of a case seen by him in which a girl, who had been struck on the neck with a stick, was confined for months to the bed and suffered from partial paralysis and complete aphasia. The diagnosis of hysteria was made and was confirmed by subsequent events.

Dr. Küster said that he had thought of the possibility of hysteria in his case, but that this idea was rejected by Dr. Wernicke after a careful examination. Furthermore, the improvement, though so striking, had been gradual and resembled in no way recovery from hysteria.

A second paper was read by Dr. Küster, describing a new amputation of the foot.

The operation was necessitated by traumatic gangrene involving the metatarsus on the outer side of the foot. It was found possible to save the first metatarsal bone, and the result was a very useful foot. The patient could not only walk but could even skate and dance.

Tumor of the kidney from a displaced supra-renal capsule.

Dr. Granville, of Berlin, read an article with the above title in which he stated his belief that the nodular tumors of the kidney were composed of the tissue of the supra-renal capsules. In support of this view he stated that:

1. In the kidney substance itself it was by no means uncommon to find little pieces of the supra-renal gland, the frequency of which occurrence would explain the frequency also of the little tumors under question. 2. These little islets of the supra-renal tissue correspond in their position to the part in which the gland tumors are found. 3. The structure of the nodules is such that it is difficult to conceive of their having originated from the renal tissues. They differ wholly from the tumors arising from the uriniferous tubules. 4. Finally these growths correspond in structure with tumors of the supra-renal capsules themselves. Furthermore they exhibit a tendency to mucus degeneration and very frequently present little hemorrhagic spots in their centre, in which also they resemble the supra-renal tumors.

Dr. Crède, Jr., of Dresden, presented a patient upon whom he had performed extirpation of a goitre two years before with excellent result.

A sarcoma of the spleen was exhibited by Dr. v. Hacker, of Vienna, which had been successfully removed by Professor Billroth, on March 20th. The patient had made a good recovery and had no swelling of the lymphatic glands nor pain in the bones, nor had he exhibited any signs of irritability.

Dr. Zabludowsky, of Berlin, related his experiences with massage, and the results obtained by him in the physiological institute of Berlin in experiments made to determine the mode of action. He was followed by Dr. v. Lüer, of Leipzig, who made some remarks in condemnation of the materials now supplied to the German soldiers for the primary dressings on the battle-field, which he regarded as useless and even dangerous. And he described the contents of a package which he thought more suitable in emergencies of that kind. His remarks elicited some discussion by Drs. Roth, Starcke, and Es- man.

In an article upon the presence of bacteria in metastatic joint diseases, Dr. Scheller, of Berlin, stated that almost invariably he had found micro-organisms in the articulations in meta-
A report was then made by Dr. E. Hahn, of Berlin, upon five cases of 

**Exstirpation of the Larynx** in carcinoma. Two of the patients died of pneumonia, the others were exhibited to the Congress. The author stated that some discredit was thrown upon this operation at the International Congress in London, because of alleged disturbance to nutrition, but his cases had not suffered in this respect. The patients were able to drink with ease by using a slightly modified Gussenbauer's canula. One had gained thirty pounds in weight since the operation. His method of operating was as follows: an incision was first made on a level with the hyoid bone toward the diseased side, and from this another incision was carried along the median line down to the cricoideal cartilage. Then the soft parts were dissected away on either side, and after the ligature of any bleeding vessels, the thyroid was divided and an inspection made to determine the extent of the disease. If the unilateral operation was deemed sufficient, it was performed by dissecting away the thyroid cartilage and removing it with a portion of the cricoid and arytenoid. In total extirpation, after dividing the cricoid cartilage, the year first tamponed with cotton wool, then dissected off the soft parts and removed the cricoideal, proceeding from below upward. The oesophagus and the hyothyroid membrane were then stitched together.

Dr. Scheide presented a patient upon whom he had performed unilateral extirpation with very gratifying result. He said that the statistics of the earlier cases of extirpation of the larynx for carcinoma would seem to show that it was an unjustifiable procedure, but the successful termination in the more recent cases showed that this judgment should be reversed, and he hoped that the results in the future would be such as to give to this operation a recognized standing. He did not believe that the danger of relapse, only greatly increased by partial operation than after total extirpation, while the restoration of function obtained in the former procedure should always give it the preference when possible.

Dr. Köster also exhibited a patient upon whom the unilateral operation had been performed, and agreed with the last speaker in giving this operation the preference in suitable cases over a removal of the entire larynx.

The remaining hours of the session were occupied with the presentation of pathological specimens and the narration of interesting cases.

The President closed the proceedings by congratulating the members upon the success of the Thirteenth Congress, a success which showed that Germany was by no means quiescent, but was making constant advances and would continue to progress in the time to come.

**Incised Wound of Sclera, Cornea, Iris, and Capsule; Recovery**—Dr. M. J. Davis, of Springfield, Mass., sends us the history of a young man, eighteen years of age, who severely wounded his right eye with the sharp edge of a chisel. The corner of the chisel penetrated the sclera at about three millimetres from the outer margin of the cornea, while a portion of its edge made an incised wound of the cornea, extending across the entire width and terminating in the sciera about two millimetres from the inner margin of the cornea, being driven in through the anterior chamber, dividing the iris horizontally, with prolapse of the iris, opening into the pupil, passing in through the posterior chamber, making a free wound of the capsule, and penetrating the lens, with slight loss of vitreous. Dr. Davis carefully replaced the iris, a drop or two of a four-grain solution of atropine was instilled into the eye, and on the application of a bandage were applied. The patient recovered with absorbed lens and distorted pupil, but with fair vision.

---

The discussion of the case was as follows:

**Incised Wound of Sclera, Cornea, Iris, and Capsule; Recovery**—Dr. M. J. Davis.

**Results of Osten's Operation**—his own experience of twenty-two cases he was convinced that the unfavorable judgment passed upon this procedure was unjust. The operation was performed, the only modification being a sprinkling of the saw with cool carbolic water to prevent overheating. He exhibited four patients upon whom he had operated.

**Dr. Volkman** did not deny that the results obtained by Osten were excellent, yet he could not approve the operation. Even were a hundred favorable cases occur in succession it would in no way prove that there were not better and safer methods of cure for such a case.

Dr. Mikulicz regarded any discussion of Osten's operation as useless, since the superiority of other methods, in which the joint was not opened, needed no demonstration.

**Fissures of the Maxilla, Lips, and Face,** which elicited a mild discussion.

Dr. Neuber, of Kiel, next read a paper on 

**Restrictions of the Hip and Knee,** which he demonstrated the method followed in the clinic at Kiel. The incision through the soft parts is carried down around the trochanter major, the tip of which is sawn off. Then after the operation on the joint is completed the flap is returned and the attached trochanter is fastened in its former place by pegs. The soft parts are then approximated by sutures, and the limb put up in plaster-of-Paris, in a position of abduction.

Dr. Schönhewet, of Brussels, read a learned disquisition on the morphological significance of 

**Wood, Wool, and Sublimated Dressings.** They were of a very satisfying character. The material was cheap, and the results obtained were better than in the unmodified Lister dressing. This was followed by a paper by Dr. Mikulicz, of Tacow, upon 

**Some Modifications in Antiseptic Treatment,** which the author showed by the good results obtained by him, when operating under the most unfavorable circumstances, that the spray was superfluous.

Dr. Partsch, of Breslau, then read an article on the

**The Medical Record.**
THE THIRD GERMAN CONGRESS FOR INTERNAL MEDICINE.

_Held at Berlin, April 21, 22, and 23, 1884._

**Herr von Frerichs, President, in the Chair.**

(Special Report for The Medical Record.)

The first session was opened by Professor von Frerichs, who welcomed the members and pointed out briefly the various subjects which would engage their attention at the coming meetings.

The scientific work was opened by Professor Jürgensen, of Tubingen, who read an elaborate paper upon True Pneumonia: its etiology, pathology, clinical course, and therapy.

The author gave a history of the growth of our knowledge of croupous pneumonia, and showed how opinions as to its nature had changed, until now the belief exists that pneumonia is a general infectious disease, the lung inflammation being only symptomatic. Experimental pathology had recently given indirect confirmation of this view.

The speaker then took up the alleged exciting causes of the disease, and showed that the facts regarding these did not accord with the infection theory. Cold has been alleged to be a cause. At one time it was even said: "Frigus unica pneumonie cause." Different authorities reported cold to be a cause in between two and twenty per cent. and twenty per cent. of the cases. Jürgensen had in ten years' observation found cold as a cause apparently in ten per cent., really in only 4.1 per cent. It might easily be thought that exposure will produce a catarrah rendering easy the access of the infectious organisms of pneumonia.

It is a prevalent error, says Jürgensen, that pneumonia attacks by preference the strong and full-blooded. Among a population of all ages three-fifths of the pneumonias occur in those between one and fourteen years, while twice as many occur after forty-five as between twenty and forty-four. Dittell found that the disease occurred in those previously weakened, in eighteen per cent. of cases; Flint, of Danemarck, in twenty-one per cent.; the author in 29.3 per cent. Immermann, of Basel, recently confirmed this view. The disease has some relation to the meteorological conditions, being increased when there is an increased humidity of the soil (Keller) and when the atmospheric precipitates are above the mean. These facts might be explained by the theory of an organic poison. Pneumonia is a disease of dwelling-houses, like typhoid. Jürgensen had seen pneumonia in a dwelling in Amberg. Some time later the pneumonia cocci were found in the walls of the chamber. The disease occurred in epidemics, especially affecting single houses, or prisons, asylums, etc. The possibility of direct passage of the disease from one person to another cannot be denied, but the occurrence is rare. Flint, of Danemarck, found some relation between earlier and later cases in two-thirds of his patients.

The question of the purity or multiplicity of the pneumonia poison would soon be settled.

Clinically the disease presents great diversity even in the same families and sick-rooms. This the author was inclined to explain by assuming a variation in the extent of the development of the infectious poison. He believed that this poison, circulating in the blood, affected with special inflammation or disturbance other organs than the lungs. He cited thirteen cases of pneumonia with acute nephritis in which the kidneys were found to contain the special cocci. He believed that these produced special disturbances of the brain membranes or stomach or other organs. Their development gave rise to the irregular curve of pneumonia.

Clinically the disease may be separated into three great groups: first, those in which the general symptoms of infection; second, those in which heart symptoms; and third, those in which the lung symptoms are more pronounced.

In reference to prevention, the discovery of the cocci, and the knowledge that it is a house-plant is of importance. As to treatment the author had tried iodine as an abortant without effect. The author gave a caution to antipyretics, considering them heart-depressants. He pleaded for prophylactic therapy. He was doubtful of the ultimate value of bleeding, though it might temporarily relieve the heart. Finally he announced the following conclusions: first, True pneumonia is an infectious disease, usually but not uniformly localized in the lungs; second, exposure to cold is a rare cause. The febrile are more susceptible than the strong.

Herr Frankel, of Berlin, continued the discussion, and took up the subject of Micrococcus of Pneumonia.

This coccus is distinguished from others by its pus-like capsule, which may surround two or more cocci. The capsules are not always present. The cocci are stained by a mixture of gentian-violet in water, injected into rabbits they produce no uniform effect, in man they cause pneumonia and pleurisy. In dogs pneumonia is sometimes produced. The author found that reactions in inoculation effects depended somewhat upon the cultures, which apparently had an effect of diminishing the virulence of the virus. There was also another encapsulated coccus found in the human mouth, and was the coccus of sputum-pticemia. The author announced the following theses:

1. The cocci of pneumonia, which may be isolated by pure cultures from the human being, is inoculable to various animals. Rabbits the blood proving refractory or become affected with severe general disease, with special localization of the virus in the internal organs—this depending on the mode of culture.

2. Further experiments must determine upon what depends the varying virulence of the coccus.

3. The capsules of the cocci, as well as the "nagelform" growth of the pneumonia cultures, are not constant phenomena.

4. The capsules and the "nagelcultur" characteristic of other micro-organisms, and it cannot be said at present that the pneumonia cocci can be distinguished by them.

Herr Friedlander, of Berlin, said that the cocci of pneumonia were found in the blood. He had recently obtained the blood by wet-caps in cases of croupous pneumonia, every precaution being taken to keep it pure. The blood thus obtained was cultivated for cocci. In one out of the five cases the blood, developed and showed their characteristic action was inoculated. Friedlander thought the capsule and growth in "nagelform" very characteristic, but not sufficient for a positive diagnosis. The whole life-history must be taken into account. This life-history appears to differ, and this may account for the various forms of pneumonia. Either there are various forms of pneumonia, and only one has the cocci, or in the different forms the same cocci has a different life-history. In chief efforts must now be made to follow out the different changes in the growth of the organism.

Dr. Gerhardt, of Würzburg, accepted Jürgensen's view of the infectiousness of the disease. He accepted also completely the view of the unity of the disease, and considered it a happy explanation that the various complications of meningitis, pleuritis, etc., were due to local inflammation rather than to the primary disease, it must be expectant and symptomatic; in the anemic and feeble a stimulating treatment. As anti-febrile means he thought veratrine dangerous; digitalis had not achieved
much as was expected; kainin acted too irregularly. The most regularly acting substance was nitre (nitrin); in severe cases quinine; in the worst (febrile) cases cold baths with stimulants.

Dr. Frantzel, of Berlin, argued against Jürgens's view that pneumonia was a house-disease, citing its occurrence in military hospitals, and its frequency after open-air festivals and exposures. He thought theoccus entered the blood through the lungs. He explained the haematogenous jaundice of pneumonia by the theory that the cocci attack the red blood-cells.

Dr. Ruhnke, of Bonn, contended that the view of the infectious nature of pneumonia was not so firmly established as its advocates assumed. It is necessary still to harmonize some of the known facts as to the etiology of pneumonia with the theory of a cocuss. Besides, this cocuss had not been found in all cases yet.

Professor Nothnagel said that in pneumonia, as in all infectious diseases, we look for a specific, and meanwhile treat symptomatically. In the last twenty-five years alcohol had entered largely into the therapeutics of the disease. Dr. Nothnagel thought that it was often used unnecessarily and excessively; alcohol is not indicated in ordinary cases of pneumonia, and should not be used except when specially indicated by the failure of heart-power.

Dr. Rosenstein, of Leyden, thought that "though a supposed pneumonia may be an infectious disease in many cases, it is not in all." He did not believe in the unity of the disease.

Dr. Baümler, of Freiburg, said that a patient, a gardener, fell one day into the fire; next day he was brought to the hospital with croupous pneumonia. When first seen, the case played no such a case was for the future to discover. If pneumonia is an infectious disease, it might be asked whether it is at first a local infection or a general one. With reference to the localization of the alleged pneumonia in other organs, he recalled cases of pneumonia that started off with an acute nephritis; others with a meningitis. These diseases generally ran a parallel course with the pneumonia.

Professor Rosenthal, of Erlangen, read an article upon

THE REFLEXES.

The essential point in the author's paper was that the "reflex-time" is diminished by increase of the sensory stimulus, and varies with the strength of the stimulus. This fact Rosenthal had demonstrated, and he explained it by assuming that a sensory stimulus and impulse pass up the cord toward the medulla, and not directly over to the motor nuclei. This view he based upon experiments in which various sections of the cord were made.

It was suggested, in a brief discussion that followed, that these facts would explain the contradictory results of studies of the tendon-reflex.

Dr. Pfeiffer, of Weimar, read a paper upon

VACCINE AND VARIOLO.

He discussed the modes of entrance and development of these viruses, which he evidently considers modifications of the same thing. He then referred to the various means of enfeebling the variolous virus, e.g., inoculation in man and in animals. He finally described the methods of vaccinating, and recommended the use of calf-lymph. The paper, on the whole, had not much in it that was new.

Dr. Voigt, of Hamburg, contended that calf-lymph by cultivation lost its power, while human lymph, passed from child to child, did not do so.

Professor Leyden, of Berlin, opened a discussion upon

POLIOMYELITIS AND MULTIPLE NEURITIS.

He gave a historical survey of the discoveries in the pathology of progressive muscular atrophy and spinal paralysis of Duchenne.

He then called attention to the fact established by several observers, that certain forms of paralysis and atrophy, involving two or more extremities, were due to a

DIFFUSE MULTIPLE NEURITIS.

This disease began in a more or less acute manner, and ran generally a subacute course. In severity it was mild, severe, or medium, depending on the degree and extent of paralysis and atrophy. It generally progressed symmetrically, the paralysis beginning at the periphery. The tendon-reflexes are lost, and sensory disturbances occur. The pains are peripheral, and there is tenderness, more in the muscles than skin. Degenerative reactions occur in the severest cases.

The progress is not unfavorable generally, and it is these cases which form the reported recoveries from progressive muscular atrophy. The cause is generally rheumatic inflammation of joints and the infectious diseases, while some occur spontaneously after exposure.

Treatment is very important, and upon it depends largely the future course of the disease. Constitutional remedies must be given, with rest. Only later can electricity and mechanical measures be used.

In the discussion which followed Schultz, of Heidelberg, S. Guttmann, Bernhardt, Rumpf, Remak, Althaus, and others took part. It turned upon the pathology of rheumatic paralysis and the differential diagnosis between poliomyelitis and multiple neuritis. Two cases were related, but no especially new investigations reported. The fact that in neuritis the paralysis and atrophy are slower than in myelitis was dwelt upon. The absence of sensory disturbances, and the paralysis and atrophy occurring in muscular groups also characterize poliomyelitis.

Dr. Löfler, of Berlin, read a paper upon

MICRO-ORGANISMS OF DIPHTHERIA.

He examined material from thirty-two cases, and found numerous forms, which he divided into three groups. The first, various bacteria and micrococci; the second, chain-forming cocci, found especially in necrotic parts. They were found also in the internal organs, spleen, heart, kidneys, lungs, etc. A third group consisted of short rods, such as Klebs had found and described. He cultivated the second and third groups by the gelatine method, and inoculated them in mice, rats, and small birds. The results were varying, and had led him to conclude that no special form could be associated with diphtheria. He believes, however, that some organisms had important relations to the disease, and probably developed a special chemical poison.

Dr. Weber, of London, read a paper upon

SCHOOL HYGIENE IN ENGLAND, ESPECIALLY IN RELATION TO INFECTIOUS DISEASES.

Dr. Staahl, of Berlin, demonstrated a series of

MICRO-ORGANISMS OF THE INTESTINAL CONTENTS.

He had found and cultivated twenty-five different forms of organisms—micrococci, bacilli, bacteria, etc.

Professor Baginsky, of Berlin, said that for two or three years he had examined the intestines of children. In health he found scarcely any organisms, but in gastroenteritis and diarrhoea he had found cocci and rod bacteria of various forms.

Dr. Finkler, of Bonn, read a paper upon

PAPAYOTIN.

Most of the preparations of this substance were of very feeble activity. He had made or obtained some preparations, however, which readily digested one thousand times their weight of fibrin. The papayotin acted in acid, neutral, or alkaline media, and was especially valuable, therefore, for rectal injections of food, also for peptonizing milk. He had also used it successfully in digesting and dissolving of croup and diphtheric membrane.
THE MEDICAL RECORD. [May 24, 1884.

Dr. Rossbach, of Jena, confirmed the opinion of the value of the papoytin in diphtheria. Dr. Rossbach, of Jena, presented a paper describing

A NEW THERAPEUTIC ACTION FOR NAPHTHA LIN.

This was as a germ-destroyer in diseases of the stomach and intestine, especially chronic diarrhea and dysentery. Naphthalin was very poisonous to the lower organisms, and but slightly injurious to man. It could be given in doses of five grammes daily without bad effects.

[To be continued.]

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from May 11 to May 17, 1884.

Waters, William E., Major and Surgeon. Ordered to report for temporary duty to the Commanding Officer at Plattsburg Barracks, New York. S. O. 90, par. 4, Headquarters Department of the East, May 10, 1884.

Hubbard, Van Buren, Major and Surgeon. Re-located from Fort Stanton, New Mexico, and ordered to Fort Bayard, New Mexico, for duty. S. O. 96, par. 3, Headquarters Department of Missouri, May 12, 1884.

Mosley, E. B., Captain and Assistant Surgeon. Assigned to temporary duty at Vancouver Barracks, Washington Territory. S. O. 59, par. 6, Headquarters Department of Columbia, May 8, 1884.

Wilcox, Timothy E., Captain and Assistant Surgeon. Assigned to duty at Washington Barracks, D. C. S. O. 90, par. 2, Headquarters Department of the East, May 10, 1884.

Wales, P. G., First Lieutenant and Assistant Surgeon. Assigned to duty at Old Fort Colville, Washington Territory, until further orders. S. O. 58, par. 3, Headquarters Department of Columbia, May 7, 1884.

Official List of Changes in the Medical Corps of the U. S. Navy, during the week ending May 17, 1884.

Kindleberger, D., Medical Inspector. To be Fleet Surgeon of Pacific Station.

Leach, Philip, Assistant Surgeon. Detached from U.S. New-Hampshire, and ordered to Naval Hospital, Chelsea.

Bertolette, D. N., Passed Assistant Surgeon. Detached from Naval Academy and ordered to Practice Ship Dale.

Medical Items.

EXTERMINATION OF THE LARYNX IN AN OLD MAN.—In August last (British Medical Journal), Dr. H. Leiszat extirpated the larynx in a man aged seventy-two years, on account of a cancerous tumor which nearly filled the cavity and threatened suffocation. The patient recovered from the operation, and remained in good health for four months. He died in December, of croupous pneumonia. There had been no return of the disease from which the operation was performed.

THE USE OF THE ELECTRICAL CURRENT IN THE TREATMENT OF SUBINWOLUTION.—Dr. Finlay Ellwood, of Manteno, Ill., writes: "I have treated four cases of subinvolution with the galvanic current, all of which followed confinement. The method I have adopted is to apply the positive electrode for a short time over the sacral plexus, and then for a short time over the fundus uteri and abdominal muscles, with the negative electrode at the os uteri. In those cases of not more than six or eight weeks' duration two or three applications were generally sufficient, and the effect was like magic, a satisfactory cure resulting in each case. The last case was one of long standing, the uterine hypertrophy having existed for at least three years, as the patient had been treated three years previously and the result was the same from the same as the symptoms exhibited to me. The symptoms, at the time of my first visit, were severe in the extreme. A retention of urine had existed for forty-eight hours; the temperature and pulse were elevated, and the pain and suffering were intense. After evacuating the bladder an examination revealed a uterus prolapsed greatly enlarged, and actually impinged upon the pelvic walls. There also existed a complete laceration of the cervix of long standing, which had probably occurred at the time of her only confinement, seven years previously. I had her assume the genu-pectoral posture, and after careful and prolonged manipulation succeeded in replacing the womb. I submitted the patient to an electric treatment for two consecutive days, and on the third my patient said she had been free from pain. The galvanic current, the result of which was in every way satisfactory. She refused to submit to an operation for the laceration, claiming after the galvanic treatment to enjoy better health than for years before."

TREATMENT OF EARACHE.—It is said that by the following simple method almost instant relief of earache is afforded: Put five drops of chloroform on a little cotton or wool in the bowl of a clay pipe, then blow the vapor through the stem into the aching ear.

A PHYSICIAN'S PRAYER.—The following prayer was found on a copy of the paper of the late Dr. C. F. Couch, of Petersburg, and it is so good an one for physicians that I ask the favor of an insertion in your valuable paper. Perhaps some others of the faculty may gain a blessing on their practice by using it. Truly yours, B.

"O Thou Great Bestower of Health and Comfort, grant Thy blessing upon the professional duties in which this day I may engage. Give me judgment to discover disease, and skill to treat it; and crown with Thy favor the means that may be devised for recovery; for with Thine assistance the humblest instrument may succeed, as without it the ablest must prove unavailing. Save me from all sordid motives, and endow me with a spirit of pity and liberality toward the poor and of tenderness and sympathy toward all, that I may enter into the various feelings by which they are respectively tried; may weep with those that weep, and rejoice with those that rejoice. And sanctify their souls as well as heal their bodies. Let faith and patience, and every Christian virtue they are called upon to exercise have their perfect work, so that in the gracious dealings of Thy Spirit and Thy will I may find I have entered the end may be, that it has been good for them to have been afflicted. Grant this, O Heavenly Father! for the love of that adorable Redeemer who while on earth went about doing good, and now ever liveth to make intercession in heaven. Amen."—The Parish Visitor.

ALBUMIN AND ITS NOMENCLATURE AND TESTS, AND THE SIGNIFICANCE OF ALBUMINURIA.

By HENRY B. MILLARD, M.D., A.M.,

It is incomprehensible to me that nearly all English-writing physicians, among whom are to be numbered many who have achieved distinction in medical pathology and in their writings upon renal affections, should continue to use the word albumen to denote what it does not signify, that is, neither the proximate principle of albumen, nor serum albumen or parargulbin. I know no medical dictionary, encyclopaedia, nor chemistry published for a long time that uses the termination en at all. In the best Latin dictionaries albumen signifies simply the white of the egg. Very few authorities or writers on chemistry speak of egg albumen;—the word albumen being, I believe, exclusively used. The celebrated French medical dictionary of Littre and Robin gives two different words: "albumen, a Latin word employed sometimes in French to designate the white of the egg," and "albume, the coagulable matter or lymph of serum." In the Real Encyclopædia, I do not find the word albumen at all, the termination en only being used. Nor is the termination en used in Watts' "Dictionary of Chemistry." In French, the word albumine is used; in Spanish and Italian, albumina. If the word albumen be the correct one to use in physiological chemistry, we must use the word albumenuria, instead of albuminuria.

As regards the practical value of accurate nomenclature, I would simply say that the language of science should represent as nearly as possible what it is intended to. I believe, however, the termination is will in time be generally employed.

THE MOST ACCURATE TESTS FOR ALBUMIN.

Aside from the recognition by the microscope of pathological changes in the kidney, the importance of the presence or absence of albumin in the urine, as demonstrated by chemical examination, is very great. It is consequently a desideratum, by tests which are not too elaborate for the general and busy practitioner, to be able to recognize unerringly the existence of albumin, and not to mistake for it other substances whose presence often produces, with certain tests, a simulation of it, as the paraperopeines, vegetable alkaloids, mucin, etc.

Although in my work on Bright's disease, published last year, I described some tests which their prominence last at that time seemed to make it necessary for me to do, and which, indeed, after considerable use seemed to me to have certain merits, I have since discarded them. I refer to Roberts' brine test and picric acid. The chief objections to picric acid are that although it is a delicate test for albumen, like the brine test, it is objectionable from producing a precipitate with the paraperopeines and all protein compounds. (The existence of peptones in the blood has not yet, I believe, been demonstrated.) It is stated that these may be recognized by their clearing up on the application of a low degree of heat. I do not find this, however, to be the case, either in peptonuria or in artificially prepared peptones. Picric acid also precipitates mucin, which may be known by its forming filaments upon the application of heat; that it forms precipitates with quinine and the oleoresins is unimportant, as these disappear by heat or on the addition of alcohol.

I have repeatedly found the brine test, used by Heller's method, to show a clear white line like that produced by nitric acid, where the existence of albumin could not be shown by any unmistakable tests. Nor does it offer any advantages over certain other absolutely positive and accurate tests which I shall describe.

Among the tests which may be mentioned as a matter more perhaps of interest than for their practical value are metaphosphoric acid and terchloracetic acid. The former, I think, has more to recommend it than the two preceding tests, as it gives no reaction with quinine, and but a very slight one with artificially prepared peptones; this latter, however, only disappears in part upon the application of heat. I am not certain if it will give all with peptonuria. It is, however, an equally delicate test with the tungstate of soda and picric acid, and more so than nitric acid.

Terchloracetic acid is a more sensitive test for albumin than nitric acid, and is quite as sensitive as tungstate of soda or Tanret's test. I have not convinced myself, however, that it does not give a reaction with the paraperopeines. If it did not, it would be valuable. As it is, it cannot be depended upon, inasmuch as the cloudiness or disk produced by it with albumin disappears upon applying heat. It gives no reaction with artificial peptones.

The most reliable and delicate tests I believe to be, in the order of their sensitiveness, heat, nitric acid, the tungstate of soda, the double 0xide of mercury and potassium (Tanret's test), and the phenic acid acid test, the last two, perhaps, being about equal in delicacy.

Heat. I have found the least sensitive, though Dr. Roberts claims to be able to detect 1 part in 250,000 of water. The urine should be clarified before using this test by filtration or boiling with liquor potasse, and should be rendered faintly acid by adding acetic acid before applying heat. I have used the heat test with serum albumin chemically prepared and with albuminous urine, but have not found it to show the presence of albumin in the slight degree stated by Roberts. Nevertheless, if care be taken not to acidulate the specimen too much, heat is in many cases, perhaps in most, a good test. My own experience, however, has been to the effect that it could be dispensed with in favor of the other four above mentioned.

Nitric acid.—The reaction produced by this reagent is not likely to be mistaken for anything but the urater, and these are easy of recognition. It is not so sensitive a test, however, as the three following, which show it in a more highly diluted urine and solutions of dried albumin from the blood than does nitric acid. It is valuable, however, because albuminuria so slight in quantity as not to be shown by nitric acid is frequently, ceteris paribus, of but little practical importance, because there should be no difficulty in distinguishing the reaction produced by it from that produced by other substances; and finally, because the thickness of the line or layer produced by Heller's method with it gives, according to Hofmann and Ullmann's calculations, a very fair idea of the percentage of albumin.
The *tungstate of soda* is entitled to high commendation. It is not caustic and does not stain, it is cheap and easily prepared, and is a more sensitive test than either of the preceding. Artificial peptones are precipitated by it but very slightly, but I cannot find that it precipitates the paraperpeptones, and it gives no reaction with quinine. I have yet found no objections as regards its accuracy and freedom from reaction with other substances than albumin.

The *double iodide of mercury and potassium*, known as Tanret's test (not Tauret, as usually given; Tanret, its discoverer, being the well-known *pharmacien* of Paris who discovered ergotism and pellagra itself), is exceedingly sensitive and in every way an accurate and satisfactory test. The formula for the test is not often in England and America correctly given, and I regret that I myself in my work gave the formula usually presented, without thinking of comparing it with Tanret's, which I had; the error, however, consisted only in the omission of the acetic acid, the use of which makes unnecessary the acidulation of the urine, as I recommended. The correct formula is as follows:

Potassii iodidi .......... 3.32 grm.
Hydrargyri bichloridi ..... 1.35 grm.
Acidi aceticici ............ 20 c.c.
Aque dest. q. s. ut ft. 100 c.c.

It may be easily prepared as follows:

"The 3.32 grm. of the iodide of potassium are placed in the bottom of a glass and a slight quantity more of distilled water than is necessary to dissolve the salt poured upon it; then in a second glass is placed 1.35 grm. of the bichloride of mercury and a few drops of water are added. If it does not dissolve at once, then there is poured upon this gently down the side of the glass the contents of the first glass, taking care to agitate it constantly; the biniodide of mercury is immediately found manifested by an intense red. This mixture is stirred and distilled water added drop by drop till the redness has completely disappeared; the slightly yellowish liquid thus obtained is poured into 80 c.c. of distilled water, 20 c.c. of acetic acid are added, and the mixture filtered. A liquid is thus obtained which is very transparent, almost colorless, and which can be preserved for a long time" (Cajalin).

I have used this test experimentally with diluted albuminous urine, dried egg- and blood-albumin, artificial peptones, and artificial acidoids, and have found it to be extremely sensitive and certain in showing the presence of all protein substances. Capitan shows that 0.0035 c.c. of albumin to 1,000 grm. or one litre (about 1/4 grain to a litre, or 1/2 part to more than 300,000) may be detected by it when all other reagents had ceased to show it. Indeed, when this test showed the presence of 0.015 grm. to the litre none of the other tests showed it. Nitric acid, picric acid, and heat did not show even 0.03 grm. to the litre. Of course, to detect the presence of such minute quantities of albumin, great care must be taken. It may be employed by placing the urine in the test-tube and letting the reagent trickle down upon it along the side of the tube by means of a pipette, when a cloudiness will result. On warming, this will remain uniform or resolve itself into flakes, according to the amount of albumin present. I think the best method, however, is to place the reagent first, and let the urine, which should be cleared if turbid, run slowly down the test-tube upon it. The two liquids thus remain separated, and the point of contact a blush disk is seen, more or less thick. This method permits the easy recognition of "absolutely infinitesimal quantities" of albumin (0.005 gr. or 0.0035 grm. to the litre). The specific gravity of the reagent thus prepared is about 1.027. It is a good plan to mark the specific gravity of this and the tungstate on the labels, as where the urine is very heavy it will take its place at the bottom of the tube.

It is important to recognize that other substances pro-

duce a reaction with this test resembling that produced by albumin; these are the urates in excess, peptones, quinine, and atropine—these are all readily soluble by heat and alcohol. The precipitate or cloud produced by mor-

phine and strychnine with this reagent is not soluble by heat, or is appreciably less soluble; the precipitate is usually prepared, but is soluble by heat in weak solutions, and would easily disappear in the minute quantities that would be likely to be found in the urine. All the above, when dissolved by heat, reappear when the urine or solu-

tion containing them becomes cold. Mucin is also coagulated by this reagent, but upon the application of heat it is not dissolved completely. The existence of mucus is also easily recognizable by the microscope. I can see, therefore, no error likely to result from this test. It is simple, and certainly sensitive enough for all pur-

poses.

*Phenic and acetic acid.*—Having seen somewhere, within a year or two, a paragraph wrongly attributed, as I have ascertainment, to the *New York Medical Journal*, to the effect that Dr. Meynott Tidy had found that equal parts of phenic and acetic acid would show the presence of a small quantity of albumin, I have recently made the subject of careful experiment, using urine containing paraperpeptones, albuminous urine, artificially prepared peptones, dried egg- and serum-albumin, and several alkaloids. The preparations recommended by Dr. Tidy are by no means satisfactory— turbidity of even distilled water being produced. A mixture of one part of a ninety-five per cent. solution of phenic acid and three and a half parts of pure acetic does not, however, produce more than transient cloudiness. I discovered, however, that albumin shown by this mixture to disappear, is precipitated upon the addition of a part of a precipitant. The test of no practical value. By adding to the phenic and acetic acid *liquor potassa*, however, I find that though the peptones, etc., disappear by heat, the *albuminum disk* or cloud does not; this I have repeatedly ver-

fied.

The proportions of the modified test as I use it are as these:

\[ \text{B. Acid. phenic. glacial (95 per cent.) } \times 3 \]
\[ \text{Acid. aceti puri. } \times 2 \]
\[ \text{M. Add liquor potassa. } \times 3 \]

It is important that the glacial carboxylic acid should be used, or the mixture, which should be quite clear, will be turbid. I have found that those recipes are satisfactory. In a number of instances where Roberts' muriated brine test and picric acid showed paraperpeptones manifested by disappearing by heat after Tanret's test, this showed no reaction. It forms a precipitate with artificially prepared peptones and with strong solutions of quinine, both easily soluble by heat and alcohol. With strychnine it presents no reaction except in strong solution, when it produces a slight cloud, and this readily disappears by heat. With strong solutions of atropine and morphine it produces a reaction, the precipitate being soluble by heat when diluted. These alkaloids would not occur in the urine in sufficient quantity to produce a reaction. I have produced slight opacity or turbidity with a solution of atropine 1/100 grm. in 200 c.c. of water. The solution had been shown by all the other tests I have mentioned, but when the urine was greatly diluted all except this one failed to give a reaction. Like Tanret's test, when albumin is present in minute quantities, as 0.005 grm. or 0.0035 grm. to the litre, it does not form a disk, but produces a loss of clearness, the opacity being of a slightly yellowish or greenish tinge, the cloudiness produced by Tanret's test being slightly opalescent.
To sum up, then: I believe that in the double iodide of mercury and potassium, the tungstate of soda, and phenic-acetic acid test, we have three reagents which combine the desiderata of extreme sensitivity, accuracy, and simplicity. The phenic-acetic test has the advantage over Tanret's that it shows no reaction with quinine, and if I adhere somewhat preferably in my examinations principally to the latter, it is because it has served me so well; it is perhaps good enough, but it is of importance to know that the phenic-acetic test seems equally good.

As to heat and nitric acid, I use them sometimes; they are less delicate than the others, and I believe the former could be dispensed with entirely, as it is sometimes possible to use with acid-albumin or alkali-albumin. The nitric acid has the advantage of showing approximately the percentage of albumin, and its indications are positive.

I cannot see, if I am correct in my observations, that there should be the embarrassment that is claimed to exist in the selection of reagents for the detection of albumin with care and certainty.

**ALBUMINURIA OCCURRING IN HEALTH.**

Previous to the extensive experiments made last year by Drs. Chateaubourg and Capitan, of Paris, the occurrence of albumin in the urine as a physiological phenomenon was conceded by several authors, first, I believe, by Gubler in 1825, and then by Vogel, Dukes, Leube, Morely, Rooke, Saundby, Senator, and others. A majority of the majority of observers, among whom may be mentioned Dr. G. Johnson, regard the occurrence of albumin in urine as "always pathological and never physiological." The observations of the above authorities are not all to be necessarily accepted as accurate, for the reason that the methods of ascertaining the presence of albumin, the reagents used, etc., are not generally given, and the report of some of the patients may sometimes have been peptonuria. In 1883, however, experiments on a large scale were instituted by Capitan and Chateaubourg, independent of each other and under the most favorable auspices. The subjects were young soldiers from various arms of the army, fulfilling all requirements of health and free as far as could be known from unfavorable antecedents, and young school-children in perfect health. The reagents and the amount of albumin are given, and the conditions under which the albumin was found stated: as after rest, long marches and manoeuvres, fasting, cold bathing, unusually hot study, etc. Capitan also showed that albumin might appear in certain portions of the brain, the spinal cord, by exciting the nerves, by irritation of the abdominal plexus, by cutaneous excitation, etc. It is, however, albuminuria occurring under the ordinary circumstances of health that we have to consider, the practical part of the matter being to determine how much the presence or absence of albumin imports as showing a normal or abnormal condition of the kidneys. The presence or absence of albumin in the urine neither indicates health or disease; but it is unjustifiable and even dangerous, because experimenters have frequently found albumin in health, to go to the extreme of decrying its great importance as a factor in diagnosis, and often as an evidence of disease of the kidneys. I am led to dwell upon these points because, in my work on Bright's disease, I gave a very meagre digest of the experiments above referred to, showing in what a large percentage of cases albumin could be found in the urine in health, and some medical journals, quoting these facts, have seemed to convey the idea that albumin occurs frequently without having any special significance. This extreme view is dangerous, since it by no means follows that, because albumin may be found after exercise, cold bathing, and even after repose, by very delicate tests, and sometimes in very minute quantity, its ordinary or frequent occurrence, particularly if considerable in amount, is not to be regarded with solicitude.

As regards the amount of albumin found in the urine of soldiers after nearly two days' rest: in 54 cases out of 98 albumin was absent; in 20 cases there was only 0.007 grm. to the litre; in two others only 0.15 grm.; the others contained more.

The urine of 120 soldiers was examined immediately after waking, and in 92 (that is, 76 per cent.) albumin was found. In 17 cases there was only 0.05 milligrm. to the litre, and in 33 only 2 to 3 cgrm. to the litre. In 22 there was 12 cgrm. (2 grains) to the litre.

In the urine of 199 soldiers, after severe manoeuvres and exercise, albumin was found in 170 cases, in nine cases it being readily recognizable by nearly all reagents, the smallest quantity being 3 milligrm. to the litre. In 11 of the experiments, however, there was only 0.005 grm. to the litre was found. The largest percentage was after the cold bath and severe exercise, as much as 25 cgrm., 4 grains to the litre (about 1 part to 4,000, or one-fourth of one per cent.), and in some cases more being found.

It will thus be seen that albumin in health is not often found, except in minute quantities, sometimes not more than one part in a million.

An article by Dr. Purdy, published within the last year in *The Journal of the American Medical Association*, gives some of the conclusions of Chateaubourg and Capitan, attributed wrongly wholly to the former, and probably taken from my own work, since it contains like parts the same unimportant errors. An article referred to gives no idea—an indispensable consideration—of the amount of albumin found.

The works of Chateaubourg and Capitan were published in Paris last year, just previous to my leaving there, and as my book went to press immediately upon my return home, I was able to incorporate in it only a few of the details and valuable results of these investigations, but was obliged to content myself with giving a few of the most important, and these afford but a faint outline of their excellence and thoroughness.

It is not impossible that albumin almost always or constantly exists in the urine in health, in too minute quantities to be detected by any means we at present possess. If we accept the conclusions of Charcot, deduced from the experiments of Nußbaum, Overbeck, Heidenhain, Goll, Stockvis and others, that the glomerulus is the seat of albuminous exudation or secretion, and that this secretion results from diminished slowness and pressure, or entire suspension of the blood-current in the glomerulus, producing an oxemia or a deoxygenated state of the blood (including albuminuria, but not albuminuria, but polypuria), we can understand that albumin recognizable in the urine may be produced by transient causes, and there are many such affecting the rapidity and pressure of the blood-current in the glomerulus, quite independent of any renal lesion or changes. I beg to quote the following relative to this point from my own work (page 47):

"The theory that albumin makes its way through the capillary plexus and the basement membrane, when there is great congestion, is erroneous. Many authorities state that in parenchymatous nephritis, where the epithelia have perished, there is a constant leakage through the basement membrane of the tubules. But the albumin must then make its way through the blood-vessels and structureless membrane. I have shown, too, that when the epithelia perish they are invariably replaced by an endothelial growth. The albumin would then have three layers of tissue, unlike in their formation, to traverse.

"It has been repeatedly demonstrated, also, that the albumin of the blood cannot transude, under ordinary circumstances, animal membrane. The urine and albumin are in all cases affected, as is easily shown, by all variations of the arterial or venous circulation of the kidney, and serum albumin in the urine cannot exist without

---

2 Recherches Expérimentales et Cliniques sur les Albuminuries Transitoires.
these variations. And it is indeed within the capsule of Bowman that albumin is transudosed or secreted. In the language of Charcort, 'numerous cases may be cited in which albumin is found in the urine without any apparent cause.' In all instances, however, it be it said, where albumin be present in urine, albumin was completely absent.'"

It can thus be readily understood that without the existence of nephritis, albumin may often be found in the urine; nevertheless when it occurs frequently, and in such quantities as the one-fortieth to the one-tenth of one per cent., it may be regarded in the majority of cases as an evidence of renal lesion. Of course we must except the existence of albumin produced by other causes, as cystitis, hematuria, etc. I believe that in all cases where the albumin exists in the urine almost constantly, and in such quantity as I have mentioned, the microscope will show evidences of renal inflammation.

In fatal cirrhosis of the kidneys, however, where the average specific gravity of the urine will not exceed 1.006 or 1.007, all abnormal elements may be temporarily absent, and when they are present numerous and careful examinations may be necessary before they can be recognized. Constant albuminuria, even with a considerable amount of albumin, does not always denote extensive lesions of the connective tissue or epithelia of the kidney, I have repeatedly convinced myself. I have had under my care for more than a year a number of patients whose cases exemplify this fact. The first is a gentleman seventy years of age, the average specific gravity of whose urine is 1.021, and which always contains at least one-tenth of one per cent., often one-fifth of one per cent. or more of albumin. His own constitution and those of his family on both sides are remarkably excellent. There is often a tendency to a considerable increase of the percentage of albumin, and there was before he came under my care a severe headache and lassitude. No loss of flesh. I have often found considerable uric acid and urate of soda in the urine, a condition which does not ordinarily correspond to extensive interstitial nephritis. The microscope usually shows a few epithelia from the renal tubules, and an occasional hyaline cast. There is no hypertrophy of the heart, a fact not in accordance with the belief of many writers, among others Bartels, that this always exists in chronic interstitial nephritis. I have, however, often found the latter without the former. Sixteen years he suffered from croupous nephritis with dropsy, and it is possible that this may have laid the foundation of the ailment which now exists. I believe the nephritis in this case affects only a limited portion of the connective tissue, or that the inflammation may be limited to one kidney. Certainly there is enough of the kidneys untouched by disease to enable the secretivne functions to be carried on without much detriment to the health. I would not have it understood, however, that I regard the disease in his case to be unimportant; on the contrary, I think without certain precautions and measures of treatment there may be a great danger of uræmic symptoms; some of these consist in the use of the hot-air bath two or three times weekly; a non-nitrogenous, or only moderately nitrogenous diet, freedom from fatigue, which is possible in this case, the use of some medicines, among which may be mentioned the chloride of iron, arsenic, the Bilin (thiia), and sometimes water (alkaline, iron, and arsenical). The same precautions and care have been taken in the following cases:

Mrs. X—, sixty-five years of age, like the preceding patient having an excellent constitution, and belonging to a family noted for longevity. The average specific gravity of her urine is 1.020. Previous to consulting me she suffered from headache, dryness of mouth, and torpidity. Urine highly albuminous, showing under the microscope the existence of chronic interstitial nephritis.

Heart somewhat hypertrophied. Treatment, hot-air baths, etc., have brought about an improved condition, so that the health and strength are now practically good. The amount of albumin is small, not usually more than one-fortieth to one-tenth of one per cent., and is occasionally absent. I believe from her symptoms that the nephritis had existed in this case for a long time before I saw the patient.

The third case is that of a lawyer, forty-five years of age, actively engaged in practice. Like the others, the constitutions of this patient and his family are remark- able. The result was nephritis in this man, on the result of scarlatina, which he contracted two years ago. Of that, I am not certain. When I first saw him, last October, he suffered from great exhaustion and a tendency to headaches. Some loss of flesh; heart not hypertrophied. The chemical and microscopic examination showed the existence of chronic interstitial nephritis; albumin always found in quantities of one-tenth to one-fifth of one per cent. With a careful diet, plenty of sleep, the hot-air baths and same treatment, he experienced no symptoms of any sort, and is able to attend to a large law practice. In January, however, he became over-sanguine about his health and seemed to think my injunctions unnecessary, and neglected his baths and diet. He developed a severe interstitial nephritis, consisting of constant headache, which disappeared with a resumption of treatment, etc.

Cases like the above, occurring in people of poor constitution and with bad inherited tendencies, would not long remain mild and comparatively harmless nephritis. Much depends upon the soil the seed is sown in, and I have known chronic interstitial nephritis come on in the mildest possible way, in persons of scrofulous and consumptive families, to prove fatal within a year without the slightest impression that I could recognize being made upon the disease by any measures of treatment or hygiene.

In a case of cirrhosis of the kidney with hypertrophy of the heart, in a girl thirteen years old, which had existed a long time before she came under my care last November, albumin was in February absent from the urine for nearly four weeks, during which period, however, the uremic symptoms were most prominent, there being congestive headaches, fainting, violent and irregular action of the heart, and occasionally a little oedema; but in no case was the gravity of the symptoms such that the death seemed likely to occur at any moment. At present (May 1st) she enjoys better health than for a year or two, except that she is thin and somewhat pale, and the hypertrophy of the heart is easily recognizable; she is entirely free from symptoms of every sort, and her albumin, about one-fifth of one per cent., can almost always be found. Thus one may have chronic albuminuria accompanying nephritis, and the health, with reasonable care, not greatly suffer thereby; while cirrhosis of the kidney may bring its possessor to death's door, and albumin be a great part of the time absent from the urine.

Specific Treatment of Diphtheria.—At a recent meeting of the Académie de Médecine, Dr. Delhilt read a memoir on 'The Specific Treatment of Diphtheria,' which may be summarized as follows. Fumigation with two hundred grammes of tar and eighty-three grammes of turpentine dissolves the false membrane of diphtheria. These fumigations are disagreeable neither to the patient nor to the attendants, and may be repeated every two or three hours according to the gravity of the case. They destroy parasites and micro-organisms. At the onset of the affection their use results in cure. The tracheotomy is the last resource, and the assurance that the chorda tympani is not affected should be obtained. Dr. Delhilt has devised a burner in which the above-mentioned substances may enter into combustion without danger.
A CASE OF LITHOTOMY.

Death after Eight Months from Miliary Tuberculosis—Autopsy.

By DUDLEY P. ALLEN, M.D.,
Lecturer on Orthopaedic and Minor Surgery in the Medical Department of Western Reserve University, Cleveland, O.

The following case seems sufficiently interesting to warrant its being detailed at some length. The details to be enumerated are an attempt at lithotomy, which failed; lithotomy, which was successful; subsequent miliary tuberculosis, and death, with autopsy.

The patient, a man of 44 years of age, had suffered during several years with difficulty in micturition. For several months he had drawn water wholly by catheter, and for ten weeks had not been out of the house. About March 1, 1883, I sounded the patient for stone, but could find none. The bladder was found to be extremely rough, and as there was no urine in the bladder and the search was made about only with difficulty, it was decided to sound a week later, when, with about four ounces of urine in the bladder, a stone was discovered.

March 15th lithotomy was attempted. For a considerable time no stone could be felt, but finally, by turning the beak of one of Bigelow's largest lithotrites down behind the pubis firmly downward into the base of the bladder, the stone could be touched. It could not be seized, however, by any manipulations, though a persistent effort was made.

The prostate was much enlarged, and an effort to push the stone upward with the finger in the rectum also failed. The conclusion was reached that the stone was encysted, and further effort to crush it was abandoned. Manipulation of the lithotrite had been very difficult on account of the great roughness of the bladder. The following morning the patient had no fever or pain. The urine was normal and there were absolutely no evil effects from the instrumentation. One week later it was decided to again attempt crushing, and if this failed to proceed at once to lithotomy.

This was done in the presence of Dr. Thayer, of Cleveland, and Dr. Noble, of Oberlin, by whom I had been called to operate the case, and who afterward aided me in caring for it.

Again crushing failed utterly, it being impossible to do more than just graze the beak of the lithotrite. Accordingly left lateral lithotomy was performed, and the stone was seized with great difficulty with curved forceps and removed. It was a stone in the form of a disk, 1/2 inch in diameter and 3/4 inch in thickness, with roughened edges and flattened upper and lower surfaces. It weighed when dry 76 grains. Although the incision was a large one, only the tip of the finger could be made to project into the bladder, and that only by pushing with considerable force. The lower lobe of the prostate could be felt projecting into the bladder perhaps half an inch.

It was noticed while washing the bladder with the finger in the wound that the outflow of water was not very free, but was thought to be sufficiently so to allow the escape of urine that might be secreted.

The patient stood the operation badly. The next morning, eighteen hours after the operation, his temperature had not risen above 97°, and the pulse was 130 and feeble. There had been constant nausea. The urine which at first had been discharged from the wound had ceased flowing, and the bladder was found on percussion to be full of urine. The water was drawn by means of a silver catheter, and though the amount withdrawn was not large, there immediately followed the most profound collapse and death seemed imminent.

The pulse was 160 and intermitting, the skin was covered with cold perspiration. There was alternately sighing and almost imperceptible respiration, the eyes were glazed and the lower jaw dropped. The pillows were removed, the foot of the bed was raised, hot bottles were placed about the body and limbs, subcutaneous injections of brandy and digitalis were given, followed by enemata of brandy. No reaction occurred for about two hours, when there was slight improvement and the patient showed some consciousness. Five hours later the temperature had risen to 99°.

During the week following the patient retained absolutely no nourishment on his stomach. Vomiting and hiccough were almost constant, hiccough continuing most of the time during sleep.

The patient was nourished solely by rectum, and was supplied by subcutaneous injections of morphia.

For two days following the operation the patient was catheterized at regular intervals, no urine passing by the wound, and the urine was extremely offensive. The third day a catheter was inserted and left in place, and the bladder was washed out, after which the character of the urine greatly improved.

After a week the patient's general condition began to improve and he gradually was nourished wholly by the mouth.

The catheter was removed from time to time, but, though attempted, it was found impossible to permanently remove it for five weeks. During this time the bladder was washed out at first with Sir Henry Thompson's solution of carbonate of soda and glycerine water, and later by a very dilute solution of nitrate of silver, which latter seemed very beneficial.

There seemed to have been no evil effects remaining from the prolonged retention of the catheter. The patient's improvement was now marked. May 8th, about six weeks after the operation, the wound in the perineum was healed; the patient could hold his water from 9 P.M. to 5 A.M., and during the day for about five hours, when he drew it with a soft rubber catheter. His relief was complete, the urine was normal, and he was riding and walking out. The first week in June, after a longer walk than usual, the patient was seized with pain in his left side, accompanied by some fever. I saw him several days later and found, on percussion, fluid rising to the nipple. June 18th, two weeks after the attack, I saw him again, and the fluid reached to the third rib in front, with the patient lying flat on his back. It was decided to aspirate, and exactly three pints of fluid slightly tinged with blood were removed.

There were afterwards no unpleasant symptoms accompanying or following the aspiration. There followed immediate and marked improvement and there was no re-collection of the fluid, and respiration and percussion were soon normal to the base of the lung.

In August the patient had an attack of orchitis in the left testicle, which continued several weeks and disappeared. In September followed a slight attack of sciatica in the right leg, the patient being subject to rheumatism.

At this time I reported the case to the medical society of this city, and from the paper read at that time I extract the following summary of the case: "1. The stone was evidently encysted, and thus could not be seized and crushed with a lithotrite; 2, although the prostate was freely incised, its size prevented the discharge of urine by the wound; 3, the catheter, retained by necessity in the urethra during five weeks, produced no evil results; 4, aspiration of a large pleuritic effusion in a man aged sixty-nine was followed by complete relief, no fluid re-collecting."

In conclusion, the case I cited two cases of encysted stones which I had seen in the hands of other surgeons. In one of these crushing had been attempted, and though the stones had previously been felt by others, at the time the operation was attempted no stone could be felt, and the operation was abandoned. Six weeks later the patient died, and at the autopsy two small encysted stones were discovered.
With regard to the failure of the urine to escape by the perineal wound I cited a discussion reported in the New York Medical Journal for January 27, 1883, in which Dr. Sands spoke of an experience similar to mine, in which he inserted a catheter the second day after the operation, leaving it in place eleven days.

Dr. Post, at the same meeting where this case was discussed, cited a similar experience, where death ensued, and also referred to a remark of Liston, of Edinburgh, stating that he was in the habit of leaving a catheter in the bladder after lithotomy. Dr. Weir also referred to a case of Dr. Buck's, followed by retention. My conclusion was that in cases where the finger is felt to be grasped by the bladder wall, it would be well to leave a catheter in the urethra.

With regard to the pleurisy, my conclusion was that, not having occurred until ten weeks after the operation for lithotomy, and being followed by complete recovery, it did not depend upon that operation.

After the above report was made, the patient was quite comfortable for some time. During the latter part of October, however, after a very rough ride he was not so well. He had a slight fever much of the time and his respiration was more rapid. I saw him November 10th, and at that time examined him carefully. In the left back there was dulness extending from the base of the lung up to the anterior angle of the scapula, but not reaching to the axillary line. There were no râles, but the respiration was very weak and jerky, and a positive diagnosis was not established. The fact that the serum which had been removed by aspiration was slightly tinged with blood suggested the possibility of some malignant disease. Occasionally the patient complained of pain, lasting for some time, in the region of the bladder. The patient gradually grew weaker and the respiration more frequent, so that he seemed oppressed for lack of air, and on December 2d, without other symptoms than slight fever and quickened respiration, he died, eight and a half months having elapsed since the operation.

The autopsy is of special interest when compared with the clinical history.

The right kidney was normal. In the pelvis of the left kidney were found several small stones, just of sufficient size to prevent their passage into the bladder.

In the bladder were found several gravel, which had evidently come from the pelvis of the kidney, and it had been their passage that had caused the pain. The mucous membrane of the bladder was somewhat roughened, but the chief point of interest was the large size of the prostate gland. The accompanying section of the bladder (Fig. 1) shows the size and form of the prostate when divided vertically. It will be seen that the lower lobe projects far into the bladder, and this is what prevented the stone being seized by the lithotrite, and what was felt when the finger was carried into the bladder through the wound. The second drawing (Fig. 1) represents the cavity of the bladder as seen from above, the superior lobe of the prostate being divided. The lower lobe was of such a size and shape that any contraction of the bladder caused this to act as a valve, covering the urethral opening, and thus preventing the escape of urine. It was this enlarged lobe that prevented the escape of urine through the wound after operation, and rendered necessary continued catheterization.

The condition of the interior of the bladder had doubtless been greatly improved by the removal of the stone and subsequent washing. It was behind and below this projecting lobe of the prostate that the calculus had been firmly held, so that it could not be removed by the lithotrite. The vesicle seminæ and vasa deferentia on either side of the base of the bladder were enlarged and indurated, and on opening the right it was found to be made up of a cheesy mass having a characteristic tubercular appearance.

The lungs were found on section to be pervaded throughout all their substance with miliary tubercles, so that there remained no healthy tissue whatever. The left pleural cavity was wholly obliterated, the lung being closely adherent to the costal pleura throughout. There was no remaining cavity containing pleuritic fluid. This had disappeared totally. The autopsy disclosed nothing further abnormal.

The following interpretation of the case is plausible and would seem satisfactory: The patient, suffering from...
PREDISPOSITION A FACTOR OF EQUAL VALUE WITH THE BACILLUS TUBERCULOSIS IN THE DEVELOPMENT OF CONSUMPTION OF THE LUNGS AND AIR-PASSAGES.

BY HARVEY L. BYRD, M.D., ETC.,
PROFESSOR OF OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN IN THE BALTIMORE MEDICAL COLLEGE, BALTIMORE, MD.

If the investigations which have been conducted with so much intelligence and energy since Professor Koch's announcement of the discovery of the bacillus tuberculosis have not actually established its agency as an essential factor in the development of consumption of the lungs and air-passages, they have, at least, to a more rational and perspicuous comprehension of the pathological conditions involved in tuberculosis. Such being the case, the duty would seem to be imperative upon all of us to aid, with our approval, at least, the efforts that able and self-sacrificing microscopists are making in behalf of the profession, both in this country and in Europe, if we can contribute nothing more. Entertaining these views, I feel quite well satisfied that, though much has been accomplished by the intelligent use of the microscope already, further efforts will, while dispelling much that is developed in the hypothesis of Koch, establish an idea of the origin of diseases, establish a truer and better system of inductive reasoning in regard to what is known or thought to be understood now by the profession generally. And if such investigations should lead to the discovery of the fact that all the diseases to which animated nature is liable or exposed have their origin in certain germs or micro-organisms that inhabit the water of the external world, except those caused or produced by traumas, the results of mechanical or chemical forces, it is easy to see that a great revolution in our therapeutics must take place at a not distant period of time. But whether Koch and his followers have actually found or discovered the true bacillus tuberculosis or not, the announcement has called into the field of investigative medicine some of the most industrious and able thinkers in our science, and the work they have already done seems to be an earnest of other and more enduring fruits to the profession than was ever known before. Already some new facts are being analyzed and systematized in a way that would have been impossible but for their perseverance, and to us, a quarter of a century ago, with the amount of value of the knowledge they have imparted to us in our daily intercourse with diseases. As far as can be gleaned from the medical periodical literature of the present time, it would seem that the malady—tuberculosis—which is annually dragging so many of the young and gifted of our race to untimely graves is being attacked through the agency of germs or organisms from without the body. It is not deemed necessary, while making this statement, to attempt to enter the arena of controversy, or to espouse with zeal any one of the theories concerning the essential nature or pathology of consumption, or whether a micro-organism having the ability to develop that disease in the lungs or elsewhere has been made manifest to our visual organs thus far. But I purpose, with your permission, to re-present for the consideration of the profession, some practical facts to which I had the honor to call attention a few months ago. It may be safely said in the beginning that a correct knowledge of consumption is of pre-eminent importance to the physician, now that all the races and conditions of the genus homo are more or less exposed to its ravages. I purpose to furnish some reasons, at a future time, why the mulatto, and even the negro, suffer from pulmonary consumption now, though the latter was thought to be entirely exempt from it until within the last few decades. If the proposition already announced is true, viz., that all the diseases from which except those of traumatic origin, are due to the presence of germs, bacilli, or micro-organisms existing or floating in the air or water—and I am quite satisfied that such is the fact...
—we have a sure, but probably not fully appreciated, at present, foundation upon which to begin the exploration of all of them, and channels thus opened through which to proceed to the Ultima Thule of scientific investigation if we will. Now, should heredity be admitted as a factor, and at its proper value in our studies of cause and effect, then we shall find our deductions and conclusions as to the origin and development of diseases rendered much less difficult of accomplishment. All intelligent persons, lay as well as professional, observe the resemblance to a parent, as seen in the tout ensemble of features, in the offspring. And in some instances a single feature is quite sufficient to impress one with the resemblance to a progenitor, or an ancestor for two or three generations back, as in the shape or development of the nose, mouth, etc. A case in point may be seen in the thick lips in an imperial house of Europe. Again, supernumerary fingers and toes have been known to occur in a family for two or three generations. These statements need no argument nor further illustration for their confirmation, and they should therefore afford reasonable assurance, even if the fact had not been demonstrated in some instances under the scalpel, that peculiarity in the form and structure in the internal organs and tissues are of equal hereditary transmission from generation to generation.

All medical practitioners of much experience know that it is rarely that a certain disease is to be found in almost every community, and accoucheurs are well aware of the fact that peculiarities in the shape and form of the pelvis and genital organs of females are transmitted from mother to daughter in many instances; and even that the physiological action of the uterus will be conspicuously marked in certain instances for several generations. If we should add to these hereditary transmissions, as I feel sure that we ought to do, a sphenic or an asthenic condition of the body, as of undoubtedly the same origin, in many cases at least, it will be found that too much emphasis has not been given to this point in the present communication to The Record.

Should the conciseness attempted in the foregoing sentences give rise to seeming ambiguity upon any of the points introduced, it will readily disappear when the two leading factors are added—to in the early part of this article, viz., the parasite or germ, and heredity, are properly considered in the development of consumption and its consequences.

Having been prepared, so to speak, hereditarily for the reception and action of the germs are they find a nidus or lodgement in the tissues of the respiratory apparatus, or elsewhere.

Being thus brought into juxtaposition, or contact, with each other, the seed finds a genial soil, and tuberculosis, or consumption, is the outcome. It would seem to be, therefore, logically certain, though we should not be able to demonstrate the fact with mathematical accuracy and precision, that if the bacillus tuberculosis has been really discovered, we have in the two above-named factors the means of clearing away the mists that have heretofore enveloped the pathology of consumption, and thus opened up to us a rational and correct basis for the employment of therapeutic agents in the treatment of that much-dreaded scourge of our race.

And if we should now add to what has been said already the fact that certain parasites and germs elect certain tissues and parts of the body or organism for their development and abode, and cannot be induced, in some instances at least, to trespass much, if any distance, upon neighboring localities, then that best possible police force for their operations, it may be readily understood why certain families are more greatly afflicted with consumption in particular climates and places than others are who have no hereditary or acquired preparation for the action of the germs of that disease, abounding in such localities, and may remain thus the neighbors of the unfortunate ones for generations, entirely free from its ravages. What may be thus true of the action of the bacillus that produces consumption of the lungs and air-passages, is equally true, I feel satisfied, in regard to the germs of other diseases under other circumstances. Nearly thirty years ago I stated, in a published article on yellow fever, and demonstrated, to my own satisfaction at least, but proofs that must stand the test of experience in the future, that it owed its origin to the action of certain germs upon the blood and other organs of the system (vide Philadelphia Medical Times, vol. iii, pages 726–739). And from observation and experience with almost every form of disease to which humanity is liable from that time until now, I feel assured that all diseases, at least, the suppurating or those that owe their origin to micro-organisms, germs, or bacilli, which exist in the air, or in the water we consume, or which result from actual contact with contagious or infectious matter! I will not trespass upon the attention of your readers but a very little further, however inviting the subject might be to me personally to continue its discussion, and will remark, first, that predispositions, either hereditary or acquired, seems to be essentially necessary as a "condition precedent" to the development of consumption or tuberculosis, and that a certain germ or micro-organism, probably the bacillus tuberculosis of Koch, always finds a nidus, or developing soil, in the predisposed surface to which it comes into contact. I now ventured to think that I look forward to a time in the not distant future when we may confidently expect to treat consumption successfully, as well as almost all other forms of disease, upon strictly scientific principles, and when contingency and empiricism may be safely and properly eliminated from our technical vocabulary.

ELEMINA AS A REMEDY FOR COUGHS.—Dr. Valenzuela has recently met with considerable success in the treatment of troublesome coughs by eleminin given in pill form or in tincture (El Siglo Medico). He employed it in bronchitis and phthisis in doses of one-eighth grain in pill ten times a day, or five drops of the tincture three times a day. In every case he states that the cough was moderated, the expectoration was lessened in quantity and became mucous, and the constitutional symptoms were greatly ameliorated. The drug also increased the appetite and improved digestion. It is possessed of no narcotic properties. Eleminin is not a new remedy, for it was known, though but little esteemed, by our fathers. Further trials with this drug will have to be made before the indications for its use shall be sufficiently clear and definite to establish its claims as a reliable remedy for coughs.

USE OF PILOCARPINE IN PLEURISY AND PERITONITIS.—An experience of several years induces De Dominicus to believe that great benefit may be obtained, not only in pleurisy and pleuro-pneumonia, but also in peritonitis, from the use of pilocarpine, rapid reabsorption of the exudation, even when copious, taking place. The author gives shortly the history of some of his cases of both chronic and acute pleurisy, in which the administration of jabonardi or of pilocarpine (by hypodermic injection) was followed by rapid recovery. When the effect was not obtained, it was due to some special complication of the disease. In the course of these experiments in treatment, the author made careful observations on the mode of action of the drug, from which he arrives at the following conclusions: 1. The injection of the heart, except during the stage of asepsis, is increased rather than lessened, unless the nutrition of the myocardium is interfered with. 2. The effects on the sudoriferous glands endure after the repeated administration of the drug. 3. Caffein and quinine moderate the action of pilocarpine.
RENAL SYPHILIS.—In an inaugural thesis by Dr. Negel, quoted in the Journal of Cutaneous and Venereal Disease, May, 1884, and the subject of renal syphilis: 1. Syphilis, in any of its stages, may affect the kidneys; the same is true of hereditary syphilis, in infantile or adult life. 2. Certain renal complications are precocious, others late. The first, only studied within the last few years, manifest themselves in the first months after infection with all the characteristics of the nephritis of the infectious fevers; when the debut of the chancre dates back several months, the clinical history of the renal affection is similar to cases of glomerulonephritis which are seen in scarlatina, for example. 3. Syphilitic nephrites occurring in the secondary stage are always grave accidents; nevertheless they are curable, not only in the acquired syphilis of adults, but also in the hereditary syphilis of childhood. Their gravity appears to bear a certain relation to the age of the syphils and the time which the patients have been subjected to specific treatment. 4. Albuminuria being the principal symptom in the examination of these renal accidents, we understand how specific nephritis may pass from view beneath the other secondary accidents of syphilis. When once the process is sufficiently marked to attract the attention of the patient and physician, another cause is generally assigned to it, so that syphilis is readily eliminated from the diagnosis. 6. These albuminuric patients being improved under the influence of specific treatment, and taking no further care of themselves after the secondary accidents have disappeared, the disease is slowly to issue its course; and, when, later, the patient comes under the care of the physician, it is more than probable that his suspicions will be directed to another cause than syphilis, especially since it so often happens that the patient declines to confess to a disease which he has every interest in concealing. It is necessary, then, when a patient presented to the physician has symptoms of an acute or chronic nephritis and the etiology generally adopted proves dubious, to think of syphilis and institute a specific treatment. If the patient bears any traces of syphilis (either upon the organs appreciable to view, or upon the visera, nervous centres, liver, etc.), these accidents only confirm the diagnosis of a syphilitic renal lesion. 7. Precocious syphilitic albuminuria is generally persistent and of quite long duration. There remains a question of extreme importance to be resolved: what will be the outcome, in a time more or less remote, of the secondary syphilitic nephrites considered as cured? The presumption is probable that a certain number of cases of Bright's disease may be the result of the latent form of this particular manifestation of the kidneys (precocious syphilitic nephritis). 8. Specific treatment gives the same results as in the other precocious accidents of syphilis. Milk diet should be regarded as a simple adjuvant, but not recognized as a necessity. 9. Renal complications occurring in an advanced stage of syphilis (tertiary and quaternary accidents) exist; presenting sometimes the character of acute or chronic Bright's disease, sometimes the characters of amyloid degeneration; in the last case, contrary to the opinion generally held, we think with Wagner that the amyloid kidney is a consequence of syphilis, and not of a concomitant suppuration or of a mercurial or venereal cachexia, for cases occur in which there is no suppuration, and the patients, far from being cachectic, are on the contrary quite vigorous. 10. These specific renal alterations are more grave than those which appear in the first years of syphilis. Nevertheless they may be benefited by specific treatment, the sole condition being that the renal lesion be not too far advanced; for, as in the case of the disease of the centres, we meet with exceptions. 11. Guma of the kidneys, although quite rare, exist; but no pathognomonic symptom reveals their presence during the life of the patient. It is probable that anti-syphilitic treatment will have the same results as in guma of other viscera.

THE HYPODERMIC ADMINISTRATION OF CALOMEL IN SYPHILIS.—Dr. Louis Jullien strongly advocates the above treatment in the Annales de Dermatologie et de Syphiligraphie, February 25, 1884. The author refers to the suggestion of this method by Scareenzo, of Pavia, and its further development to George Smirnoff, of Helsingfors, Finland. The proportions of the fluid used for injections are as follows: calomel, 10 to 15 cts.; gum arabic, powdered, 5 cts.; distilled water, 1 gm. The ordinary hypodermic syringes of Berwald is employed, but the needle must be at least three centimetres long. The author concludes that the method in question presents notable advantages over other modes of administration of mercurials, for the following reasons: Four injections of 10 cts. each, made two by two, on the buttock, at intervals of three weeks, suffice for the cure of an ordinary case of syphilis. Suppuration rarely follows the injections, particularly if these be made on the buttock. The method is equally applicable to the treatment of syphilis in all its stages, and is well tolerated even by very young children.

MALIGNANT TUMORS IN CHILDREN.—These tumors are, according to Picot, of not infrequent occurrence, and are most frequent in the first year of life. Congenital tumors affect, chiefly, the kidneys and the genitals, but tumors of the eyes and bones predominate later. After the seventh year, the frequency is much less and the tumors are less frequent. Boys are more often affected. Those organs which are the favorite seat of malignant tumors in adult life are seldom affected in childhood. The kidneys and the eye are involved with great frequency. Sarcoma and encephaloid carcinomata are the usual forms of malignant neoplasmata found in children. The cachexia is so characteristic in adults and the peculiar color of the face are seldom seen. The course is rapid. Adjoining villages are often endemically affected. Recurrence is frequent. The treatment is excision, as some permanent cures have been observed.

DEUTSCHE MEDIZIN.ZEITUNG, March 3, 1884.

COLOTOMY IN VESICO-RECTAL FISTULA.—Dr. Duménil, writing in the Revue de Chirurgie for April, 1884, complains that the French, though active in popularizing and perfecting the technique of colotomy, have hitherto made very restricted use of the operation. And it argues its employment in other complaints of the intestines, particularly in vesico-intestinal fistula. Although the operation in these cases has thus far been only palliative in its results, it is nevertheless allowable to hope that it may, in favorable cases, either alone or in connection with other means, lead to a radical cure of this distressing condition.

FAILURE OF JEOIRITY IN GRANULAR CONJUNCTIVITIS.—An original article on this subject by Drs. Galekowozi and Parissoti appeared in the Recueil d'Ophthalmologie for January, 1884. Four cases treated with jequirity are adduced as a basis for the conclusions reached by the authors of the paper, of which the following is a brief summary: The statistics thus far accumulated go to show that the so-called cures of granulations effected by jequirity consist only in a temporary amelioration of the symptoms, and that the disease reappears in its original severity, if not in a more aggravated form, soon after the cessation of the treatment. Some experimenters report successful cures with the drug in question, but the majority, among whom are Drs. Osio and Fortunati, of Rome, have found the remedy either inefficacious or even dangerous on account of the intense inflammation it excites. In three out of the four cases cited by Drs. Galezowski and Parissoti the granulations diminished with their original intensity, about two months after the application of the remedy. Pannus is favorably influenced by jequirity, but this result is obtained by the employment of any intensely irritating substance, and the action of jequirity in this particular is also merely temporary.
BENZOATE OF SODA IN SUMMER DIARRHEA. — Regarding summer diarrheas as a symptomatic disease due to the presence of a special microbe, Dr. Guaita was led to test the efficacy of benzoate of soda as a remedial agent. Life was saved, although in up to fifty cases occurring in children from six months to two years of age. In those cases in which the disease had existed for from twenty-four to thirty hours a cure was obtained in four to eight days, but where treatment was not begun until one or two weeks after the inception of the diarrheas, an average of twenty-one days was required to effect a cure. There were no deaths in the course of five years (calomel or jalap) the author administered a drachm to a drachm and a half of benzoate of soda in three ounces of water each day for two days. On the third day a laxative (magnesia or manna) was given, and then the administration of the benzoate was resumed. Within forty-eight hours an improvement was noticeable, the stools were less offensive and the vomiting ceased. During the treatment the giving of food was forbidden, only a few spoonfuls of wine being allowed. Nursing children were permitted to take the breast four times a day, but to older children milk was a forbidden article.

1. THE CAUSE OF DEATH AFTER SEVERE BURNS. — Various theories have been advanced at different times to account for the occurrence of death following burns of moderate degree though of considerable extent. Dupuytren thought that immediate death was often caused by excessive pain, the irritation of the nerve terminations inducing a paralysis of the centres. Others have regarded it as due to an arrest of the cutaneous perspiration, consequently of the respiration, due to the centres, with disturbance especially of the medulla oblongata. The fact that the danger of a burn depends upon its extent rather than upon its intensity, led him to see whether there was not some substance already present on the skin which, by rapid heating, might become changed into a poison and thus give rise to these disturbances. He supposed that sweat of a large part of the body, normally of acid reaction by reason of the formic acid which it contains, but this is neutralized on the skin by ammonia, forming the very soluble formate of ammonium, NH₂CHO. But when this salt is quickly heated it gives up its water and becomes converted into hydrocyanic acid, NH₂CHO = (H₂O) + NH₂CN. In order to give probability to this theory it is necessary to show that the symptoms following extensive burns or scalds are the same as those of prussic-acid poisoning, and also to demonstrate the presence of the acid in the blood. The first point is easily determined, for the symptoms of hydrocyanic-acid poisoning are similar to those following burns. The latter produce nervousness, headache, nausea, small pulse, and finally coma. The heart continues to pulsate after respiration has ceased. Examination after death reveals nothing beyond the very red fluid blood and intense intestinal catarrh. The second point is as yet undetermined. Catiano was not able to discover any prussic acid in the blood. But this negative result is hardly conclusive, he thinks, since the toxic dose is so minute and the poison itself so easily changed into other substances. Yet he believes that he has found evidences of its presence in the secondary changes produced in other organs—nephritis, embolism, intestinal ulcers, etc. As regards the therapeutics of burns, he only recommends thorough douching with cold water, and stimulates the nervous centres and to promote resorption.

NEPHRITIS A SEQUELA OF MUMPS. — At the meeting of the Verein für Innere Medizin, held at Berlin, February 11, 1884, Dr. Croner reported an unusual case of bilateral parotiditis which was followed, after an interval of ten days, by acute hemorrhoidea nephritis with all its characteristic symptoms. Simultaneously with the nephritis there occurred severe inflammation of the lymphatic glands at the angle of the jaw, on either side, together with inflammation of the neighboring connective tissue. The society was inclined to admit an etiological relation between the mumps and the acute hemorrhoidea nephritis, more than a local inflammation, analogous to the orchitis which sometimes complicates parotiditis.

*Deutsche Medizinische Zeitung*, February 25, 1884.
1 Psychosis from the Use of Chloral Hydrate.—Dr. Kirn reports the case of a man, thirty-five years of age, who was attacked with asthma five years since. At first the paroxysms recurred every eight or ten days. Two years ago a mixture of chloral hydrate 0.6, and morphia 0.05 was prescribed for him. He consumed one-half of this quantity in about a week. In December, 1882, the attacks have become diurnal, the patient took, daily, about 6.0 of chloral and 0.06 of morphia. Symptoms of chronic chloral-poisoning having appeared, the drug was first partly and then wholly withdrawn, small doses of morphia being administered hypodermically as a substitute. Hallucinations of hearing at once occurred, but were only present in the daytime. The patient lost 20 kilos in weight, and suffered from violent tenesmus, nausea, and neuralgic pains. This condition persisted about four weeks, when the symptoms of chloral-poisoning disappeared, and the asthma, which had been latent for this period, returned in its former severity. Dr. Kirn explains this psychosis by the assumption that vascular paralysis is occasioned in the central nervous system by chloral, and that the resulting venous congestion and arterial anemia produce trophic disturbances in the brain. —Centralblatt für Klinische Medicin, January 26, 1884.

Corrosive Sublimate in Granular Conjunctivitis.—In an original paper upon the use of corrosive sublimate in trachoma (Receuil d’Ophthalmologie, January, 1884), Dr. Dujardin, of Lille, gives the results of his experience with this remedy during a period of several months in a very large number of cases. Finding that the solution proposed by Sattler at the Heidelberg Congress in 1881, as well as that of Lego, was too weak to produce any decidedly caustic or astringent action upon the granulation tissue, Dr. Dujardin adopted a solution prepared according to the following formula: Corrosive sublimate, 1 grm.; alcohol, 10 grm.; distilled water, 240 grm. The remedy is applied, by means of a camel’s-hair brush, over the entire surface of the everted lid two or three times a week, and it is not necessary to subsequently neutralize the caustic with water. The author does not decide the question as to the modus operandi of the remedy, but suggests that the disinfectant properties of the sublimate may, by destroying microorganisms, materially assist the astringent action of the drug. Although the solution prepared by Dr. Dujardin is not to be condemned, it is not to be endorsed. Dr. Dujardin still prefers the nitrate of silver, and reserves the sublimate for cases of longer standing and for those complicated by pannus.

Treatment of Ascites Symptomatic of Hepatic Disease.—The permanent cure of ascites arising from disease of the liver, with obstruction to the portal circulation, is a thing often attempted and devoutly hoped for, but seldom, in fact, accomplished. Purgatives and diuretics have been freely used, and diaphoresis has had many advocates, but in the end resort is usually had to paracentesis. Richter has reported two cases in which a cure of this troublesome symptom was obtained by pilocarpine. The first patient had already suffered paracentesis five times, but each time the fluid reaccumulated more rapidly than before. After the sixth operation pilocarpine was exhibited in doses of one-fifth grain in an ounce of whiskey twice a day. Six days of this treatment sufficed to effect a cure, and the patient was able to leave hospital and resume his work. Five months later there was no sign of a return of the ascites.

In the second case three punctures were made, followed each time by the administration of one-third to one-half of a grain of pilocarpine. The improvement was successful. As an offset to these favorable cases Dr. de Luca states, in the Rivista Clinica e Terapeutica for March, 1884, that he had observed a trial of pilocarpine by the hypodermic method made in two cases without any apparent result. It would seem, then, that we have in pilocarpine a remedy of value in some cases, but unreliable in others. And it would, perhaps, not be amiss to make trial of the drug, where no contra-indications are present, after the bulk of the fluid has been removed by paracentesis, and possibly, after a more thorough test, it may be found to be of real utility.

Subcutaneous Vaccination.—In an article in the Bulletin Général de Thérapeutique of April 30, 1884, Dr. Bourgeois recommends the subcutaneous injection of vaccine virus. He claims that by this method the number of successful vaccinations is, at least, as great as by the ordinary plan, while the pain of which the patient is reduced to a minimum, and the inconvenience sometimes occasioned by a rather profuse oozing of blood is obviated. The procedure is also saving of time when a number of persons are to be vaccinated. He employs a needle of medium calibre, attached to a small rubber bulb, or preferably to a metallic box resembling an aneroid barometer. Two or three drops of virus are used for each injection. The caution is to be observed not to relax the pressure on the bulb until the needle has been withdrawn from the tissues. Two needles may be used when the economy of time is an object, one being cleaned by an assistant while the other is in use.

The Bichloride of Mercury in Fetal Bronchitis.—The universality of the wound-healing power of corrosive sublimate to arrest decomposition and destroy bacterial life would naturally suggest its use in purulent inflammations of mucous membranes so situated as to permit of the local application of the drug. According to Keyes, as we noticed in a recent issue, it is unsuited to the treatment of gonorrhoea, owing to its irritant effects upon the urethra, even when applied in very mild solution, but this is no argument against its utility in inflammations of other less sensitive mucous membranes. Korányi (Il Movimento, March 14, 1884) reported a case of pleurisy and mitral regurgitation, complicated with fetid bronchitis, in which inhalations of the bichloride were used with marked effect. The patient had previously used inhalations of phenic acid and turpentine continuously for four weeks with negative results. He was then instructed to inhale about half an ounce morning and evening of a solution of corrosive sublimate, 1 part to 10,000. At the end of six days he was apyretic, coughed but little, and the expectoration became much less offensive. A few more inhalations sufficed to render the bronchial secretion clearer and less offensive.

It seems not unreasonable to ascribe the amelioration of the symptoms to the remedy employed, and if further trials of the drug in similar cases are equally successful we shall have gained a valuable point in the treatment of this troublesome affection.

A Mode of Treatment for Paronychia.—It is pretty generally submitted that the evil results, as regards the usefulness of the finger, so often seen to follow from a felon, are due to neglect in the early stages, and might be averted by prompt and active treatment. The management at first is usually domestic, and consists in the application of poultices or ointments of various sorts. But the inflammation goes on, and finally, when medical advice is sought, it is frequently impossible to prevent necrosis of one or more of the phalanges, and at best, the last joint of the finger oftens remains stiff. In these cases Professor von Nussbaum advises an incision to be made down to the bone on one or the other lateral aspect of the phalanx, and prolonged across the joint to the next segment of the finger. The patient should be placed under an anesthetic, and the cutting should be continued until it is certain that the pus is entirely evacuated. The incision is made down to the bone instead of on the volar surface, so as to avoid wounding the flexor tendons. The cicatrix is also less apt to give annoyance when it is on the lateral aspect of the member. The observance of antiseptic precautions during the operation is enjoined.
OUR PUBLIC HEALTH SERVICE.

We are in receipt of letters from officers of the Marine Hospital Service requesting that publicity be given to the following statements in regard to the bill before the Public Health Committee of the House of Representatives, entitled "A Bill to Protect the Public Health," and which has been the subject of comment in these columns.  
1. "The bill in question was not under discussion as stated, but was simply introduced as a substitute to House Bill 2,785 (which was under discussion)."
2. "The grounds taken by those opposing the passage of House Bill 2,785 were that no further legislation was needed than that already existing under the act appropriating $100,000 to be used at the discretion of the President, and to establish quarantines at points of danger."  
3. "That if Congress in its wisdom thought further legislation was necessary, then to substitute for the bill under discussion House Bill 5,603, 'A Bill to Protect the Public Health.'"  
4. "That no efforts whatever were made, or have since been made, to obtain a favorable action upon this United States Board of Health bill."  
5. "That it was merely introduced to kill the bill then under discussion."

These explanations throw new light on the merits of the controversy, and on the motives of those engaged in it. On the one hand the National Board of Health is endeavoring to recover the powers and duties which it lost by the lapse of the law of June 2, 1879, which had four years to run, and expired June 2, 1883. House Bill 2,785, above referred to, is designed to accomplish that object. This bill is opposed by the Marine Hospital Service, one branch of the Board, on the ground that an annual appropriation of an epidemic fund of $100,000, to be used at the discretion of the President, renders further legislation unnecessary. This opinion is possibly based on the fact that, by the action of the Secretary of the Treasury, this fund, which was formerly among the appropriations of the Board of Health, is now expended at the sole discretion of the chief officer of the Marine Hospital Service, with the approval of the Secretary. If, however, Congress should deem legislation necessary, then House Bill 5,603, prepared by the Marine Hospital Service, and which creates the United States Board of Health, is to be substituted for House Bill 2,785, and thus not only "kill" that bill, but also the National Board of Health.

Thus it appears that two strongly antagonizing forces are struggling for supremacy in the field of national leg-
May 31, 1884.]  

THE MEDICAL RECORD.

MOBILITY OF THE BRAIN.

The paper recently read before the Académie de Médicine by M. Luys cannot fail to be of great interest to the physiologist.

The cerebral mass, he says, enclosed in the cranial cavity is surrounded by an empty space which permits its displacement in different attitudes of the body, and enables it to obey the laws of gravity. When a man is placed in an inverted position, the forehead being on a horizontal plane, the cerebrum glides from before backward; in the vertical position it always obeys the laws of its weight, recedes from the cranial vault, and leaves an unoccupied space at the vault. In a position of lateral decubitus the lower lobe sinks down and the upper presses upon it, slightly displacing the falx cerebri. In this position the vacant space is between the temporal lobes and the skull. Luys' experiments enable him to state that the gliding movement of the cerebral mass takes place in an automatic manner; that this movement does not take place suddenly, and that five or six minutes are required for the displaced part to regain its normal situation.

This mobility (or locomobility, as Luys terms it) of the brain should, from a physiological point of view, have a considerable influence in the phenomena of cerebral life. In the vertical position, the brain, in pressing upon itself, causes a certain degree of folding in the compressed parts. Hence we notice various ischaemic troubles in debilitated subjects who have been confined in bed for a long period of time; and that syncopal state known as sunstroke, which often takes place during a prolonged vertical position; and the various phenomena—vertigo, tinitations, loss of consciousness, etc.—which depend upon arrest of circulation in the basal capillaries. So true is this, that the empirical remedy, horizontalizing the patient, is one which nature always employs in order that the pressure upon the capillaries may be removed and the circulation re-established.

It is very probable that this automatic displacement may have a large influence in the causation of sea-sickness. The rapid succession of tosses experienced by the cerebral mass should be expected to contribute largely to the development of that curious state of nausea and cerebral malaise; and it is well known that the horizontal position will tend to relieve it. Even during the period of diurnal activity, the head being in the erect position, the locomobility of the brain should, by reason of its keeping that organ in one position, and by the constant moving about of the body, subjecting it to series of slight tosses or jars, cause a fatigue sui generis analogous to that felt by other organs. In the domain of pathology this phenomenon must necessarily play an important part. When the meninges become inflamed, thus interfering with the gliding movements of the brain, we at once see an array of very intense symptoms. Persons with cardiac affections or subject to frequent congestions of the encephalon often experience marked relief from the vertigo and other symptoms by change of position. Cerebral troubles, apoplexy, etc., are more frequent in the morning when the subjects suddenly assume the erect position. It is well known that nocturnal attacks of epilepsy may frequently be arrested by placing the sufferer in the erect position; and that nervous subjects who see disagreeable objects whilst lying down may be relieved by assuming an erect or reclining position.

At each expiratory movement there is an ebbing of the venous current toward the capillaries, so that when expiratory movements succeed each other rapidly, the cerebral mass is literally projected upward against the cranial vault. This explains the mechanism of certain cases of cephalalgia, especially that seen in infants with grave diseases. On the other hand, the concussions produced by an external cause, the repeated shocks during a long carriage ride for example, are known to cause cerebral fatigue, and often nausea. In young and healthy subjects this is not of especial moment; but in subjects of cerebral congestions, or hemorrhages, or softening, great damage may be done by a short journey, especially if the journey be rough. When these patients are compelled to travel, the distance journeyed each day should be as short as possible, and so arranged that the patient may be able to rest during the afternoon and night.

MEDICAL EXPERT TESTIMONY.

The North American Review, in its June issue, contains a symposium upon the subject of expert testimony. The contributors to lucidity upon this much- vexed subject are Drs. W. W. Godding and C. L. Dana, and Messrs. Roster Johnson and T. O'Connor Sloan. Mr. Johnson takes the ground that the remedy for the present defects in the methods of giving expert testimony is, not to pay the experts. They should, he thinks, be compelled to furnish their services on the same conditions and at the same rate of pay with ordinary witnesses. This view is strenuously argued against by the other contributors, who anticipate possible pecuniary losses if Mr. Johnson's view were adopted. The question of the special payment of experts has been much agitated in certain States where the law now compels the doctor to furnish his professional opinions to the court for a nominal charge. The medical expert is expected to testify as to matters of opinion as well as of fact. He is expected to interpret facts in the light of his scientific knowledge and professional skill. As he is asked to furnish that special knowledge by which he earns his bread and butter, it is argued with reason that the court has no more right to demand this service of the doctor than to require a carpenter to build for it a house, or a mechanic to make for it a special tool.

The other point brought up in the symposium in question was that of the mode in which experts are called. Curiously enough, Mr. Sloan, who writes as a patent-law expert, asserts that the present course of calling experts on both sides of the case is "an admirable method of reaching the truth as regards the scientific aspects of the question at issue." This opinion is not shared by medical writers, nor is it, we believe, in harmony with the general opinion of medical jurists at least.

It is agreed that the function of the expert is to instruct and enlighten the Court without exhibiting bias toward either of the contending parties. At present the experts are all summoned for the purpose of helping, not the truth, but one side of the truth, the only safeguard
against exaggerations and errors being the cross-examina-
tion.

It can hardly be expected that expert testimony can be given candidly and satisfactorily when the ex-
erts are specially called either to help plaintiff or de-
defendant.

The plans suggested for remedying the present evils
all agree in this one point, that the Court should summon
experts. Objection is made, however, to submitting the
case to one or more persons, however skilful and
impartial, for final settlement. This plan, which is fol-
lowed in France, would settle matters too peremptorily to
be satisfactory to the American mind. It would be
better, therefore, that experts be appointed to whom
technical and scientific questions be referred to be ex-
amined and reported upon. These experts can then be
cross-examined by the counsel upon each side.

Even if no such commission of experts be established,
some good might be accomplished by putting certain re-
strictions upon those who are summoned as medical ex-
erts. At the present the law can call upon medical
students, quacks, and midwives to serve as experts. In
cases of insanity this is especially unfortunate, and it
is particularly in regard to this class of cases that reform
in the methods of giving medical expert testimony be
brought about.

FRENCH MEDICAL JOURNALS AGAIN.

In the issue of The Medical Record for November 13,
1884, appeared an editorial, entitled "French Medical
Journals." We find that this has excited an amount of
comment among our confrères across the water which
was entirely unexpected, in view of the fact that the eyes
of the French medical journalist so rarely range beyond
the Parisian horizon.

The article was written for our American readers, and
was intended simply to state the impression made by the
perusal for a good many years of a great many French
medical journals. We intended to do no injustice, and
still believe that the criticism was in the main a correct
one.

The piquant imbecilities of the Moniteur de la Polici-
nique only justified our comments, and call for no reply.
But now L'Union Médicale, a journal of the highest char-
acter, has undertaken to contradict some of our asser-
tions, and to intimate that America is too young a coun-
try to presume to do anything but bow reverently before
Gallic models.

It is a most significant fact that the Old World has be-
come sensitive to New World criticism, and perhaps im-
plies that there is some justice in this criticism.

At any rate, L'Union Médicale admits at once that we
have "touched some of its wounds," and it kindly says
that possibly something may be learned from our sugges-
tions.

But it immediately makes amends for this concession
by uttering the following remarkable diatribe:

"Americans could hardly find models of clearness in
their own country, which they admire so much; where
the physicians believe themselves educators of the entire
world [sic], where the young medical student produces

'original works' upon the nature of molecular granula-
tions before he has studied the humerus, where science is
a collection of ill-digested facts, where the subjects are
entangled, where paragraphs are piled one upon another,
where the length of the sentences and the indecision of
the style cover with a uniform cloud shallow theories and
minuscule hypotheses."

We submit that this is hardly a specimen either of good
style or good taste. The question at issue is not that of
the scientific or literary status of American medicine,
and attacks upon it do not prove in the least that French
medical journals are of a high order.

We have stated that French medical journals on the
whole were provincial, that they do not keep their read-
ers acquainted with the progress of medical science
throughout the world so systematically and thoroughly
as is done by some journals in England, Germany, and
America. This is strictly true, and is in perfect harmony
with the acknowledged peculiarities of the French char-
acter. We have stated that they lacked individuality.
There are about one hundred medical journals published
in Paris, and the backbone of each of them is articulated
out of the same local society reports. For even the
Académie de Médecine is only a local society and no
better than some others. Editorials, if they exist, take
a narrow range, are not very vigorous, and apparently do
not command great weight.

The original articles seem to be contributed chiefly by
professors and their pupils, and it strikes the cis-Atlantic
reader that periodical medical literature is in the hands
of a set of "rounders." We are assured, however, by
L'Union Médicale that this is a mistake, and if so we are
happy to admit it.

Our contemporaries allude to our editorial article as
"anonymous," which in itself shows a curious lack of
understanding of English, American, and German jour-
nalistic methods. L'Union Médicale also seems to think
that all of our criticisms were directed to itself, when, on
the contrary, we expressly said that a few, a very few of
the leading French journals were nearly equal in every
way to those published in other countries. But Paris
publishes countless journals, and a country's journalism
or literature cannot be judged exclusively by the small
per cent. of what is best.

DISCUSSION ON TUBERCULOSIS.—Dr. E. O. Shake-
speare, of Philadelphia, writes: "I notice in the issue of
The Record of May 10th, in the report of the discussion
on tuberculosis, that I am quoted as accepting as pro-
ven 'that nothing but the tubercle bacillus could
produce tuberculosis.' This is precisely what I do not
regard as proven. I endorsed nearly all of Koch's
claims, but denied that one, and the following are the
words exactly as I read them: 'On the other hand,
whilst I am not now ready to admit that by actual proof
it has been demonstrated that no other agent than the
tubercle bacillus can excite the tuberculous process,
the same breath I most emphatically deny that it has
been satisfactorily shown that anything else is endowed
with such a power.' Will you oblige me by placing me
right on this question, by making this correction in your
next issue."
News of the Week.

Percentages Given by Instrument-makers.—It appears to be the custom among certain instrument-makers in this, and, we presume, other cities, to give the physician who sends them a patient to be fitted, a certain per cent. on the profits.

"The Collective Investigation Record."—The Collective Investigation Committee of the British Medical Association propose to publish a second number of the Collective Investigation Record early in July next.

A Druggist's Mistake.—A young lady died recently at Cherbourg in great agony after having taken an injection of aconite prepared by a pharmacist in mistake for pilocarpine. The druggist discovered his error shortly after it was committed and ran to the lady's house to warn her, but arrived just in time to see her expire.

The Study of Bacteria.—A laboratory for bacterial investigations has just been established in the Pathological Institute at Munich. The course of instruction will be conducted by Dr. Frobenius, one of the assistants in the institute.

Seaside Sanitarium in Austria.—The Common Council of Vienna has voted, at the instance of its Sanitary Committee, to send twenty scrofulous children to a seaside hospital, and it is hoped to establish a summer institution similar to the St. John's Guild of this city.

Illegal Medical Practice in Paris.—The notorious quack, known as the Zouave Jacob, was arrested in December last in Paris and condemned to sixteen days' imprisonment and to pay a fine of one hundred francs. He appealed from this decision, and the Cours des Appels has now confirmed the judgment and added thereto five hundred francs for costs. And yet nowhere is quackery more profitable than in Paris.

Medical Journalism in Russia.—The medical press in Russia shows signs of increasing prosperity. According to Vratch, a medical journal is soon to be established, which is to appear three times a week, and it is also contemplated establishing another periodical devoted to medicine and hygiene.

Association of German Alienists.—The committee has decided that the next meeting of the Association of German Alienists shall be held in Leipzig on September 16 and 17, 1884. Those desiring to present papers are requested to notify Dr. Nasse, of Bohn, before August 1.

The French Association for the Advancement of Science will hold its thirteenth annual session in the city of Blois from September 4 to 11, 1884.

Public Health Legislation in Massachusetts.—The opponents to the enforcement, by the Massachusetts State Board of Health, of the law to prevent the adulteration of food and drugs, have introduced an amending bill into the present legislature, by which they hope to destroy the efficiency of the present law. By those strange fatalities which affect State legislative bodies, says The Sanitary News, the majority of the members of the committee on public health are men inimical to the best health interests of the State, and the bill referred to was drawn and is championed by the chairman of the health committee. He has succeeded in securing a majority report in favor of his bill, but it is a report from the "unsound majority." A minority of the committee reports a good bill as a substitute for the amending bill.

Ergot, Grass, and the Kansas Epidemic.—We have received several communications kindly instructing us as to the relations of ergot and grass. We ventured to intimate, in a previous issue, that ergot does not usually grow upon grass. Dr. Salmon, of Washington, D. C., among others, has sent us references to some elementary text-books which state that it does grow elsewhere than on corn. This is not denied, but ergot is not usually nor commonly found on the grass which animals graze upon. Hence when it is asserted that an epidemic of ergotism has appeared among grazing cattle, the evidence that ergot grew upon the grass in large amount must be quite strong.

Dr. Stephen Smith.—The General Secretary of the Committee of Organization of the International Congress of Hygiene, Professor Van Overbeck de Meijer, has informed Dr. Smith that the Committee have selected him to read a paper before the Congress at its session, on August 25th next. The invitation has, we are informed, been accepted.

Dr. Morell Mackenzie's Work.—We regret to learn that the second volume of Dr. Morell Mackenzie's work on Diseases of the Throat and Nose, which has been so long looked for by the medical profession in this country as well as in England, has been destroyed in a fire which broke out a few weeks ago in the premises of Messrs. Pardon & Sons, printers, in the city of London. Fortunately some proof-sheets remained in the possession of the author from which the book can be reprinted, but the publication, which was near at hand, will, of course, be considerably delayed by this unfortunate accident.

Actinomycosis in American Cattle.—Professor James Law, of Cornell University, writes to the Journal of Comparative Medicine that actinomycosis in American cattle was recognized by American veterinarians long before Dr. Belfield described it. Professor Law had taught its true nature in his lectures and had treated it successfully with phenol. We fear that Professor Law has been alone in his knowledge up to a very recent time.

A Fortunate Medical College.—A dispatch from Cleveland, O., says that some wealthy Clevelanders, name unknown, has given $150,000 for the erection of a new building for the old Cleveland Medical Society, which now goes under the name of the Medical Department of the Western Reserve University. The new building will go up on the site of the old one, at St. Clair and Erie Streets. It will be four stories high, and measure 90 by 145 feet. A sufficient endowment to keep the college running accompanies the gift.

Something New in Degrees.—A dispensary in this city, under homoeopathic auspices, has an annual commencement and grants degrees of ophthalmic and aural chirurgeon—O. & A. Chir.
THE MEDICAL RECORD. [May 31, 1884.

Considerate Colleges.—The Detroit Free Press says: "The Cincinnati Commercial Gazette is authority for the intimation that the Ohio medical colleges will not take, hereafter, for dissection, the bodies of persons who have been obviously murdered for the purpose of sale. This will be a heavy sacrifice for the colleges, but it is no more than the community has a right to expect."

Reviews and Notices.

Mr. Wood has done a real service in placing this valuable and standard work in the hands of American physicians. Sanitary science is not a subject which the ordinary practitioner can pursue with avidity; in fact, it is something he has been inclined too much to neglect. This is partly because no practical and comprehensive work on hygiene which was at the same time cheap has been in the market. The present work has been carefully edited by both American and English editors, and it can be safely depended upon in the lines of which it treats. The late Dr. Parkes divided the study of hygiene into three branches, embracing the several epochs of human life in its relation (1) to natural conditions, i.e., soil, air, food, etc.; (2) to man's social and corporate relations as a member of a community with certain customs, trades, modes of living, etc.; (3) to man's capacity as an independent being having thoughts, feelings, personal habits, etc.

The present work follows in the main the classification thus laid down. The first volume treats of water, air, food, drink, clothing, and soils. The second volume treats of dwellings, exercise, climate, meteorology, individual hygiene, disposal of the dead, and prevention of diseases. A considerable part of this volume is devoted to the care of the soldier, a matter of slight importance to Americans. There is also a good deal said about disinfectants which might be left out.

The American Appendix contains some of the best chapters in the work. It covers the subject of "Water," by Dr. Elwyn Waller; "Character of American," by Dr. N. M. C. Strong; "Climatology," by Dr. J. G. Richison; "Ventilation and Warning," by Dr. F. D. Lincoln; "Removal of House Waste," by E. S. Philbrick; "Food Adulteration," by Dr. E. G. Love; "Some Hints to Sanitary Inspectors," by Mr. Frederick Owen, to whom belongs the credit of preparing and supervising the Appendix.

The present volume is prepared from notes of lectures delivered at the London Hospital in 1882. Like the previous volume it represents the results of a vast deal of conscientious labor as well as practical experience. In fact, the author seems at times to be painfully careful that no detail or phase of his subject escape him. Owing to this fact, and the tendency to classify and sub-classify, the work is not in all of its parts easy reading. The author's plan of not interpolating cases but of putting together at the end of his chapter is an excellent one and does much to keep up the continuity and interest of the discussions.

The present volume treats of legitimacy and maternity; pregnancy and abortion; rape, indecent exposure, sodomy and bestiality; live birth and infanticide; asphyxia, drowning, strangulation, and suffocation.

We can hardly criticise the method in which these different subjects have been treated. Perhaps the subject of sexual perversion receives less attention than it deserves, especially in view of the numerous recent contributions to the subject.

The chapters on hanging and suffocation are, aside from the microscopical pathology, very complete. One turns with some interest to the subject of the post-mortem appearances after hanging and strangulation, in view of the recent discussions over the Dwight case. The careful descriptions here given, when compared with the post-mortem record of Col. Dwight, show that there was almost nothing in the latter, aside from the hypothecated cause, to justify the view of self-strangulation, which Dr. Tidy's work, which this second volume finishes, will rank with the best treatises upon medical jurisprudence in any language.

The second edition of this useful little volume differs in no essential respect from its predecessor, which was published two years ago. This work is understood in our country to-day, it commends itself to the student as well as to the practitioner who may desire to refresh his memory without having recourse to the more voluminous treatises of Leishman, Playfair, Lusk, and others.

Practical Pathology. By G. Sims Woodhead, M.D., F.R.C.P.E., Demonstrator of Pathology in the University of Edinburgh, etc. With one hundred and thirty-six colored plates. Philadelphia: H. C. Lea's Son & Co. 1884.

There has been lately manifested a quite unusual degree of activity in the department of pathology. It seems as if in England, as well as in our own country, we had but recently come to realize the surpassing significance of this science, and its direct relation to the more practical branches of medicine. Besides translations of such standard works as Cornil and Ranvier, and Zigler, we have had several original treatises by English authors. All have been well received and still the demand for good pathology would seem to be increasing. Dr. Woodhead is of opinion that a thoroughly practical guide to the work involved in the preparation and examination of diseased organs and tissues has been a want so keenly felt as to have become almost a reproach to pathologists. Whether we are willing to admit this rather sweeping assertion or not, we must unhesitatingly pronounce the author's work a decided success. It is not a systematic treatise on pathology, nor even a complete index of all the tissue-changes that may be wrought by disease. But it forms a real guide to the student and practitioner who is thoroughly in earnest in his endeavor to see for himself and to do for himself. Not that the necessity of tuition is thereby done away with. By no means. But the work supplements, in a very thorough manner, the lectures usually delivered in our medical schools. And it is true that no work of precisely this kind has hitherto appeared in English. To the laboratory student Woodhead's "Pathology" will be a helpful companion, and all those who may wish to familiarize themselves with modern methods of examining morbid tissues are strongly urged to provide themselves with this manual.

A commendable feature of the book is the artistic beauty of the numerous drawings which illustrate the text. Moreover, these drawings are not fanciful pictures, or merely schematic diagrams, but they represent faith-
fully the actual images seen under the microscope. We are not of opinion that the work should have been burdened with synoptical descriptions relating to normal histology, a knowledge of which is to be presupposed before pathology can be profitably studied. Nor do we think that it was necessary to introduce explicit directions for conducting post-mortem examinations. It is also pain-
fully apparent that the different chapters are very une-
qually dealt with, the author having a seeming fondness for some organs, and perhaps a certain amount of con-
tempt for others. But these are minor faults, and may be easily remedied in a second edition. The work will be found so useful by increasing numbers of students that a new issue will doubtless soon be called for. In the meantime the author merits all praise for having pro-
duced a valuable work, and the publishers may be con-
gratulated on having creditably issued the same.

This work has been prepared, says the editor, with a desire to present in a concise form a practical manual of the diseases and injuries of the horse and their treatment, for the use of physicians and other intelligent horse-
owners.

We have no doubt that most physicians will welcome a book which tells them of the ailments of the horse. The present volume is written with clearness and concisness, and is well illustrated; the practical therapeu-
tical recommendations can also be trusted.

The illustrations are numerous and excellent.

**Bacteria.** By Dr. Antoine Magnin, Licentiate of Natural Sciences, etc., and George M. Sternberg, M.D., F.R.M.S., Major and Surgeon U.S.A., etc. New York: William Wood & Co. 1884.

In 1880 there appeared a translation of Magnin's work on bacteria, the translator being Dr. Sternberg. So great has been the progress in mycology within the past few years, that the book, which was then fairly representative of our knowledge on the subject, is to-day in more than one respect behind the times. Dr. Sternberg has, there-
fore, kindly consented, we think, to rewrite theodule, in order to bring it up to modern requirements. His own rich experience in this department of science, coupled with the fact that his clear judgment is never disturbed by undue enthusiasm for micro-organisms or exaggerated notions concerning their surprising signifi-
cance, render him peculiarly fit to accomplish this rather difficult task.

In its present shape the book is vastly superior to the issue of 1880. For those who take an interest in the study of bacteria and bacterial diseases, and they should include all earnest and conscientious physicians, the work of Magnin and Sternberg will commend itself as the best of what is actually known concerning these intimate and interesting topics.

**The Hip and its Diseases.** By V. P. Gibney, A.M., M.D., Professor of Orthopedic Surgery New York Polyclinic, Assistant Surgeon to Hospital for Ruptured and Crippled, etc. 8vo, pp. 412. New York: Ber-
tingham & Co.

This volume of four hundred and twelve pages and sixty-
four engravings reflects great credit upon its author and is justly meeting with a cordial reception on the part of the profession, because it supplies the want for a special treatise upon the lesions and conditions of the hip.

These have been until within a few years included under the general term of hip disease, without reference to the special anatomical and pathological features by which they are now distinguished.

Dr. Gibney aims to contribute something to still fur-
ther perfect Barwell's classification, and has succeeded in placing prominently before the reader pathological and clinical characteristics of some diseases of the soft parts which have not heretofore received due attention. His experience of thirteen years in the Hospital for the Ruptured and Crippled, where more cases of hip disease are annually treated than in any similar institution in this country, eminently qualifies him for this work, and he has labored to produce a volume, which he modestly depre-
crates in his preface, but which is very complete in the departments of pathology, symptomatology, etiology, and diagnosis. An introductory chapter is followed by one on the anatomy of the hip, containing many valuable and unusual features, and this is succeeded by one upon sprains and contusions, in which an effort has been made to render diagnosis easy, and some suggestions are given as to prognosis which the author claims are at variance with popular teachings.

The chapter upon nerves includes neurornimesis and is especially clear and forcible, while a chapter on rheumatism of the hip has been introduced, illustrated by several conclusive cases. Chronic rheumatic arthritis and coxo-femoral periartithritis are next considered, the latter being the term given to periarthritis of the acetabulum, and the author insists that these diseases appear long prior to the development of the acute symptoms as an essential point in the history. The subject of bursitis has been given a special chapter for the first time, and is followed by a chapter upon acute primary synovitis, which the author describes at length, and insists that the thorough study of a case would shake one's faith in the curative power of present disease.

Acute epiphysitis of the hip is a subject which is at present of growing interest, and the author thinks that many cases that have been habitually classed among cases of cogenital luxation and traumatic separation of the epiphysis, may now be looked upon as due to acute inflammatory diseases occurring in very early life.

The remainder of this chapter is devoted to a dissertation of the head of the femur, while the following chapter in-
cludes periostitis and malignant diseases. A large part of the volume is devoted to chronic articular ostitis, which is made synonymous with morbus coxaris, morbus coxae, hip-joint disease, etc., and its pathology is exhaust-
ively considered. After which the author introduces the chapters upon the etiology to define the relations between traumatiso and struma in an impartial manner.

Many other points of equal importance are elucidated in the chapters upon the clinical history, symptomatology and diagnosis, and a striking feature of this entire work is the number of illustrative cases which are cited from the author's record books.

The treatment of chronic articular ostitis as pursued at the institution with which Dr. Gibney is associated is extremely conservative, the method which he dignifies by the name of the 'expectant' being the ordinary course pursued. For this reason the pages devoted to the con-
consideration of the various more scientific methods based upon the use of mechanical appliances have the same value as the previous portions of this highly commendable work, since the present policy of the hospital is too restricted to permit their employment in its wards, and consequently the author's opinions of their compara-
tive merits do not evince that intimate acquaintance with the minutest details of the treatment which characterizes the rest of the book, and renders it so valuable. This is to be the more regretted, as this hospital, if man-
gaged upon more liberal and modern principles would prove of the greatest possible benefit to this department of surgery, by permitting impartial and intelligent com-
parisons of the various methods of treatment.

As a whole, this book is a valuable contribution to this special department of surgery, and reflects credit upon its originator, and will achieve for itself a prominent position in the literature of joint diseases.

On the whole the editor has presented a very complete and judicious collection of the therapeutic contributions of the past year. The book contains also some records of pharmacological studies which are of permanent value.

We make the criticism that the large proportion of the paragraphs are taken second- or even third-hand, the editor evidently not having consulted the original articles. Scant justice is also done toward American writers. The book is very well printed, and it will form a substantial addition to the physician's library.

This little work is an excellent guide to the charitable institutions of the city. It will prove of especial value to those who have occasion to contribute to eleemosynary institutions, or whose profession or business necessitates familiarity with organized charity. The insertion of advertising slips between the pages of the tract is to be regretted; but is perhaps open to extenuation for personal reasons. That some errors may have crept into the text is to be anticipated; but this is not surprising considering the extent of the subject, and the difficulties attending the collection of reliable statistics.

A HANDBOOK OF SKIN DISEASES AND THEIR HOMEO- PATHIC TREATMENT. By JOHN R. KIPFOX, M.D., LL.B., Professor of Principles and Practice of Medicine and Medical Jurisprudence, Chicago Homoeopathic Medical College, Visiting Physician to Cook County Hospital, etc., etc. Second edition, revised, enlarged, and illustrated. 12mo, pp. 292. Chicago: Duncan Brothers. 1884.

This little volume is more directly presented to the students and practitioners of homoeopathy. In it the author has given a very complete résumé of the essentials of practical dermatology. The anatomy, physiology, and pathology of the skin, together with the symptomatology, etiology and diagnosis of cutaneous diseases, first receive attention, followed by a description of each affection in detail, and its clinical history and treatment (Part II.). Part III. consists of a chart or tabulated form, wherein the several affections are systematically arranged, showing their diagnostic characteristics, together with therapeutic and dietetic observations. This latter will be found to be a most serviceable feature of the book. On the whole the matter is presented with a conciseness which will receive due appreciation, since the author states that the work is really a condensation of material originally intended for a much larger volume.

"I HAVE written this book," says the author in his preface, "for those members of the intelligent reading public who, without desiring to trench on the province of the physician and surgeon, or to dabble in the science and art of medical treatment of disease, wish to know the leading facts about the diseases of the human family, their causes and prevention. Anyone, therefore, who opens this book with the expectation of finding in it receipts and nostrums, will not have that expectation fulfilled, and will discover reference to no remedies except such as are purely preventive in character." Although the book is thus nominally a popular treatise, it is by no means wanting in interest or value to the professional reader. The usual, almost the inevitable fault with books of this kind is, that they are too technical for the layman, yet too puerile for the expert. Precisely the same difficulty and the same fault attend all efforts to teach a foreign language. Unless the author, who is for the nonce the teacher, is constantly on his guard, he unconsciously lapses into some medical idiom which bewilders and perplexes the student. Now, it is just this rare and happy sympathy with his hearers that raises Dr. Richardson's efforts as a teacher distinctly above the plane of mediocrity.

With a rhetorical vigor as charming as it is impressive, he unfolds his argument in a delightfully natural and common-sense way. His touch, at once firm and delicate, is never uncertain. His workmanship is always direct, and often artistic. He is incisive, never involved; terse, but never turgid. No detail is slurred, no grouping is careless or purposeless; while the final pose of each subject is always striking, forcible, and correct. He has carefully avoided anything like extravagance or excess of information so that the sonority is stamped on every page, he has not taken advantage of the untrained ear of his audience to inveigle them in the pursuit of personal hobbies. He has in this instance, as in former writings, kept free from the crying fault of all our efforts to "educate the laity," viz., a proneness to dispose of intricate subjects in a casual manner, or else to shower abuse of hopelessly scientific argot, with a view to dazzle the awestricken beholder, in much the same off-hand way a gymnast manipulates the heavy dumb-bells at the circus.

There is an air of quiet strength, however, in all that Dr. Richardson says that is far more telling than any display of literary or scientific gymnastics.

As the main drift of medical research is at present distinctly in the direction of the development of means for the prevention of disease, any honest attempt at an analysis of medicine from such a standpoint by an observer as candid and acute as Dr. Richardson appeals to the progressive physician. Especially must this be so when the method employed is strictly and thoroughly scientific, as it certainly is in this case. Very natural and very appropriately, the author addresses the public primarily because he recognizes that no progress can be made in preventive medicine without "a sympathy of action, based on knowledge, to enable every man and woman to assist." The benefit to the professional reader is that he has the whole weight of the author's presentation thrown from a fresh standpoint and hence gains a truer, even new, perception of many details, not to speak of a more intelligent grasp of whole subjects. He loses nothing from the truth being presented to him in simple language. The style is really rather a gain than otherwise.

Now, we are far from claiming that Dr. Richardson's treatise is not faulty. It assuredly is, both from a public and professional standpoint. We have noted the difficulties that assail the writer of a popular medical book. Dr. Richardson, with consummate tact, rarely gets his readers beyond their depth. That he does err often than usual in this case is to be attributed to the double motive of the work, which throws a double responsibility upon his pen. He must not only present the broad facts clearly to the public, but must preserve intact a correct analysis and treatment which will satisfy the technical critic. There is no such thing as perfection to be expected in such a task, a fact the author has well appreciated and frankly stated. We feel sure the profession will receive the importance of the subject which Dr. Richardson has, on the whole, so well handled, and do not doubt the book will soon gain the widespread popularity it surely deserves.
In this little work Dr. Oliver describes the various new urinary tests which have of late become the vogue. He gives his opinion rather in favor of sodium tungstate and potassium-mercuric iodide as the most delicate. Dr. Oliver also gives a new method of quantitatively estimating albumen, this method depending upon the variations in opacity produced by test-papers of given strength. A new method of quantitatively estimating sugar by indigo-carmine is also given. Dr. Oliver's main object is to present the merits of test-papers as carriers of the reagents necessary for detecting albumen and sugar in the urine. With these he believes that the practice of bedside urinary tests will be made more common as well as easier. Dr. Oliver rather exaggerates the importance or necessity of bedside testing. Even by his own showing, and with the test-papers, one must often have to filter and boil the urine. A serious objection also to all these new tests is that they require the use of citric acid, which precipitates mucus, and produces a cloud that may interfere with the subsequent reaction. The practical value of Dr. Oliver's book is great, but it does not depend very much upon the test-papers. And further, he tells everything except how to make them and where to get them.

The author begins with an anatomical and physiological résumé; he then gives the armamentarium necessary for treating nasal and throat disease. Then follows a description of the pharmacopia, manipulation methods, and special diseases. The book is systematic and clear. Being a "digest," details are necessarily omitted, yet these are things which the physician often needs most.

Reports of Societies.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, May 26, 1884.

ANDREW H. SMITH, M.D., Vice-PRESIDENT, IN THE CHAIR.

DR. MILTON JOSIAH ROBERTS read a paper on THE TREATMENT OF ANKLE-JOINT DISEASE AND THE MECHANISM OF ITS CURE, and presented a patient cured without deformity and without arthritis.

The general principle was laid down that, in treating chronic articular inflammation locally, while maintaining the function of the healthy joint, limited movement of the diseased one should be permitted under the restrictions of lateral tension, variously exercised under efficient resilient support, elastic linear sustentation, or traction, etc. The plan was analogous to that which he had already published concerning hip-joint disease, the pivotal idea being correlation and conservation of forces. We had been accustomed to regard a healthy joint as different in some way from a diseased one; but a study of the subject showed that health merged into disease and disease into health by imperceptible gradations, so much so that it was impossible to determine when one ceased and the other began.

The author of the paper submitted the following preliminary proposition: That studying a patient suffering from ankle-joint disease, resulting in a lowering or abolition of functional activity, ultimately becoming cured, so that the parts shall be strong and capable of performing normal functions, involved the conception of a series of transformations, the last of which is the return to the healthy state, also a series of metamorphoses from a condition of health to one of disease, and, further, of some fundamental cause for the effects produced.

The cause is called force. The forces which produce changes in inorganic bodies are called physical; those which produce changes in organic bodies are known as vital forces, and the latter are sometimes alluded to under two heads—vital forces of plants and vital forces of animals.

Forces produce definite effects, and the relation which exists between cause and effect is law. Law signifies previous intimacy between cause and effect; and also a constancy in their relations.

From these statements it followed that certain definite conditions must always produce from the same cause the same effect; that the same cause acting under different determining conditions may produce entirely different effects; that different causes may produce the same effect.

The author of the paper then reached the idea he set out to gain—namely—that varying dynamical effects may be produced by different statical environments; that the forces of nature are correlated; that the physical can be transformed into the vital force; that one vital force can be transformed into another; and that the determining condition of vital force, the same as of physical force, can be developed artificially.

The remedial problem, stated in general terms, was: Upon the acquisition of the controlling amount and kind of knowledge just indicated, it will be the duty of physicians to at once re-establish as nearly as may be, by artificial means, the normal equilibrium of the involved part, thereby giving physiological direction to the action of the vital forces. By such means it was confidently expected that the scientific physician would be able to rapidly and successfully conduct his patient from the condition of disease to one of health.

Passing the symptomatology, etc., Dr. Roberts directed attention to the therapeutic utilization and correlation of vital forces in the treatment of ankle-joint disease. Dr. Oliver gave an account of the condition of the patient referred to, and the author of the paper spoke of the conditions upon which a healthy ankle-joint depended, and reviewed the harmonious action of the physiological forces, and the fundamental determining conditions which gave rise to them. As an outcome he thought that was sufficient to encourage research in the direction that would finally enable the surgeon to transform pathological into physiological forces.

How are the environments involved in healthy action to be produced artificially in a given case of ankle-joint disease? The functions of the muscles have been interfered with, and they are in a state of reflex spasm, consequently the placing of these under the control of mind is one of the objects of treatment, and when this can be done, something in the way of surrounding the diseased joint with the environments of a healthy joint will have been accomplished.

There are several methods for accomplishing this, including circumferential compression, motion, elastic traction and support, etc. Immobilizing the joint operates against all the physiological indications. Although cure is effected under the influence of rigid traction and abolition of motion as far as possible, it is a long process. If the diseased joint can be immediately placed, by artificial means, very close to the physiological condition, so that all its component parts can perform as much as possible their function, such environments conduce to rapid restoration of structure where this restoration is possible.
Dr. Roberts then exhibited his apparatus, and also the patient, who suffered from supplicative carious inflammation of the ankle-joint and was cured in eight months without ankylosis and without deformity. He took issue with the statements made by an eminent New York surgeon who had recently published a series of cases of ankle-joint disease and said that it would be necessary for the patient to wear mechanical support during the active period.

The discussion was opened by Dr. F. Lange who asked Dr. Roberts if he referred to a paper which he (Dr. Lange) read before the New York Surgical Society, and published in its proceedings.

Dr. Roberts said that he did.

Dr. Lange said he simply wished to say that the statement of Roberts was erroneous, and that he did not mention that his patients would probably need mechanical support for life. On the contrary, he presented the cases and the plan of treatment to illustrate the fact that some of them had already, within a comparatively short time, regained very good functional result, and that as a precaution, until new formation of bone was complete, the patients should wear the apparatus which kept up the physiological movements and gave the parts support.

He thought that Dr. Roberts had not yet exhausted all therapeutic procedures in the treatment of joint affections. For the real nature of the disease, in by far the larger number of cases was tuberculous, and the extent and nature of the morbid processes must greatly influence the surgeon's decision concerning the kind of therapeutic procedure which should be resorted to. Despite mechanical appliances, there remains a certain number of cases in which the indication for excision exists. Before the actual value of Dr. Roberts' apparatus in the case presented could be determined, it was necessary to know to what degree the joint was implicated, which had not been stated. He could not imagine recovery with normal mobility occurring in a case in which there had been actual carious destruction of the joint. It should not be forgotten that, in children, almost the whole of the articular ends of the bones are cartilaginous, and the fact that a number of pieces of bone escaped from the fistulous openings, made it seem to him probable that the disease in Dr. Roberts' case, was located at the epiphyseal junction. To what extent secondary changes occurred was not known, and this should be stated before the efficacy of the plan of treatment could be correctly estimated.

Again, with carious destruction of the joint, it was necessary to determine whether the movements were apparent or real, as they were very apt to be apparent, and not really belonging to the joint, especially after some repair had taken place.

Dr. J. L. Corning had had the opportunity to see Dr. Roberts' case from the very beginning, and could vouch for the accuracy of all the statements that had been made concerning its history and treatment. The joint presented the same appearance as that for which he had frequently seen excision performed in clinics at Heidelberg and elsewhere. He regarded the principles upon which Dr. Roberts' plan of treatment was based as a substantial advance in scientific orthopedic therapy.

Dr. J. F. Ridlon said his experience had led him to believe that most cases of joint disease recover under the influence of fixation, protection from injurious concussion, and rigid traction to meet special indications. There were certainly many cases which called for protection of the joint, and the apparatus exhibited by Dr. Roberts failed to accomplish this. Doubtless, the patient presented was able to walk within a few hours after the apparatus was applied, but there were many cases in which it would not have afforded sufficient support. Traction to more than twenty or thirty pounds requires a perineal support to make it endurable and effectual.

Dr. Ridlon also cited a case in which just as good a result as that seen in Dr. Roberts' case, which was most excellent, took place without any treatment except cleanliness and the use of an ordinary bandage. That fact showed that possibly many cases would get well without any mechanical appliance, and that mechanical apparatus might get more credit than it was entitled to. He thought it wrong for Dr. Roberts to give the impression that a single form of apparatus was applicable to all cases.

Dr. G. R. Elliott had watched Dr. Roberts' case throughout, and thought that the duration of treatment was much shorter than it would have been by adopting the method of immobilizing the joint. He had yet to see a case which had not been fully relieved by the treatment, except some in which abscesses had formed about the joint, and there the pain was not relieved until the abscesses had been evacuated. If destruction of the joint occurs, the principle of converting pathological into physiological forces could be applied.

Dr. Levi regarded rest in the treatment of inflammation as the great essential, and thought that an apparatus which permitted motion in an inflamed joint was one that operated in violation of the laws of nature. He maintained that thwarting nature was prolonging the disease in this class of cases. What Dr. Roberts had done was included in motion and pressure, a method of treatment which had long ago been adopted for certain stages in this class of cases. Doubtless there are cases in which motion more than is permitted could be allowed with benefit, especially in the later stages of joint diseases; but there is a time when motion is detrimental.

Dr. Roberts said he did not bring his method forward as a cure for all cases, as there are cases in which no treatment will avail. He believed that protection of a diseased joint was afforded more surely by leaving the muscles so that they could act, and bringing the limb into angular positions so as to break the force of the concussional, than by rendering the limb rigid by means of mechanical apparatus.

Of course the diseased muscles could not protect the joint as could normal muscles, and for that reason artificial muscles were used to compensate for the loss of power, and then motion can take place without harm.

The report of the Committee on Hygiene, on overcrowding in public schools, was received and ordered to be printed in the minutes.

Dr. J. A. Irwin offered the following resolution, which was seconded by Dr. C. C. Lee, and unanimously adopted:

MEDICAL SERVICE ON TRANSatlANTIC STEAMERS.

"Resolved, That this Society, being convinced that the medical and sanitary administration of ocean steamships is unreliable, and often far from satisfactory, whereby many lives are needlessly sacrificed, and foreign infection is freely imported to this country, desires to press upon Congress the necessity of such legislation as may protect the health of citizens and intending citizens during the time of their journey, and guard against the now constant danger of epidemic invasion."

Unanimous consent being obtained, the by-laws were suspended, and the Society adjourned, to meet on the fourth Monday in September, 1884.

A NEW TREATMENT FOR TAPE-WORM.—A correspondent of the Medical and Surgical Reporter recommends the following: [B. Chloroform, ex. fil. maris, ââ 1/3; emul. ol. ricini (50 per cent.), f 3 iij. M. Sig.—All to be taken at once after twenty-four hours fast. He adds that in every case the medicine was well borne, and the worm expelled entirely. In two cases he omitted the male form, and the result was the same as when the latter drug was in combination.
THE THIRD GERMAN CONGRESS FOR INTERNAL MEDICINE.

 Held at Berlin, April 21, 22, 23, and 24, 1884.

HERR VON FREIRICH, PRESIDENT, IN THE CHAIR.

(Special Report for The Medical Record.)

(Concluded from p. 600.)

The morning session of Wednesday, April 23d, was occupied in a discussion upon

NERVOUS DYSPESIA.

HERR LEUBE, of Erlangen, reviewed briefly the literature of the subject, and then proceeded to give his conclusions derived from the study of a hundred cases of the affection. Since anatomical changes in the stomach are wanting, our observations must be confined to the clinical symptoms. During the continuance of the digestive process the patients are troubled by nervous symptoms of one sort or another, such as cerebral congestion, vertigo, lassitude, palpitation of the heart, aortic pulsations, etc. The symptoms directly referable to the stomach are those of congestion, eructations of an odorless gas, frequently nausea, and sometimes vomiting. A very constant symptom is a feeling of fulness and distress sometimes passing into eructation. The globus and heartburn are very commonly present. Sometimes there is a ravenous hunger, and sometimes the appetite is lost after taking a few mouthfuls. There is usually constipation, seldom diarrhea. The sleep is generally disturbed; the disposition is not joyous, yet a hypo-chondrial depression of spirits is infrequent. Some patients suffer from mental and all of these symptoms, while others may have but one, as, for example, a feeling of gastric fulness, although the digestion is perfectly performed.

Dr. Leube then detailed an analysis of the cases observed by him, noting the frequency with which each of the individual symptoms above mentioned occurred. The great difference between organic indigestion and nervous dyspepsia is that the former runs a more rapid and irregular course, while the latter is of a more purely symptomatic nature. In individual cases the diagnosis may be determined by observing whether the digestive process is completed within the proper time or not. The stomach is always emptied by the patient, although not without distress, as is evidenced by washing out the stomach six or seven hours after the ingestion of food. If it be empty, digestion is normal, and we have to deal with nervous dyspepsia. The affection consists in an abnormal irritability of the gastric nerves, which may be of peripheral or central nature, although in the latter case it must not be forgotten that the parasympus is always determined by irritation originating in the stomach. The cause of nervous dyspepsia may be found in septic infection, or the disease may be dependent upon uremia, malaria, or, finally, upon nicotine poisoning. Anemia or debilitating diseases of any kind may be the basis for the abnormal nervous irritability, or it may arise in hysteria or simple "nervousness." Finally comes the so-called reflex dyspepsia, from disease of the genito-urinary organs in either sex, or from constipation.

The prognosis of this affection is unfavorable. The author believed that a complete cure was very seldom obtained. Change of air, a carefully regulated diet, and the cold-water treatment he regarded as the most suitable therapeutic measures. Pyrogallic, which he had formerly looked upon with favor, had proved to be of little value.

HERR Ewald, of Berlin, regarded the classification of nervous dyspepsia among diseases of the stomach as a real advance, yet it was improper to confine the consideration of the question to the gastric symptoms alone, for often those referable to the intestinal tract were much the most prominent. He proposed as a more suitable name for the affection the term

NEURASTHENIA DYSEPSICA, AUT VAGO-SYMPATHICA.

He was disposed to differ somewhat from the last speaker in that he laid more stress upon the nervous, rather than upon the organic, or toxic origin of the affection. He regarded it as a symptom rather than a disease. He thought the examination of the contents of the stomach was often a valuable aid to diagnosis, yet by no means necessary in all cases, and even at times misleading. He had found remains of food in the stomach of a perfectly healthy woman seven hours after a meal, and on the other hand had found the opposite in cases of true disease. As regards treatment, the only object to be aimed at is the direct or indirect strengthening of the nervous system. For this purpose the speaker advised sedatives, especially potassium bromide, gymnastic exercises, sea or mountain air, a bland nourishing diet, and the avoidance of fatigueing mental or physical labor. Regarding the diet, he believed with Trouseau that the most suitable for each case was that which the patient preferred. Tonics might be indicated, but a proper management of each case was all essential. The doctor, and not the doctor's stuff, was what cured this disease.

HERR FINKLER, of Bonn, took exception to the name of dyspepsia for this condition, since there was in reality no dyspepsia. He also looked with disfavor upon the plan of washing out the stomach and thought it of very doubtful utility.

HERR SENATOR, of Berlin, thought that too narrow a view was often taken of the affection, and related a case of a man who had gone the rounds and had tried every variety of treatment for a supposed nervous dyspepsia, but all in vain until somebody treated him for tape-worm and cured his indigestion. The speaker said he had seen several women who presented symptoms of a typical nervous dyspepsia which were found to be due to wandering kidney. So changes in other organs outside of the stomach might give rise to purely gastric symptoms. He agreed with Dr. Finkler in regarding the examination of the contents of the stomach as of no certain diagnostic value.

HERR JURGENS, of Berlin, said the gastric symptoms were to be referred not alone to disturbance in the stomach and intestines, but that often there were lesions of the mesenteric and splanchic nerves.

HERR RÖSSLACH, of Jena, did not like the name of nervous dyspepsia, and proposed the appellation

DIGESTIVE REFLEX NEUROSIS

as less misleading, and as tending to distinguish these symptoms more sharply from true organic dyspepsia.

HERR RÜHLE, of Bonn, remarked that nervous dyspepsia might terminate in death through the refusal of the patient to take nourishment.

HERR MEINERT, of Dresden, was inclined to regard true nervous dyspepsia as of rather doubtful occurrence, and believed the cause could in nearly every instance be discovered by painstaking investigation. The great clinicians were anxious to increase their number of nervous dyspepsias, but the simple practitioner sought rather to take his cases out of such a category, to find the cause of the symptoms, and to cure the disease.

The afternoon session was occupied by the reading of a paper by Dr. Goltz upon

LOCALIZATION OF THE CEREBRAL FUNCTIONS.

After a brief review of the theories of Ferrier, Frisch, Hitzig, Schiff, and Munk, the speaker said that all these authors had arrived at only partial truth. There was no paralysis following the removal of the so-called motor centres, but merely a sort of difficulty in the use of the muscles; there was no true anæsthesia, but only under certain circumstances a deadening of sensation. His experiments showed that the modern theory of cerebral
localization was false. The dogs which had suffered a symmetrical loss of substance in the anterior lobes, were not paralyzed but were awkward in the use of their muscles. They could eat, but were unable to hold a bone by their fore-paws. There seemed to be a disturbance of co-ordination. There was at the same time an increase in certain of the reflexes. Scratching the tail would be followed by protrusion of the tongue, and ruffling the hair on the back of the neck would cause the animal to shiver. There was also a return of certain reflexes which are present in young dogs but not in older ones, possibly because the latter have learned that they are unnecessary and therefore restrain them. Another curious result of this destruction of tissue in the anterior lobes was the character of the animal's movements, because cross and fretful, snarling and snapping, and sometimes are seized with fits of rage. The exact contrary was observed in dogs in which the occipital lobes had been removed by a frontal incision through the descending horn of the lateral ventricle. These dogs became gentle and harmless, wagging their tails whenever any attention was bestowed upon them. This was especially noticed in those dogs whose former disposition was vicious. Besides this, although the dogs were not actually blind, deaf, etc., the special senses were remarkably blunt.

The author then exhibited a dog from whose brain the so-called motor centres had been removed in October last, and which presented the appearance just described. The dog was afterward killed, and on the following day Dr. Goltz demonstrated the loss of brain substance.

Dr. Günther had studied the question of the localization of the motor centres in a number of cases of wounds of the head. But his investigations had not gone far toward a solution of the problem, since the results obtained were by no means uniform.

Dr. Rosenthal, of Erlangen, thought that the fact of certain disturbances of function always following certain local diseases in the brain was too well established to admit of doubt. And if the results of experiments upon animals were not in accord with clinical facts, then the experiments were at fault. In Goltz' experiment the ataxic symptoms might be the consequence of a primary disturbance of sensibility.

Dr. Rothnagel, of Vienna, thought the contradiction between physiological experiments and clinical observations might be explained by the very great difference between the organization of the human brain and that of the dog. The motor functions of nervous supply in the dog might perhaps be analogous to the innervation of the lower extremities in man. In slight paraplegia in man the lower extremity may escape entirely or quickly recover its function, while the arm never, or only after the lapse of considerable time, recovers its power.

At the next session Dr. Rossbach, of Jena, presented a REPORT OF THE COMMISSION FOR THE TREATMENT OF INFECTIOUS DISEASES.

The object of this commission, as stated at the last Congress, is to discover specific remedies for those infectious diseases which as yet are without any known antidotes. This object is to be attained by systematic observations and experiments made by a large number of physicians throughout Germany. The speaker hoped that soon all would be joined shoulder to shoulder in a warfare against the great enemy—infected disease.

Dr. Rieker, of Giessen, next read a paper upon PREPARATIONS OF CAFFEINE.

Although digitalis will always remain the great remedy in cardiac disease, it is yet of importance to find some other drug which may be substituted for this when necessary. Caffeine is, in the speaker's opinion, such a drug. He regarded it as deserving a place alongside of digitalis, and in certain cases as even worthy of the first rank. As regards the dose, the author advised beginning with 16 grains (0.8 grm.) per diem, and rapidly increasing until the desired result is obtained. The maximum dose was 27 grains (1.8 grm.). It is best to give the daily quantity divided into a number of small doses. The effects are obtained more speedily than is the case with digitalis, and there is no danger of a cumulative action.

A communication from Dr. Unna, of Hamburg, concerning INTESTINAL PILLS

was then read. These are coated with keratin, which is said to act upon by the gastric secretions, but is soluble in the intestines.

Dr. Ewald had used silicate of soda as a coating for such pills, but had obtained no particular satisfaction from their use.

Dr. Schreiber, of Königsberg, then read a paper on THE PATELLAR TENDON REFLEX, in which he stated his belief that it could not be regarded as a direct muscle phenomenon, but rather as a reflex phenomenon.

Dr. Kühne, of Wiesbaden, described an article much used in Russia called \(\text{KEFIR}\).

It is very similar to koumiss in its properties.

Dr. Schumacher, of Aix, read a paper on HEMOGLOBINURIA AND SYPHILIS,

in which he concluded that very probably hemoglobinuria was caused by syphilis. He related a case in support of this view, in which very favorable results were obtained by an anti-syphilitic treatment of the disease in question.

Dr. Edlefsen, of Kiel, presented a paper upon THE ACTION OF POTASSIUM CHLORATE ON THE BLOOD.

His conclusions were that chlorate of potash could exert but little deleterious effect upon the blood as long as the absorption of oxygen was not interfered with.

The last paper of the session was read by Dr. Zülzer, of Berlin, and was entitled CERTAIN CONSIDERATIONS CONCERNING WEIGHT.

The author sought to determine the weight of a man per cubic metre.

Upon motion of Dr. Rühlle, it was determined to hold the next Congress in Wiesbaden.

Dr. Leyden then closed the labors of the Congress with a few words in which he said the members could look back over their work with satisfaction. In the discussions which had taken place considerable attention had been directed to theoretical points, yet matters of practical interest to the every-day practitioner had not been neglected, and it rejoiced him to say that the Congress had fulfilled its mission in this respect, and had opened up new paths for the physician to tread. In the name of the Congress he thanked all who had read papers or taken part in the discussions, as well as those who had by their presence and their interest contributed to the success of the meeting. Hoping to meet them all next year at Wiesbaden, he bade them farewell.

PRURITUS VULVÆ.—Dr. William Goodell, of Philadelphia, prescribes for this disease—Carbolic acid, 1 drachm; morphia sulphate, 10 grains; boracic acid, 2 drachms; vaseline, 2 ounces. Also, pat the parts with a sponge soaked in boiling-hot water. This is also the most excellent application for that rawness so often found between the thighs of the newly-born.—Louisville Med. News and Analytic.
NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, April 23, 1884.

GEORGE F. SHRADY, M.D., PRESIDENT, IN THE CHAIR.

DR. E. L. PARTRIDGE presented, on behalf of a candidate, a specimen of acute colitis occurring in the puerperal period.

DR. W. P. NORTHROP presented specimens illustrating GENERAL TUBERCULOSIS—RUPTURE INTO TRACHEA OF BROKEN-DOWN GLANDS—OBSTRUCTION OF RIGHT BRONCHUS—ASYMPHIA.

Patient is a female, aged two years and ten months, inmate of the New York Foundling Asylum. She had measles and scarlet fever a year ago, and has always been considered a delicate child. She was in usual health, with her nurse, out in the city, till five hours before death. After breakfast the nurse reports that the child was taken with a sudden severe "fit of strangling," followed by violent cough, and that followed by severe dyspnea and cyanosis.

The child was brought to Dr. Simpson, of the Out-door Department, the child was moribund.

Emetics were given, but did not act. The child grew worse and worse, and died, asphyxiated, five hours from the first attack.

On percussion the left lung gave a duller note than the right. Since there was nothing found in the left, at autopsy, to give an abnormal note, the conclusion is that the note from the right lung was exaggerated pulmonar y resonance. As for auscultation, posteriorly, no air could be heard entering either lung.

Autopsy, April 10, 1884.—Body: poorly nourished. "Rachitic Rosary" well marked. Frontal diameter of skull so contracted as to give a triangular shape to the calvarium. Long bones appear normal. Larynx and upper portion of trachea contained a large amount of tenacious mucus and pus. Lungs: On opening the thorax the right lung is found distended to its utmost, and does not retract. Distended alveoli are distinctly seen at the surface. The left retracts promptly the instant the pleura of that side is tapped. There are no adhesions over either lung. The trachea is cut across at about the middle portion and both lungs together are removed by separating the posterior attachments along the vertebral column from the cross-cut of the trachea downward. At the bifurcation and along the posterior and right sides of the trachea is found a mass of enlarged agglutinated glands. On opening into this mass a large mass of cheesy material, the size of an orange, is found protruding from both ends of the trachea. The trachea is opened, and is found to have, just above and to the right of the bifurcation, an aperture, the size of an old-fashioned silver three cent piece, communicating with the cavity in the broken-down glands. In the right bronchus is a plug of cheesy material and tenacious mucus tightly filling it. On grasping the plug and gently moving it from side to side air escapes from beside the plug in bubbles and with some noise. A fragment comes away in the forceps, and again the plug keeps back the air. Piece by piece the plug is removed, each time some air escapes and the lung collapses. Miliary tubercles in moderate numbers are scattered over both lungs. No consolidation except at apex of right, where it comes in contact with the mass of glands above described. Liver: Few small glassy miliary tubercles are found on peritoneal surface and on section. Spleen: Thickly studded with tubercles, rather larger and opaque in appearance. Heart and kidneys are normal. Stomach: Moderate congestion, probably from irritating emetics given just before death. Intestines: Mesenteric glands somewhat enlarged and tender. Bowel sounds distended, pale. Contents, yellow grumous material, with some tenacious, slightly greenish masses of mucus. Brain: Not examined.

Remarks.—The case presented to the out-door physician, then, was this: A child, two years and ten months old, rather poorly nourished, with a history of having been well till three hours before. It was then taken suddenly with "strangling," cough, dyspnea. The nurse announced that just before coming to the asylum she pulled from the child's mouth "four long worms." The larynx seemed free, there was no hoarseness, no stridor; but there was intense dyspnea, the child seemed "struggling for breath." In short, there were symptoms of bronchial obstruction, and a history of "worms" expelled from the mouth. At autopsy no worms were found, and doubtless the so-called "worms" were stringy mucus, which, to the excited mind of the nurse, seemed sufficiently large.

The death-book of the New York Foundling Asylum has records of several cases in which enlarged bronchial glands have given rise to medical physical signs. The most common of these is persistent cough, often paroxysmal in character. Such symptoms are frequently observed in poorly nourished children, the subject of numerous attacks of bronchitis or broncho-pneumonia. In one case there was well-marked asthma, due to pressure upon the bronchi.

In this case the broken-down glands opened into the bronchi, and emptied part of their contents into the lung, but so gradually as not to cause any bronchial obstruction.

The present case is one of general tuberculosi s and rachitis, in which the broken-down bronchial glands ulcerated into the trachea, plugged the right bronchus, and caused death from asphyxia.

BRONCHO-PNEUMONIA—GENERAL TUBERCULOSIS.

Dr. Northrup also presented the lungs of a case of broncho-pneumonia in which there was marked infiltration of the bronchi, and side by side with this a case of general tuberculosis with disseminated miliary tubercles in the lung. The second was without hesitation to be pronounced tubercle. There were tubercles in the liver, spleen, and brain.

The first case showed the same miliary light-colored spots upon a reddish background. These could be seen from the pleura and upon section of the lung. The case was thought from its history to be pneumonia of protracted course. In December, 1883, scarlet fever in January, 1884. Since that time the child had been out of observation, and returned shortly before death with ordinary signs of consolidation—bronchial breathing and high pitched rales. The case was presented together with the case of undoubted miliary tuberculosis, to illustrate how difficult it is at the routine of being, in certain cases of children's lungs, whether the bronchi are infiltrated and look like miliary tubercles, or whether there are indeed tubercles present.

The present case is thought to be broncho-pneumonia. It having been removed from the body only about four hours when examined, no microscopical report was prepared, and it would be reported at the next meeting.

DR. F. FERGUSON presented a specimen of THROMBUS OF THE RIGHT VERTEBRAL ARTERY, accompanied by the following history, furnished by Dr. Francis E. Dwight, Senior Assistant Physician, New York Hospital:

T. M., twenty-eight years of age; Ireland; single; salesman; admitted April 2, 1884. No family history obtainable. Patient has always been in good health. No alcoholic or specific history can be obtained. For the past five weeks he has complained of earache and headache. About three weeks ago a slight discharge began from the painful ear. Of late his headache has become worse, and he has consulted his physician, but until two days ago, when he had a sudden attack of convulsions. Since then he has been drowsy and stupid, or subdilios. On admission he was well nourished; his
temperature was 98° F., respiration 16, and pulse 56. There is no edema. The face is expressionless. Pu-pils normal. There is no paralysis, hyperasthesia, or photophobia. Reflexes are exaggerated. There is slight stupor. Utterance is very slow and hesitating. Respi-
ration and pulse are regular. There is retention of urine. Physical examination: There is no apparent lesion of the thoracic or abdominal viscera. Urine, 1,020 acid, no albumen; microscopical examination negative. Or-
dered potass. iodid, gr. xx. i. d.
April 7th: Since admission his temperature has varied from 97° to 102.5° F.; respiration, 15 to 24; pulse, 60 to 100. There has been no change in the patient's con-
dition until this morning, when he had a general con-
vulsion, followed by coma. Temperature, 97° F.; res-
piration, 18; pulse, 70. April 14th: During the past week temperature has been 98° to 102° F.; respiration, 18 to 30; pulse, 80 to 110. The patient has been alternately comatose and very restless. The pulse has become feeble and the tongue dry. There is obstinate constipa-
tion. The patient is stimulated with whiskey and dig-
itals. April 18th: There is no marked change. April 23d: Since last note, temperature, 98° to 102° F.; respira-
tion, 14 to 19; pulse, 100 to 150. There is an increase in the pulse and temperature. May 3d: The patient has been in deep coma. This morning his temperature began to rise, and at 3 P.M. was 107.8° F.; at 3.30 the patient died.

Autopsy.—One of the kidneys exhibited several small abscesses, but beyond that these organs were normal. The bladder was intensely congested. There was a purulent abscess which seemed to be in communication with the tissues of the pelvis, surrounded to a limited extent the rectum, and was possibly caused by the persistent reten-
tion of urine. The heart was normal. The brain showed thrombosis of the right vertebral artery, just where it blends with the left to form the basilar. There was some hemorrhage into the lateral ventricles, and the brain was considerably congested. Communication through the autopsy was made about twenty minutes after death. There was no point at which softening had occurred.

MYOMATA OF THE UTERUS.

Dr. Ferguson presented a specimen of multiple myo-
fibroma of the uterus, removed from the body of a woman, forty-five years of age, who had been in the presence of the United States in 1874, and a cook by occupation, who was admitted into the New York Hospital on March 26, 1884. Her menses had been always regular until one year ago, when she began to flow constantly but slightly. She first noticed enlargement of the abdomen in 1874, which she thought was more prominent on the left than on the right side. This enlargement increased in size, and she suffered occasionally from nausea and vomit-
ing. Two months previous to her admission into the hospital she complained of dizziness, headache, and great weakness. Her abdomen began to increase rap-
idly in size, and her feet and legs became swollen. She had dyspnea, and was obliged to keep in bed. On ad-
mission she was fairly nourished, suffering from dyspnea. She had moderate edema of the ankles. Her abdomen was distended with fluid. She was aspirated, and one hundred and ninety-two ounces of clear serum withdrawn from the peritoneal cavity, which gave her great relief.

After aspiration a number of hard, smooth tumors could be felt through the abdominal parietes. The peritoneal cavity was filled up after aspiration, and on April 1st she was again relieved of two hundred and eighty-eight ounces of ascitic fluid. She was stimulated and felt much relieved; she passed from six to twenty ounces of urine a day.

While her dyspnea was much relieved by each aspira-
tion, it continued, and with the return of the fluid in the peritoneal cavity it began again. She was again aspirated on April 10th, and one hundred and twenty-eight ounces withdrawn. She vomited latterly quite frequently; she was troubled with flatulence.

On April 15th she was relieved of two hundred and twenty-eight ounces of fluid from the peritoneal cavity, similar in character to that already referred to, and on April 20th she died from heart-failure.

On autopsy there were 5,500 c.c. of pure serum in the peritoneal cavity. All the organs were congested. The heart was flabby, its ventricular walls thin, and vegetation on the auricular surface of the mitral valve. During life a murmur was audible over the site of the mitral valve. The temperature ranged from normal to 100° F. The total amount of fluid which accumulated in the peritoneal cavity was about one thousand and eight ounces.

Dr. Ferguson also presented microscopic sections of these growths which showed the lymph spaces very well indeed. The tumors were multiple, and of the three varieties usually described—submucous, intramural, and subserous. One of the subserous tumors was nearly as large as a human skull of average size.

Dr. Lewis A. Sayre presented a specimen with the following history:

POT'S DISEASE OF SECOND TO NINTH DORSAL VERTEBRA OF THREE YEARS' STANDING—PARALYSIS OF THE LOWER EXTREMITIES FOR EIGHTEEN MONTHS—CURED BY PARTIAL SUSPENSION AND THE PLASTER-OF-PARIS JACKET.

Dennis C., thirty-five years of age; Cork, Ireland; signal-man on the Great Southern & Western Railway, Ireland. Does not remember of any fall or injury, but attributes his disease to lifting at the Punchtown Races in 1874, and remaining all day afterwards in wet clothes. He took a violent cold, felt very weak, and shortly after had swelling in the glands of his neck, pains between his shoulders like pins and needles pricking him, and cold, as if a piece of ice were there. After about five months he noticed that his knees gave way with him, the right one first. Dr. Hobart, of Cork, applied dry dressings to the spine, considering it to be a tumor. It was said that he was sent to the Northern Infirmary, in Cork, where he was under the care of Dr. Tanner for five and a half months. He then returned home, where he stayed three months, his mother being obliged to turn him over in bed, his legs now completely paralyzed. He then spent five months in the Southern Infirmary of Cork, and was transferred to St. Patrick's Home for Incurables in Cork, where he remained two and a half years, the curvature in his spine growing more marked, and all motion and feeling gone from his legs, so that after the nurse had put his feet in bed he would still think they were on the floor. He had to be lifted in and out of bed, and on to the closest stools. Dr. Hall Sayre, assisted by Dr. O'Sullivan, of Cork, applied to him a "plaster-of-
paris jacket," while he was partially suspended in the ward of St. Patrick's Home. The next day, while the nurse was lifting him out of bed, he moved his feet from the bed of his own accord, the first voluntary movement that he had made in nearly three years. In two weeks he walked about the wards on crutches, and in a week walked well without any support. He wore this jacket for two and a half years, when Dr. Hobart, of Cork, re-
moved it and applied another. Dr. Hobart informed me that when he removed the jacket there was not the slightest abrasion of the skin on any part of his body, and that he had never complained of the slightest incon-
venience, and for some months he had been doing full duty as assistant orderly in the hospital.

The jacket applied by Dr. Hobart, in January, 1880, was worn eleven months, and when removed consolid-
ation of his spinal column was complete, and the patient in excellent health. There was no abrasion on his skin, and he states that he never suffered the slightest incon-
venience from any hitch.

He came to this county in July, 1883, and got an ap-
pointment as orderly in the Lunatic Asylum on Black-
well's Island, under Dr. Macdonald, and remained there
until after the building was burned in January, 1884. He had not worn any jacket or other support for over two years, and was in excellent health, and did not have a very conspicuous deformity. He lost his position as nurse at the hospital after the fire, and for some weeks was severely exposed in walking the streets hunting employment. During this time he could have been attack with pneumonia about March 1, 1884. He was placed in St. Francis’ Hospital, in Fifth Street, on March 6th, and died very suddenly on the 9th, while eating his dinner.

I was not present at the post-mortem, which was made by some members of the house staff; but I was informed that death was caused by failure of the heart’s action from fatty degeneration.

I afterward obtained this portion of the spinal column and cord. The third and fourth dorsal vertebral are fused together, as are also the sixth, seventh, and eighth. The intervertebral cartilages between the other vertebrae remain quite distinct. At the junction of the fourth rib, with the vertebral was an encysted cheesy mass, the size of a hazel-nut. The cord has not yet been microscopically examined.

On motion, the spinal cord was referred to the Committee on Microscopy.

Dr. Sayre remarked that this was the first opportunity he had had to obtain an autopsy since he had removed the jacket in the treatment of spinal caries, and the specimen was especially interesting to him because the patient was not under his care, and yet it showed how complete a cure could be effected by the plan of treatment when carried out with ordinary intelligence.

Dr. W. M. Carpenter referred to a case in which the patient, at his suggestion, consulted Dr. Sayre, who applied partial extension and a plaster-of-Paris jacket. Mr. M., about fifty years of age, who had been humpbacked from youth, and also had a stiff neck, got crushed between a load of hay and the upper part of the door while driving into a barn. The violence inflicted upon the hump nearly killed him on the spot. From the immediate effects of the injury he recovered after a short time, but was conscious that his back was not as sound as it was before the accident. Not very long afterward he began to experience peculiar sensations in the lower extremities, soon accompanied by impairment of motion, which gradually increased until finally motor paralysis set in. The patient was examined by experienced neurologists, the jerking of the limbs being so violent as to necessitate fastening his feet and legs to the foot-piece of his chair to prevent them from throwing him to the floor. The bladder and rectum remained unaffected, and the appetite and general condition of the patient were good. The painful violent spasmodic movements of the lower extremities continued for more than a year, and then gradually subsided, although the paralysis of motion existed for about two years and a half, when he came to New York and was carried to Dr. Sayre’s office.

The extension apparatus was applied—the patient weighing probably one hundred and seventy pounds—partial extension was made, a plaster-of-Paris jacket was applied, and, after three or four hours, the patient was removed to his room, a few blocks away.

While applying the extension the patient had the idea that the more he could bear the better it would be for him, and therefore more extension was made than was just sufficient to make him comfortable, he being a man of resolution and willing to do all in his power to aid in the treatment. The result was that on the following morning paralysis of sensation in the lower extremities was complete. The jacket was divided at once and removed, and, within eight or ten hours sensation was as good as it was before the jacket was applied. Not a little discouraged, the patient resolved to return home, and left the city on the next day, but he carried with him a definite idea concerning the principle of the treatment, and had erected over his bed a set of pulleys, by means of which partial extension could be made, and this was practised more or less—gradually, cautiously—according to his determination and decision. It was not long before slight improvement began to manifest itself, which went on, and after a time he was able to walk some by the aid of crutches. At the present time, probably seven or eight years from his visit to New York, he is able to walk nearly, if not quite—his neighbors say better—as well as he could before he received the injury while upon the load of hay.

The case illustrates what can be accomplished, sometimes at least, by an intelligent application of the principle of treatment without support by any mechanical appliance, for he was unable to wear the jacket except in a very imperfect manner.

Dr. Sayre said he remembered the case very well. He also read from a letter just received from a patient in Longfield, Ireland, which sustained the experience in the case just related by Dr. Carpenter. The patient wrote as follows:

"There is one point on which I don’t think you dwell enough—the point—the turning-point of the whole. You are so convinced of it yourself, and you have that kind of mind that seizes the main point and does not go folliculating with petty details."

"Alpka. Extension in its ramifications. Suspension to produce far-reaching extension. Limb: extension produced by lateral pull; both resulting in separation of inflamed surfaces, restoration of normal posture to joint. Putting nature in a handy way of going about her own business, and all resulting in, produced by, and going back to, extension. Omega."

"Does it matter one straw how, why, or wherefore extension is made, or what kind of bar of steel, or wall of plaster, or lath, or wood supports the outer surface, when the principle is there?"

TREATMENT OF TAPE-WORM.

Dr. Thomas Wilde presented a specimen of the beef tape-worm, removed completely by a plan of treatment which he had adopted with uniform success in five other cases. The head of the parasite could be seen distinctly. He objects to having the patient fast, and believes that when the intestines are full the likelihood of removing the worm is much greater than when they are empty. Without fasting, then, he says, he is unable by examination of the faeces to discover the tapeworm. Two ounces of the bark of the pomegranate root made into a pint of infusion, and taken in the morning, say before eleven o’clock, to be followed in two hours by castor-oil, ⅕ iij.; oil of turpentine, 3 j.; ethereal extract of malefern, 3 j.

The Society then went into executive session.

THE LIMITS OF TEMPERATURE OF THE BODY IN HEALTH.—A correspondent asks for the best treatise on clinical thermometry, and says: "My particular question, at this time, is what are the limits as to temperature in healthy persons, so far as has been as yet ascertained? A child, aged five years, under my care had diphtheria in October last. She was now, he orders the following: "Two ounces of the bark of the pomegranate root made into a pint of infusion, and taken in the morning, say before eleven o’clock, to be followed in two hours by castor-oil, ⅕ iij.; oil of turpentine, 3 j.; ethereal extract of malefern, 3 j.

"Wunderlich’s "Clinical Thermometry" has been translated into English. A large number of references to the subject of temperature in health will be found in "Neale’s Digest," page 94."
Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

LONDON, May 17, 1884.

Dr. George Harley is a bold man. He has long been known as an able and original physician, but one not quite devoid of ambitious. He is an advocate of spelling reform, and some time since a medical article from his pen appeared in one of our medical weeklies with the reformed spelling used throughout. Dr. Harley would drop all redundant letters, as, for instance, where double consonants are used he drops one, and will spell tell.

As yet, Dr. Harley's eccentricities have been harmless, but he now seems disposed to introduce them into the domain of medicine. On the 13th inst. he read a paper before the Medico-Chirurgical Society, on what he termed "An Easy and Safe Method of Sounding for Gall-stones." The method might be safe for Dr. Harley, but it certainly was not so for his patient, who died of peritonitis. Dr. Harley contended that the temporary improvement followed the procedure adopted, but the Fellows present who discussed the paper were almost unanimous in condemnation of the method.

Dr. Harley's patient was a lady aged thirty-six, who had suffered for some weeks from symptoms of obstructed bile-duct. By the insertion (under anaesthesia) of a six-inch French trocar about two inches to the right of the umbilicus and a little higher up, and pushing it upward and backward, its point struck against a hard substance. This he presumed to be a biliary calculus, and to be about as large as a hazel-nut. The trocar was withdrawn, the punctures closed, and the abdomen bandaged. After the operation the signs of obstruction disappeared, and Dr. Harley believes the stone was dislodged. Convalescence began, but was interrupted by an attack of enteritis, and peritonitis ensued, ending in death, twenty-seven days after the sounding. At the post-mortem thirteen calculi were found in the gall-bladder, and the facets on one of them showed that another must have been present but not ascertained.

At last week's meeting of the Clinical Society a short but interesting paper was read by Mr. Christopher Heath on the treatment of recent patellar fractures. Mr. Heath's plan is to apply plaster-of-Paris immediately after the accident. He agreed with Mr. Hutchinson that the old idea that separation depended on muscular action was a mistake, but the difficulty was the fluid in the joint. Mr. Heath aspired the joint when necessary, but preferred to prevent effusion by enclosing the joint at once in plaster. This needed to be renewed in six weeks, and after three months he applied a leather splint to the knee and thigh. Three patients were exhibited on whom the plaster had been applied within an hour of fracture having occurred, and the result was that in each case there was short fibrous union.

Dr. Angus Smith has recently died. He was well known for his researches on the impurities of air, references to which are to be found in all text-books of hygiene.

I also have to record the death of Dr. Fairlie Clarke. Dr. Clarke was an Oxford graduate, and formerly in London consulting practice as a surgeon. He was attached to Charing Cross Hospital. A small manual of surgery by him achieved some success, and he made some repute by his studies on diseases of the tongue. Poets did not come in very fast, so Dr. Clarke finally determined to quit the arena of consulting practice.

This he did about eight years ago. He returned to Oxford to take M.D., and then began provincial general practice. He is not the first whom the res angusta domi has forced to quit the ranks of the consultants.

Recent actions of the Council of the English College of Surgeons have given great offence. This body has entirely disregarded the wishes of its fellows and members, as expressed in the late general meeting, and has made up its mind to persevere in the old track. One result has been the starting of an association of "Members" of the College of Surgeons. A society of "Fellows" was instituted a year or two ago, and was the main agent in procuring the concession to country Fellows of voting by proxy at the election of councillors.

The College of Surgeons is true to its own traditions as an obstructive of reform. Members have no voice. Fellows elect the Council, but, as voting by proxy is not un fait accompli, metropolitan Fellows have it pretty much their own way. The Council has all the authority and its members elect one another alternately to the presidency. I know of no instance on record where the freedom of election of officers is so practically denied.

Naturally these old fogies do not wish any deviation from the "good old plan." As for doing anything to promote the dignity of the profession, or put down unlicensed practice, "far be it from them!" The College in Lincoln's Inn Fields has indeed made itself contemptible.

A NEW ABSORBENT DRESSING FOR WOUNDS.

To the Editor of The Medical Record.

SIR:—In a recent editorial on the subject of "Antiseptic Field Surgery," you allude to Dr. Stevenson's suggestion as to the use of saturated sponges of staphylococci cut into small squares as a primary dressing. As a substitute for spongiopiline—a very expensive article by the way—I would suggest a dressing which I have been using for some little time as a dressing for operation and other wounds. This consists in the application of a piece of spun such as the dentists use as an absorbent. This substance I prepare for use by saturating it in a solution of the bichloride of mercury 1 to 200, and afterward drying thoroughly. In the majority of cases the wound is washed thoroughly with a 1 to 1,000 solution of the bichloride—a proceeding which would, of course, be impracticable in primary field dressings; it is then closed, preferably with catgut sutures, and the edges sprinkled with iodine. The dressing is then removed in about twenty-four hours. A protective moistened in the bichloride solution is then applied, and over this the sublimated spun is placed, the dressings being held in place by borated cotton and a bandage. I do not know but the spun has been used by other surgeons, although I have not heard of its use, but as far as I am able to judge it is the best dressing for all wounds to which it is practicable to apply it. It is cheap, and very easily prepared. It is a splendid absorbent, of close texture, and not impermeable to air—a point of great importance in my estimation, as it is filtration of the air rather than hermetic sealing of the wound that should be sought for. A by no means insignificant feature of the spun is its elasticity and compactness. Prepared as I have suggested it is a reliable antiseptic dressing, and when properly used, putrefactive changes in the wound-discharges can hardly occur.

I have several pieces that I have used in dressing wounds at different times; one in particular, that I used to dress a case of sloughing chancre simply as a test. All were saturated with blood and pus, it is elasticity dry when laid away, and at no time has any putrefactive odor been perceptible.

G. FRANK LYDESTON, M.D.

235 State Street, Chicago.

Vaccine Powder.—Reissner and V. Hager urge the use of vaccine matter in the form of a dried powder.
Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from May 15 to May 24, 1884.

WILSON, George F., First Lieutenant and Assistant Surgeon. Ordered to proceed to Fort Canby, Washington Territory, for temporary duty at that post, relieving Assistant Surgeon W. O. Owen, Jr., U.S.A., who will report in person at these Headquarters for further orders. S. O. 62, par. 5, Headquarters Department of Columbia, May 12, 1884.

Sternberg, George M., Major and Surgeon. Relieved from duty in Department of the East, and ordered to report to the Surgeon-General of the Army for temporary duty. S. O. 115, par. 3, A. G. O., May 17, 1884.

Magruder, David L., Lieutenant-Colonel and Surgeon. Ordered to be relieved from duty as Medical Director, Department of the Missouri, and to proceed to Philadelphia, Pa., and assume duties of Attending Surgeon and Examiner of Recruits in that city. S. O. 115, par. 7, A. G. O., May 17, 1884.

Fryer, Blencowe E., Major and Surgeon. From Department of the Missouri to Department of Dakota. S. O. 115, par. 7, A. G. O., May 17, 1884.

Ewen, Clarence, Captain and Assistant Surgeon. From Department of the Missouri to Department of the Platte. S. O. 115, par. 7, A. G. O., May 17, 1884.

Strong, Norton, First Lieutenant and Assistant Surgeon. From Department of the Platte to Department of the Missouri. S. O. 115, par. 7, A. G. O., May 17, 1884.

The Female Insane Criminals in the Auburn Asylum, N. Y., are in proportion to the males as 1 to 15.

Post-mortem inoculation of Tubercle.—A house-surgeon at St. Eugénie Hospital is believed by M. Verneuil to have become inoculated with tubercle during a post-mortem examination. The same accident, it will be remembered, occurred to Laennec, but he did not die till twenty years later.

A Case Illustrating the Course and Treatment of Traumatic Tetanus.—Dr. Louis Kolipinski, of Washington, D. C., sends us the history of a case of traumatic tetanus occurring in the service of Dr. Johnson Eliot at the Children’s Hospital. The patient, a child, aged seven years, had been kicked in the face by a horse about two weeks prior to the onset of the symptoms. The convulsions were general, and at first occurred ten times daily. By the end of a week they were reduced to two daily, or less. It was over four weeks before the child was entirely free from the bromide of pannas, chloral, Calabar bean, and whiskey were used in large doses, and with evident effect, as shown by a carefully prepared chart which Dr. Kolipinski has sent us: "There was used during the treatment 720 grains of chloral, 960 grains of potassium bromide, 2 fluid drachms of fluid extract of Calabar bean, and 36 fluid ounces of whiskey. The patient was seen in daily consultations by the general practitioner of the Consulting Board and the attending medical staff of the hospital. As points of interest in this case were: 1, involvement of the upper extremities; 2, no constipation; 3, the facial paralysis; 4, no evening rise of body heat, and the almost normal temperature which was present after the sixth day. The evening increase, which Dr. Kolipinski says occurred at the same hour, might have been prevented by the remedies, and seems to show that they influence the tetanic contractions, which, in part at least, are the cause of the elevation. As this observation was made on but a single case, it yet remains to test its accuracy."

"The American Journal of Ophthalmology" is the title of a new monthly periodical published in St. Louis, and edited by Dr. Adolf Alt in conjunction with a number of other representative specialists. The first number contains only original articles, most of them being interesting and valuable.

The Bacillus Question.—At a meeting of the Cincinnati Medical Society, March 25th, Dr. Sattler said that while no bacilli were found in the breath of phtisisical patients, yet plates of glass covered with glycchine and hung in consumptive wards became covered with bacilli.

Removal of Both Ovaries to Prevent Loss of Vision.—Dr. Priestley Smith, in the Ophthalmic Review, details a most interesting case of a young woman suffering from blindness, and relieved by removal of the ovaries. The patient was a married woman, aged twenty-four. She had suddenly and completely lost the sight of the left eye after a fainting fit, consequent upon ovarian or uterine disease, as it was preceded by pain in the pelvic region. Subsequent attacks of the same nature affected the right eye temporarily, its field of vision becoming permanently lessened. The retinal arteries of the left eye were shrunken and the disk pale. The ovaries and Fallopian tubes were removed, both being diseased. Vision was restored in the right eye.

A Formula for Use in Irregular Heart Action.—In a discussion upon heart disease before the Boston Society for Medical Improvement, Professor Bowditch said that he had found the following formula of great service in relieving even the most serious cardiac affections. He had used it for the last twenty-five years: B. Pulv. digitalis, gr. x; pulv. colchici sem., gr. xx; sodii bicarbonat, gr. xxx. M. et div. in pil. viginti. One of these is to be taken three or four times daily at first; subsequently to be reduced until only one is taken at bedtime; the treatment to be continued from three to nine months.—Boston Med. and Surg. Jour.
THE MEDICAL RECORD. [May 31, 1884.

PILOCARPINE IN HICCough.—Dr. W. C. Pipino, of Mexico, Mo., reports another case (St. Louis Courier of Medicine) in which a hypodermic injection of pilocarpine cured an obstinate case of hiccough.

DARWINISM AND CIRCUMCISION.—A correspondent writes: "The only explanation I have ever heard given by a scientific man to the fact of Jews continuing to be born with foreskins, is the witty reptare, attributed to Professor Huxley, who immediately answered the question, when propounded by a country clergyman, with the quotation, 'There's a divinity that shapes our ends, rough-hew them as we will.'"

THE PASSAGE OF A PENNY THROUGH THE BOWELS.—Dr. Samuel W. Francis, of Newport, R. I., writes: "An interesting case is reported in your journal of a penny accidentally swallowed being discovered in the fecal passage six months after. This is not always the case; for a young patient of mine swallowed a nickel cent one morning. An emetic, administered soon after by me, not bringing it up, I gave a large dose of castor oil, when she passed the penny before the twenty-four hours were over. On another occasion, a little girl swallowed a glass marble. I saw her some two hours after, and having tried an emetic without success, I administered a cathartic, which caused her to pass the marble in some ten hours from the time that she had swallowed it. The size of the penny and its lodgment, may have caused the delay in Dr. Ten Eyck's case."

ERYsipelas IN INFANTS FROM THE SCRATCH OF A PIN.—Dr. M. J. B. Messemeser, of this city, deputy coroner, sends us the following notes: "A nurse, in changing the diapers of a baby child eight months old, accidentally pricked its skin with a diaper pin. Traumatic erysipelas set in, and four days later the child was dead. A mother, whilst fastening the bandage about an infant two weeks old, accidentally scratched the skin with an ordinary pin. Traumatic erysipelas set in, and the child, which was otherwise healthy, died from the effects of the erysipelas in forty-eight hours."

THE CAUSE OF SUDDEN DEATH IN GANGLIONE OF THE HAND OR ARM.—Dr. M. J. B. Messemeser writes: "Frequently patients suffering from gangrene of the right hand or arm die suddenly. A little girl, about six years old, cases that the cause is the gangrene which follows an injury to the right hand or arm, or frost-bites will send its gases along the veins of the arm into the vena cava and right side of the heart, and as soon as the gases reach the heart death results from collapse or syncope. On cutting into right side of heart a puff of gangrenous gas can be plainly smelt."

NOTES ON THE ETIOLOGY AND TREATMENT OF TONSILLITIS.—Under this head Dr. W. H. Dudeman, of Oleum, N. Y., sends us a brief communication. Dudeman thinks that "tonsillitis is a local disease, to which certain persons are predisposed. Its exciting cause is the vitiated air of houses or exposure. Acute attacks can be successfully treated or aborted, in his experience, by aconite and gray powder in small doses. The chronic form can be successfully and rapidly cured by electricity. In chronic cases the aconite treatment is of no avail. I have also tried astringents and escharetics, put my patients on good tonic treatment, and have sacrificed the glands to relieve the chronic congestion. But the results were unsatisfactory. I then thought I would try the use of electricity, and in this agent I found a remedy which gave perfect satisfaction and speedily cleared up the galvanic shock; passing an electrode of the positive pole on the back of the neck, and the metal tonsil electrode of the negative pole on the tonsil. A mild current is used for from five to thirty minutes every few days. In some cases where the tissues are much relaxed, I use in connection the primary faradic current."
Original Articles.

THE TREATMENT OF SCIATICA BY THE STRONG GALVANIC CURRENT.

By V. P. Gibney, A.M., M.D.,

New York

The treatment of sciatica is a subject in which the practitioner always feels a deep interest, and the knowledge of this fact induces me to seek a manifestation of that interest this evening. A discussion is what I especially desire, and while my title would direct your remarks to the strong galvanic current as a therapeutic agent, I am far from desirous that you should confine the discussion to any one agent. If my own preference for galvanism stands out conspicuously, it is because I have been fortunate enough to ensure permanent relief to the greatest number of sufferers by this one agent, and because I have been able to bring about that relief in the shortest space of time.

I would not have you infer, however, that I have not employed other means, and that I have not secured good results by the same. Next to galvanism the thermo-cautery has served me best. Fowler’s solution of arsenic, in the way of drugs, has yielded an occasionally brilliant result. The hot-water douche, that radicure current, and the static electrical machine are all familiar to me as agents that sometimes afford prompt and permanent relief.

The present remarks I shall make must not be considered as a new paper, or as, indeed, an old one. I have already on two former occasions presented this subject, fortified by statistics and instructive cases. Before the New York Academy of Medicine, February 6, 1879, I presented my first paper, and detailed the histories of fifteen cases, all of which were published in the American Practitioner, in March and April of the same year. Before the American Medical Association, which met in New York in 1885, I presented my second paper, and gave the results of thirty-two cases, subsequently published in the Transactions. These were statistical papers, and the present one is prepared more as a confirmation of my faith in the efficacy of the strong current, and as a means of offering explanation of the failures the plan has met with in the hands of other practitioners. Occasionally a medical friend tells me that he can’t get the results I get. In my hospital service, where I have had abundant opportunity of drilling new men, I find very often reasons of failure. I think, therefore, I am prepared to answer the objections that may be offered, and the freest criticism is invited.

Before one can judge of the value of any given therapeutic agent, a knowledge of the natural history of the disease under consideration is indispensable. It is equally important, too, that diagnosis be at one’s fingers’ ends. Time and again I have heard some orthopedist say that he is treating a case of hip-disease which some other doctor had treated for sciatica. Ordinarily there is no difficulty in making a differential diagnosis. Errors in diagnosis come, as a rule, from neglected examinations. Men grow too self-reliant, place too much value on their supposed power to make a diagnosis from a few symptoms given. Let one make a physical examination, compare the functions of the two hips, search for tender points, learn the distribution of the pain, the history of paroxysms, etc., then errors will be very infrequent.

Given, then, a case of uncomplicated sciatica, acute or chronic, the treatment by the strong current, I am convinced, by still further clinical observation, will effect a cure in a short time. I am not referring specially to acute cases, but I have in mind those of long duration wherein the exacerbations are frequent and very severe. The intermissions, we all know, are often marked by almost complete relief from suffering of any kind, while in many instances the pain is constant during the waking hours. There is always a dull, heavy pain, aggravated by exertion, by temporary excitement, and by exposure. During the exacerbations the pain may be excruciating. Sciatica which is symptomatic can often be recognized by a careful examination.

I wish now, before going into the details of the treatment, to reaffirm that when rheumatism unquestionably stands in a causative relationship, the galvanic current, in my experience, only aggravates the pain, while the radicure or the static current will give decided relief.

The kind of cell that I have employed and still employ is the Leclanché cell, and I am forced to the conviction that the current from these elements is less painful, and exercises a more soothing influence on the nerve than that from any cell with which I am acquainted. Just why it is so I cannot tell. Some of my friends who have followed the methods I advocate tell me that they induce is simply intolerable, and on investigation I find that the battery used was the ordinary portable bichromate battery in such general use. I have myself on a few occasions employed such a battery, and my patients complained bitterly of the pain, while I find it exceptional for them to complain when I employ the Leclanché current. Not that there is no pain—far from it—but it is an endurable pain, and so mild compared with the suffering induced by the neuralgia that it is borne with a kind of satisfaction. The idea that a Leclanché battery must be expensive prevents its general use. Yet I am quite sure that many of our neurologists have come to regard this as the least expensive in the end. It seldom gets out of repair, the connections are simple, and one soon becomes familiar with the strength of the current desired. The chief objection to the practitioner is that portable batteries are not constructed with these elements, so many being necessary to the strength one needs. Again, too, in the permanent batteries so many accessories are attached by electrical instrument-makers that the expense and the complications get to be decided objections.

For several years I have used only a current selector made of plain walnut, on the face of which is a dozen or so nickel-plated buttons, and arranged in a circle, while the winch is arranged like the radius of a circle. Each pin represents three or more cells, and the only galvanometer employed was my own hand. A polarity-changer is not necessary. In order, however, to make the battery useful for diagnostic purposes in nervous disease, I have had a very simple polarity-changer attached. Mr. Vedder, of Messrs. Vedder & Putnam, has, at my suggestion, placed in my office a very serviceable machine, arranged at a comparatively small cost. The cells are arranged in an open book-case on the lower shelves, while on the second shelf from the top the current selector, as represented in the accompanying cut, is placed. A

---

1 Read before the Practitioners’ Society, May, 1884.
faradic machine attached to the right-hand side of the framework, and supplied by two of the Leclanché cells, is also here represented, giving a very complete instrument for the treatment of the various kinds of neuralgias.

The patient can stand, or lie on a couch, as one prefers, while the operator places the electrode from the positive pole over the exit of nerve from the sacro-sciatic notch. The nerve-trunk can be readily found by placing one thumb over the tip of the trochanter major, the tip of the middle finger (same hand) over the tuber ischii, when the tip of the index-finger fully extended will fall directly over the nerve. If now deep pressure with the index-finger thus located be made, tingling sensations in the superficial and remote distributions of the nerve will be felt. If you do not get these sensations the finger should be moved from side to side and pressure made again. Often some little time will be required to find the nerve, and when once found a mark should be made on the skin for the application of the electrode. So much in detail for the placing of the electrode of the positive pole. Make now deep pressure here, and place the other electrode over some one of the nerve-points along the limb, preferably in the locality of greatest pain. If the patient wince much or complain of pain, diminish the number of cells in the circuit, but if not, then increase the number up to the toleration point. If now the current is passing through the nerve referred sensations—paresthesia—will be felt in its distribution. These referred sensations must be obtained or the treatment is inoperative. To get them it is necessary often to move the electrode (from the negative pole) about from point to point, and when secured then hold both electrodes absolutely quiet, making use of the "stabile method." We want a constant current, and the "labile method" does not secure this. It not infrequently happens that I find in my dispensary practice an incredulous assistant applying the current without ever getting these "referred sensations." The electrodes are of the usual size—sponges on metal disks—from three-quarters to one inch in diameter for the one over trunk of nerve, and a larger one for the thigh.

I am thus particular in giving these points because we all know how results turn on the minutiae of practice, and I have had many assistants who were baffled in their attempts to get the good results others of their number and I have obtained. By and by they give attention to details, and they are then delighted with the relief the patient experiences. Time and again I have had one of the more recent members of my staff, fresh from college, come into my examining-room and say, "Doctor, I have just succeeded in getting the tingling sensation in Mrs. So-and-so's case, and she says she feels like a new woman." Sometimes I find a man working along mechanically from day to day without any idea of art, and it is a long while before he appreciates the value to himself of the hospital position he holds.

Let me now outline the treatment of a given case—a classical case.

The patient has suffered for two or three years almost continuously with an exacerbation now marked by paroxysms coming on every two or three hours. He is able to walk only when well supported, and even then the greatest care must be exercised. I have the posterior half of the limb well exposed, seeking, in the manner above described, for the nerve-trunk, after it has emerged from the pelvis, mark the skin overlying, and apply my electrode. Before this procedure, however, I will have made myself familiar with the current I am to employ, and turn the winch so as to include about eighteen or twenty-one cells in the circuit. The positive-pole electrode having been placed at the desired point over the gluteal region, I ask the patient to indicate with his hand the locality of greatest pain. This will usually be on the posterior aspect of the thigh, near the popliteal space; sometimes about the ilio-femoral crease, sometimes below the popliteal space. Here I place my other electrode, and then turn on more cells until the patient tells me that he can stand no more. After getting from twenty-seven to thirty-three in the circuit, my limit will usually have been reached. Then, by moving about in a small area my negative-pole electrode, I am to get the paresthesia of referred sensations. These being obtained, my electrodes are then removed and the skin washed. After which time the patient will tell me how warm the sensation is, but at the same time tell me it is preferable to the "old pain." When I am ready to close the session, I get the patient to hold the handle of the upper electrode while I turn the winch backward, so as to remove the cells from the circuit. I am now ready to remove both electrodes, and dry the skin with any strong after.

The skin against which the sponges have been pressing is quite red, and occasionally presents a few small vesicles. The patient gets up and begins to move the affected limb, finding to his delight that he can move it about with much greater ease. He walks out of the room with much more facility than he expected. Next morning he returns for another application, and reports that he felt very nearly well all day until toward evening, when a pretty sharp "attack" of pain came on, but it did not last long. Then toward morning he had another "attack," which lasted up to his present visit.

I repeat the "dose," and find that he can bear a little stronger current without much inconvenience, sometimes reporting only a single paroxysm, perhaps not any.

I go on with the application daily for a week or ten days, finding my patient steadily improving, the paroxysms reduced to a minimum, and even when they do appear their force is insignificant. My aim in treatment is the same that I would aim to get in treating a case of epilepsy, viz., bring up the paroxysms by small doses until I am able to do this effectually in about a fortnight, and then I discharge the patient. Sometimes the treatment will extend over a period of six or eight weeks, but this is the exception, and generally argues for an error in the diagnosis or a faulty mode of applying the electricity.

I direct now the patient to report to me promptly on the recurrence of certain symptoms, or any other exacerbation. On tracing out my patients thus relieved, i.e., those that do not return, I find that they have either not had a return of the pain, or a return which gave them very little annoyance, not enough, in fact, to require treatment, especially as it passed away very soon. A few who can spare the time do return and get about half-dozen sittings more.

These suffice, and I have traced out enough cases, the final results of which I know to enable me to state that a very large per cent. are cured. I have not tabulated my later cases, but aimed to make this paper which I now present a plain statement of the methods employed.

To sum up, then, 1st. A differential diagnosis should be made between a sciatica depending on a rheumatic diathesis and one of purely idiopathic origin. The former will yield to faradism or static electricity, and will be
aggravated by galvanism. The latter will be relieved by galvanism and aggravated by faradism. 2d. Daily appetite.

This classification of the field, intended to systematize the search for the causes of disease, claims no originality. But while its basis has been perhaps tacitly acknowledged by everybody, its importance in etiology has never been pointed out, and, as far as the writer knows, the system as a whole has never been used.

With reference to the causes of disease a distinction can be drawn between (1) primary diseases and (2) secondary disturbances. A primary disease can be considered as the direct reaction of the living body, or any part of it, to some foreign influence of external origin sufficient to disturb the normal play of physiological processes. A secondary disturbance, on the other hand, is some disturbance of the normal processes due to a pre-existing primary disease or primary lesion or structural anomaly anywhere in the body. The type of a primary disease is represented by any infectious disorder, or by a traumatic fracture or a burn. In any of these instances the part of the organism suffering is the part directly affected by the cause of the disorder. An example of a secondary disturbance is the paralysis due to the embolism of a cerebral artery, the embolus itself being derived from a previously diseased cardiac valve. Here the secondary disturbance, serious enough, if not fatal, is not due to any fresh external cause acting upon the brain, but depends upon a pre-existing lesion. In primary diseases the cause can be traced to the outer world, while in secondary disturbances the etiological research is to be directed to some anomaly already existing in the body, possibly at quite a distance from the part involved. The utility of the distinction here maintained is not lost by the unfortunate fact that the present state of medical knowledge does not permit it to be carried out in all cases.

1. The etiology of primary diseases will gain in clearness by distinguishing between the one exciting cause and the numerous predisposing conditions. As far as our actual knowledge goes, every distinct morbid condition which can be analyzed and be fitted into one of the categories, no matter how far removed from the exciting cause, may sometimes be a series of separate reactions to separate causes.

The term predisposing causes can be dropped to advantage as illogical, although predisposing conditions, partly in the external world, more so in the latitude of our physiological factors, must be recognized as aiding the exciting cause. But such predisposing conditions, either singly or all together, cannot produce a disease, and should hence not be called the causes of disease. By way of illustration let me quote erysipelas following in the course of a wound. The only direct exciting cause of the disease is the erysipelatous virus, yet the existence of the wound must be admitted as a predisposing condition, facilitating the entrance of the poison into the body. But that the wound itself cannot cause erysipelas is a fact no longer admitting any discussion.

Our knowledge of the exciting causes of primary diseases is limited to three classes, namely: A, physical influences; B, chemical action; C, parasites.

In the range of physical influences, historical and mechanical violence and the direct effect of extreme heat or cold and intense electric currents, no addition has been made to our knowledge during the past year. But the results attributable to these physical influences are being more closely observed, in illustration of which might be quoted the warning by Luecke that the side-stapling stitch so tender worn by children can be the cause of knock-knee.

The chemical causes of disease include the actions of all poisons, using that term with the utmost latitude. The subjects to be treated under this head would also appear in a report upon therapeutics and toxicology, and may hence be here omitted. Among the chemical influences we should also refer to their negative effects—i.e., the result produced upon the body by the deprivation of any of the substances forming part of our tissues. No new additions to this topic have come to the notice of your reporter.

The third class of disease causes, and by far the most important in frequency, viz., parasites, is the one as yet viewed with too much distrust. That the first hasty and insufficient endeavors to trace these causes were received with caution was but natural and proper. But the case is now different. Modern methods used in this line of research are as accurate as those of any experimental science, and the facts developed thereby rest on as firm a basis as any in the sciences. Still, the presence of many diseases represent a struggle of the organism with parasites invading it, meets with constant and often blind opposition. But it is a noticeable fact that in the discussions on this topic or the germ theory in general, be they in the Academy of Medicine of Paris or of New York, or in some provincial society, the "germ enthusiasts," as they are called, start from demonstrated facts and appeal to logic, while their opponents invariably betray no familiarity with the actual facts and appeal to sentiment.

The proof that a disease is of parasitic origin requires the demonstration of the parasites, in all cases of the disease, to an extent commensurate with the extent of the morbid lesion and the reproduction of the typical disease by inoculation with the isolated parasites. When these proofs are given the relation of cause and effect is just as plain and certain as it can be in a case of poisoning by a drug. In all the tirades against the germ theory no one has yet suggested or demanded any better proofs of the significance of parasites than the fulfillment of the above requirements.

Perhaps much of the opposition to the germ theory may be due to the difficulty of some in keeping up with the rapid advances of medical knowledge. Ten years...
ago no absolute proof had ever been furnished that any diseases of man could be due to the invasion by vegeta-
ble parasites. In anthrax, tuberculosis, syphilis, erysipelis, and trachoma of man, and of glanders, symptomatic carbon, chicken cholera,
swine plague, and some half a dozen experimental affec-
tions of animals. In relapsing fever, leprosy, pneumo-
nia, pyemia, and typhoid fever, characteristic bacteri-
a had been found with regularity, but their significance had not
been proven experimentally.

For several years the micrococci found invariably in the lung in _croupous pneumonia_ have been cultivated outside of the body, and with these isolated parasites the disease has been produced in animals by injections into the lungs, and what is more striking, by inhalation.  

These researches have rendered it likely that _croupous pneumonia_ and pleurisy may be due to the same para-
site, the effect depending on the inhalation of the organisms.

In _esteomyelitis_ micrococci had previously been found in the diseased parts. Their variable presence has
since been confirmed by several observers, and it has been found possible to produce in animals similar affec-
tions of bones by inoculation with the isolated micrococi.  

The invasion of the bone, however, depended on some inciting cause, without which the animal could not
gain a foothold in bones. The injury by itself could not
produce osteomyelitis, but it was an indispensable pre-
disposing condition.

The splendid work done by Koch on the cause of _cholera_ has received wide publication by the various
translations of his letters to the German Government.

In numerous autopsies he has often found a bacillus in the walls of the intestines during the active stage of cholera. Neither in his extensive previous work nor in his additional experience gained in Egypt and India has he ever met with this micro-organism in cadavers dead from other diseases. His experiments in-
tended to produce the disease in animals failed, because no animals could be found susceptible to cholera. Though he could not complete the proof that this bacil-
lus is the cause of the disease, this view has been brought to the utmost degree of probability, by reason of the in-
variable presence of the bacillus in cholera and its ab-
sence in other diseases and in health. This view, more-
over, is based upon all the facts in the etiology of cholera. The French commission sent to Egypt has in its study of cholera has likewise found this bacillus in the intestines, although, it is claimed, not in the first stages. Its report 4 differs, moreover, in some other details from
that of Koch. But this commission has not given suffi-
cient evidence as yet of the trustworthiness of its work.

The presence of characteristic bacilli in the intestinal lesions and in the internal organs of _typhoid fever_ pa-
ients has been again investigated in Koch's laboratory.  
The results of former authors have been more than con-
formed, for by means of better staining methods it was shown that the bacilli are never absent during the active stage of the disease. They possess such characteristics of shape and growth that they can be distinguished with certainty from the micro-organisms of other diseases. Their cultivation outside of the body was found an easy task, so that there is good prospect of their early identi-
fication in suspicious water and soil. But since no ani-
mal was found susceptible to typhoid fever, the experi-
mental reproduction of the disease by means of the

bacilli could not be accomplished. Yet the occurrence of these bacteria is so typical, and agrees so closely with what we know of its pathology, that there can be no doubt of their etiological relation to typhoid fever.

In the etiology of _diphtheria_ a greater advance has been made during the past year than ever before, again in the laboratory of the German Board of Health.  

But the results in this disease have not been quite as positive as in the diseases above mentioned. A bacillus was found in the deeper strata of the pseudo-membranes, not entering, however, into the living mucous mem-
brane. This bacillus, isolated by means of cultivation, produced in animals diphteritic pseudo-membranes with general involvement of the health of the subject. The intense effect which could be obtained by inoculation suggested that they form some acrid soluble poison. But while the experimental study of this micro-organism pleads in favor of its relation to diphtheria, it could not be found in every case of the disease in man, possibly by reason of its early elimination. Its significance has hence not been established beyond doubt. Whether the disease produced in diphterics is rarely an uncomplicated disease, but that through the diphteritic lesion there enters very often at least one other variety of micro-organisms. This, a micrococcus forming chains, produced in animals an inflammatory reaction but not a diphteritic change. It could not be distinguished by its growth or its effects from the micro-coccus that they killed.

An eye disease known as _xerosis of the conjunctiva_, which occurs at times in epidemics, especially in institu-
tions for children, has been traced to the vegetation of bacilli in the conjunctiva.  

The disease could not be reproduced in animals, but the pathogenic character of the bacilli was shown by the injection of the liquid bacilli into the conjunctiva of the limited of the patients, viz., a desquamation of the epithelium similar to that on the surface of the conjunctiva.

In _purpura perforata_ micrococci have been found in several instances in the affected parts, which on suit-
able inoculation gave rise to similar affections in animals.  

Pasteur's researches on _hydrophobia_ have shown that this disease is due to the virus which multiplies in the body of the animal and localizes itself largely in the cen-
tral nervous system. The nature of the virus, however, could not be determined.

The unrivalled work of Koch on _Tuberculosis_ has been published in full during the past year.

It stands without parallel in the annals of medicine for the amount of research and perseverance in the work, and caution in the interpretation. The outcome of the exten-
se work is that in all tuberculous lesions the bacilli precede the structural change, increase in number so
long as the lesion grows, but ultimately die or form spores, whereupon the process ceases to be progres-
sive, and that in all the domestic warm-blooded animals the isolated bacilli produce the form of tubercu-
losis characteristic of the natural disease as it oc-
urs in that species. On reading Koch's original article no one can hesitate to admit that the relation of the bacilli to the disease is as definitely established as in any other disease of bacterial origin. From Koch's work and its confirmation by many other authors, it is certain that the tubercular virus gives rise to various reactions not hitherto considered tuberculous. The pre-

cence of the characteristic bacilli in _scrofulous glands_ and in _influenza_, as well as the proven infectious properties

of these diseased tissues, force us to the conclusion that the reaction of the tissues—i.e., the form of disease to which the tubercle bacilli give rise—varies with the power of resistance and other conditions of the tissues involved. This statement does not mean that we are to consider tuberculosis and lupus as identical in the clinical course and in the prognosis with the common form of pulmonary tuberculosis. It means simply that the three diseases have the one exciting cause in common, viz., the growth of the bacilli. If this does not agree with the hitherto conceived notions, it is time to drop those notions as incorrect.

In various other diseases vegetable parasites have been found by reliable authors, but the instances are as yet too isolated, so that experimental proof being wanting, we cannot consider the results as more than suggestive.

The search for the parasites of various disorders has brought to light the fact that some affections which appear clinically as one continuous disease are really mixed infections due to the invasion of several forms of microorganisms. Such invasions are rarely simultaneous; more often one parasite paves the way for the other, either by creating a lesion through which the other may enter, or by lowering the power of resistance of the body. Such mixed infections have been shown to occur in typhoid fever, dysentery, and several disordered pyemic. There is strong reason to suspect that such occurrences are not uncommon in other diseases.

Predisposing conditions include both the influences determining the mode of life and distribution of diseasegerms outside of the body, and the influences which may alter the resistance of the body to their invasion. Under this head, in the most important instance is, whether the micro-organisms causing a given disease can vegetate under the conditions as they occur in nature outside of the body, or whether they are limited to a purely parasitic mode of life in the bodies of animals; for on the answer to this query depends the nature of our prophylactic measures. The bacillus tuberculosis has been shown to be a true parasite. It cannot live outside of the body except under the artificially produced conditions of our culture experiments. On the other hand, the parasites of anthrax, erysipelas, pneumonia, typhoid fever, cholera, and, presumably all forms of suppurative inflammations, can readily vegetate in organic refuse. What bearing this has on the mode of infection in these diseases is a matter of substantial importance. In particular, the epidemic of cholera limited to the banks of a pond, or, as it is called by the natives, a tank, near Calcutta, Koch has detected the unmistakable cholera bacilli in the water of the tank after having failed to find the bacilli in other localities where no cholera prevailed. The inhabitants had used this water for drinking as well as for every other purpose, and thus the lacking experimental proof of the significance of these bacilli was furnished in a wholesale experiment costing no animals, but at the sacrifice of over a dozen human lives.

In a prison at Amberg, in Bavaria, a house epidemic of pneumonia had prevailed for some time. The space between floors and subjacent ceilings had originally been filled with loam saturated with organic refuse. In this filling Emmerich found, by means of culture experiments, the micrococcus of pneumonia characterized by its mode of growth and power of producing the disease in animals. In the filling of other non-infected localities this micro-organism could not be detected.

It is probable that no one has attempted to trace the origin of typhoid fever to infected wells, no results yet published are quite as precise as those obtained by Gaffky in an epidemic occurring among a body of soldiers. There was no interpretation possible of the facts in that case but that the typhoid germs had filtered through the soil from a cesspool containing typhoid stools into an ad-

to infections diseases, we are as yet completely in the dark.

Midway between primary diseases and secondary disturbances, or rather belonging to both categories in a certain sense, are those disorders in which tissues are involved in active primary disturbances, or in a similar pre-existing lesion in some other part. Instances of this kind are catarrhal disease of the middle ear in consequence of nasal catarrh, meningitis dependent upon purulent inflammation of the ear, and, in short, all so-called complications in which the primary disease extends by continuity or by metastasis. The search for the causes of such disseminating infections has been, on a successful case of gonorrheal joint affections, where the micrococci characteristic of gonorrhoeal pus have been detected in the pus of the diseased joints and in the blood.¹

2. In secondary disturbances the exciting cause is the existence of some primary disease, or primary lesion, or structural anomaly in the body, while the predisposing conditions may be any of the influences of external or internal origin acting upon the part primarily involved. The route through which a diseased part affects other organs is either through the vessels or through the nerves. The accumulation of secretions leads to the accumulation of poisonous products in the blood, as in uremia and in icterus. But new poisonous products may also be formed in the tissues under circumstances of disease, and may then cause symptoms on the part of other organs. Of late years attention has been drawn to the not rare occurrence of fatal coma in diabetes, with marked dyspnoea and restlessness, and the excretion of acetone in the urine. Senator² has shown that a similar self-poisoning may terminate life in diseases of the stomach, of the bladder, and in pernicious anaemia. In consequence of the contusion of soft parts, and more so by the reabsorption of blood extravasations, poisonous products, especially fibrin ferments, are liberated and carried into the circulation, constituting one of the factors of traumatic fever, and indeed the only one in aseptic cases. The very type of secondary disturbances is furnished by all cases of embolism; while, when these are not mere bland plugs of fibrin, but contain living parasites, as in the pyemic disorders, we obtain complications representing both secondary disturbances and fresh infections. In the central nervous system, are also secondary disturbances, being due, as Charcot and Bouchard have long since shown, to primary disease of the arteries, viz., military aneurism.

The nervous system is the more frequent route through which secondary disturbances originate. Well known are the degenerations of injured nerves, and the secondary atrophy of muscles and glands. No new additions, however, have been made to this subject. More frequent are morbid symptoms, sometimes imposing on us as disease-entities, due to the irritation of nerves in distant parts. With some impropriety these have been termed reflex disturbances. Familiar to all are the vertigo, simulating brain disease, from stomach lesion, and the headaches produced by constipation. Nor should we forget the success that Schroeder van der Kolk had years ago in the treatment of melancholia by the free use of laxatives. How often is it overlooked that the convulsions of childhood result from irritation of the bowels? Bartholow³ has rendered it plausible that even paralysis— as he terms it, "enteric paraplegia"— may result from disease of the intestines and be removed by the cure of the latter.

Disease of the sexual system is likewise not rarely the starting-point of symptoms in distant parts: witness the brilliant result of Emmet's operation for lacerated cervix, in some exceptional cases, in restoring general health. There exists a form of obstinate, almost incurable asthenia, in consequence of adhesive inflammation around the uterus. How strictures of the male urethra may lead to impotency and other functional nervous disturbances is well illustrated in a work by S. W. Gross⁴, which has, it seems, not received the recognition which it deserves.

Eye-strain as the cause of irritation in distant parts has been referred to even more by neurologists than oculists; some anomalies of refraction, requiring correction by glasses, produce not rarely headache, vertigo, and other nervous disturbances, which may depend on the eye. The writer has personally seen an extreme instance where vertigo, nausea, and loss of appetite—supposed to signify disease of the stomach—were removed by correcting by a few degrees the inclination of a cylindrical glass.

The ear, also, by its own disease may induce symptoms at a distance; amongst others epilepsy and general spasms, traceable to foreign bodies in the ear, have been reported during the past year.⁵

Some of the most interesting secondary disturbances can take their point of origin from nasal disease. A wholly new field has been revealed to us in this direction by Hachow, which have already been reported.⁶

It appears from his work that the cavernous plexus of blood-vessels on the surface of the inferior turbinate bone is capable of starting most unexpected irriations, both sensory and motor, in distant parts, when itself irritated while turgid with blood. This turgidity of the plexus may be brought on by slight peripheral irritation; for instance, chilling of the skin or excitation of the nasal lining membrane by dust. It seems the oftener this condition has set in the more readily it can be repeated, until it becomes at last almost constant. From the congested region then radiate impulses, which, according to their direction, may result in attacks of sneezing, coughing, asthma, migraine, and even epilepsy. Some of the secondary disturbances thus produced may even amount to slight structural changes like oedema of the skin, and serious effusion in the muscles of the neck. The mystery of taking cold is thus somewhat cleared up, some of the instances being reflex acts starting indirectly from this sensitive area of the nose. These assertions are startling, but more supported by an array of over a hundred cases, which have a very highly significant occurrence. The point of the disease was proven by its galvano-caustic destruction, and the subsequent cessation of all continuos symptoms and the non-return of the periodical attacks. Moreover, in some of the cases attacks of one kind or another could be experimentally obtained by touching the mucous membrane over the inferior turbinated bone. Symptoms simulating disease of other organs, especially the lungs, have also arisen in Hach's experience from disease of the pharyngeal mucous membrane. The writer might add, in confirmation, that he has been able to remove a cough of thirty years' standing by galvano-caustic destruction of an atrophied tonsil.

But has it come to the point? Have the recent advances in etiology cannot lay claim to completeness, nor even to the thoroughness desirable in discussing the value of the separate contributions, for this would be impossible in the allotted time. It can only aim to reflect the progress of the times, and perhaps aid in systematizing the subject by the arrangement and classification adopted. I have aimed to point out the necessity for close analysis in the study of the causes of disease, and to prove that we have advanced far enough to grasp tangible realities, instead of believing in vague superstitions.

ON THE VALUE OF OPHTALMOSCOPIC EXAMINATIONS IN DISEASE OF THE NERVOUS SYSTEM.

TOGETHER WITH REMARKS ON HYPEREMIA OF THE FUNDUS OCULI AND PRESSURE-ATROPHY OF THE OPTIC NERVE IN DISEASES OF THE BRAIN.

BY HENRY G. CORNWELL, M.D.,
PROFESSOR OF OPHTALMOLOGY AND OTOLGY, ST. ALBANS MEDICAL COLLEGE, COLUMBUS, O.

Although ophthalmoscopy furnishes us an important aid in the diagnosis of diseases of the nervous system, oftentimes very grave conditions, affecting one of its divisions, exist without the optic nerves or retina revealing evidences of such affections; and especially does this apply to the first stages of these diseases. That there should be these common exceptions to the rule appears strange when we remember that the optic nerves and retina are really parts of the brain, and that the eyes bear a closer relationship to the brain than to any other organ of the body. Yet not infrequently do we observe abscesses of the brain, when the characteristic hyperemia of the middle ear—a condition which excites great cerebral disturbance—go on to a fatal termination without the fundus of the eye presenting evidences of any intracranial affection. Hemorrhage into the brain is frequently followed by optic neuritis and atrophy, but it does not always give rise to intra-ocular changes. The same remarks apply to the ophthalmoscopic evidence of the middle ear—a condition which excites great cerebral disturbance—go on to a fatal termination without the fundus of the eye presenting evidences of any intracranial affection. Hemorrhage into the brain is frequently followed by optic neuritis and atrophy, but it does not always give rise to intra-ocular changes. The same remarks apply to the ophthalmoscopic evidence of the middle ear—a condition which excites great cerebral disturbance—go on to a fatal termination without the fundus of the eye presenting evidences of any intracranial affection. Hemorrhage into the brain is frequently followed by optic neuritis and atrophy, but it does not always give rise to intra-ocular changes. The same remarks apply to the ophthalmoscopic evidence of the middle ear—a condition which excites great cerebral disturbance—go on to a fatal termination without the fundus of the eye presenting evidences of any intracranial affection. Hemorrhage into the brain is frequently followed by optic neuritis and atrophy, but it does not always give rise to intra-ocular changes. The same remarks apply to the ophthalmoscopic evidence of the middle ear—a condition which excites great cerebral disturbance—go on to a fatal termination without the fundus of the eye presenting evidences of any intracranial affection. Hemorrhage into the brain is frequently followed by optic neuritis and atrophy, but it does not always give rise to intra-ocular changes.

Although the ophthalmoscope, as a rule, sooner or later reveals the presence of the more serious diseases of the brain, etc., not always are we enabled, from the changes in the fundus of the eye, to determine the exact character of the affection which has brought them about. As a rule, each there are many optic affections which may be safely said that the changes in the optic nerves or retina visible with the ophthalmoscope do not, per se, furnish sufficient evidence of the form of disease elsewhere in the nervous system to establish a diagnosis, e.g., optic neuritis is frequently seen in cerebral meningitis, simple and tubercular, acute and chronic, in pachymeningitis, in inflammation of the brain substance, etc. That form of optic neuritis attended with swelling, known as "choked disk," is not a pathognomonic sign of brain tumor, although in the great majority of such cases we do observe it; but "choked disk" is also observed in connection with abscesses, blood-clots, etc., in the brain. No exception can be made in the case of the different forms of inflammation in the fundus of the eye may be either a simple white atrophy of the disk or a congested or inflamed condition of the head of the nerve.

Further, although the ophthalmoscope may reveal a disease of the brain, and also enable us with a degree of positiveness to determine its character, its location is not thereby indicated, e.g., a tumor in any part of the cerebrum or cerebellum, in the cortex of either the right or left lobes, the pons, etc., or a syphilitic gumma at the base of the brain—in short, a tumor anywhere within the cranial cavity may give rise to "choked disk," but the ophthalmoscopic appearances in the main are identical, and moreover, both nerves are inflamed to the same degree. Perhaps one exception can be made in the case of small tumors pressing upon the chiasm and producing, together with other paralytic disturbances, primary or pressure-atrophy of the optic nerves. Rampil reports such a case to be referred to later. Evidences of a brain tumor, with rapidly progressing atrophy of the optic nerves, points to a small, perhaps syphilitic tubercular tumor pressing upon the chiasm. From what has been said we may conclude:

1. That, as a rule, the ophthalmoscope reveals evidences of the more grave diseases of the nervous system at some period during their progress.

2. That the ophthalmoscope does not to a certainty enable us to determine the exact character of the disease present.

3. That the ophthalmoscope does not enable us to locate the disease.

The effects of irritation upon the optic nerves on the one hand, and pressure upon or destruction of the optic nerves on the other hand, as they are exhibited in these nerves and the retina, are to a degree comparable to the effects of irritation of the nervous system. When this is the case, the optic nerves and retina are affected quite as much as the brain supplying the iris, or the eye-muscles. Obviously, the same results are not obtained, because the optic nerves, of which the retina are but an expansion, have but one function, that of conveying visual impressions to the sensorium. Intracranial irritation of these nerves brings about a condition which we know little or nothing of the retina, the sensations of which are that the patient sees flashes of light, bright rings, or dark spots floating before the eyes, etc. These we observe in very severe cases of active congestion of the brain. In still more marked cases of this affection, the eyes are very sensitive to light; the lids, on this account, are kept tightly closed, the pupils markedly contracted, and the eyes filled with tears.

This affection is observed in the first stage of inflammation of the meninges and brain structure, especially the former.

If during an intracranial irritation of the optic nerve, the eye is examined with the ophthalmoscope, the fundus is observed to be congested; the evidence of which is in turn reflected in the redness of the capillaries on the surface. This is especially apparent at the periphery of the disk, where the vessels continue over its border, so that the latter is less sharply defined than in a normal condition. The contrast between the nerve and the surrounding retina is also less marked. The arteries and veins of the fundus are, in extreme cases, somewhat enlarged, and their smaller branches filled with blood. In order to determine whether the fundus of the eye is, or is not, congested extreme care is necessary in making the examination. It is very important that the observer be expert in the use of the ophthalmoscope, so that he may be perfectly familiar with the appearance of the healthy fundus. The nasal half of the optic nerve is redder in the normal condition than the outer half, a fact which is liable to lead to errors in diagnosis on the part of one not sufficiently familiar with the normal appearance. It is more rosy in persons after the blonde type, on account of there being a less marked contrast between the nerve surface and the surrounding parts of the fundus. In order to determine the relation of the fovea to the disk, the direct method of examination is preferable. It is also advisable that a weak light or an unsilvered mirror be employed. The outline of the optic nerve, furthermore, is not always clearly defined in a healthy state. The physiological pulsations of the retinal veins must not be
mistaken for a pathological phenomenon. Lastly, individual peculiarities in the course taken by the retinal vessels are not to be misinterpreted.

The absence of active congestion of the fundus of the eye in cases of supposed congestion of the brain is not to be taken as opposing such a diagnosis. It may be said that only in the severest cases of brain-congestion, such as that which forms the first stages of inflammation of the meninges or the brain itself, is hyperemia of the optic nerves and retina to be discovered. It is very probable that in most of the cases of inflammation, acute and chronic, affecting the membranes at the base of the brain, more or less congestion of the optic nerves would, on examination, be found, since, by their close proximity to the seat of the inflammation—being, indeed, after their exit from the cranial cavity, enveloped in sheaths formed from these membranes—they must be involved, at least, to the extent of being congested. In a very large percentage of such cases of inflammation, the optic nerves participate in the inflammatory process, and, manifestly, if this be so, a large percentage must be affected likewise to the extent of, at least, being congested.

Hyperemia of the optic nerves attending inflammation, limited to the substance of the brain, doubtless is, for anatomical reasons, less frequently observed than in connection with inflammation limited to the meninges. The blood-supply of the head of the optic nerve is obtained from capillary branches of the central artery of the retina, which, as a rule, is given off from the ophthalmic artery, the main vessel of the orbit, and the branch of the central artery of the retina does not penetrate the optic nerve until it arrives at a point about fifteen or twenty millimetres from the sclerotic, so that the nerve behind this point only receives its blood-supply from the capillaries of its sheaths, and from the delicate network of vessels surrounding the individual bundles of the nerve.

At times the retinal artery is given off from one of the ciliary or muscular branches of the ophthalmic. The capillaries on the optic disk anastomose with the vessels which come from the "vascular ring" of Haller, which is formed by the short ciliary arteries, and encircles the head of the nerve. From this we see that the intraocular extremity of the nerve is almost wholly supplied with blood directly from the large vessels at the base of the brain, and since this is, so the nerve surface must give evidence of irritation in this locality oftener than a like amount of irritation in the structure of the brain itself.

Hyperemia of the optic nerve has not been observed in active congestion of the brain, after prolonged mental application. Niemeyer failed to find in dangerous cases, after excessive study without sleep, even a hyperemia of the conjunctiva of the globe and lids. Förster says that the supposition that in active congestion of the brain, hyperemia of the fundus of the eye would be discovered, has not been verified on examination. He, however, calls attention to the fact that the convulsions of infancy due to intestinal affections, etc., the pupils are frequently contracted, and the conjunctive congested.

Increased redness of the optic nerves, together with congestion of the lining membrane and margin of the lids, in general, an irritative condition of the eyes is not infrequently observed in the case of persons who have errors in the refraction of the eye, especially hypermetropia and astigmatism, also weakness of the extra-ocular muscles. Headaches very often accompany such affections of the eye. It is only necessary that this fact be mentioned here in order that errors in diagnosis may be avoided.

Intramural atrophy of the optic nerves (i.e., atrophy of the nerves not preceded by inflammation of their structure) due to intracranial pressure, is comparatively a rare condition, for two reasons: in the first place, because tumors, blood-clots, etc., either in the substance of the brain, or at its base, directly in contact with one or both nerve-trunks, are more apt to excite inflammation in these structures. The irritation which their presence brings about produces active congestion of the head of the nerve, which finally develops into optic neuritis. This, in turn, is followed by secondary atrophy, a form of atrophy which, more especially in its earlier stages, differs pathologically from its ophthalmoscopic eccentric features in that which I have under consideration at this time. A tumor, e.g., a gloma, may spring from the chiasma and destroy it in its growth, or it may press it against the brain substance, or against the sella turcica. If the growth be situated so that the chiasma is fairly pressed upon, primary atrophy of both optic nerves may take place. If the tumor is situated far from the chiasma, the atrophy of both optic nerves, the papilla whitish and slightly sunken, blood-vessels normal, and no trace of a former neuritis discoverable. The patient died while under treatment, and at the autopsy an aneurism of the left internal carotid was found, which pressed upon the optic nerve and chiasma.

It is also possible for a tumor to spring from the optic nerve anterior to the chiasma, and constricting the bone it against the bone at the optic foramen. In general, it may be said that tumors growing from the chiasma or its neighborhood, must in the great majority of cases excite irritation which would be referred to the head of the nerve. Of course, an inflammation so excited may not extend to the globe, but may extend through the optic foramen, destruct the ganglion at the base of the optic nerve, and give no intra-ocular evidence of a retrobulbar neuritis. The same remarks apply to tumors, such as stenoses, aneurisms, syphilitic gummatum, tubercular formations, sarcomatous or carcinomatous growths at the base of the brain, but not connected with the optic nerves; also to hyperostosis at the optic foramen, constriciting the nerve. If a tumor presses upon the anterior fibres of the chiasma, blindness of the internal halves of the retina occurs—nasal heteronymous (crossed) hemianopia. If a tumor press upon one of the optic tracts, homonymous hemianopia is the result. If one of the lateral halves of the chiasma be pressed upon, homonymous hemianopia occurs. Hjort in 1867 published such a case. A man aged forty-four years had pain on the right side of the head, partial paralysis of the third nerve on the right side, parsis of the facial, and left-sided homonymous hemianopia. At the autopsy a soft tubercle the size of a hazel-nut was found in the right half of the chiasma. The right optic nerve was smaller than the left. If a tumor press on the ophthalmic nerve, the fibres of the optic nerve, or in the nerve of one side, monocular, heteronymous hemianopia is the result. It is very improbable that tumor would be so situated on the outer side of the tracts, chiasm, or nerve-trunks, that binocular heteronymous hemianopia would be produced.

Hemianopia superioris and inferioris have been known to occur from the pressure of tumors directly over or underneath the chiasma, but the cases have been so few that but little is known about the condition.

Although an ophthalmoscopic examination in recent cases of hemianopia shows the optic nerves to be healthy in appearance, after a time atrophy undoubtedly would be observed. The reason for the late appearance of the signs of this condition at the disk is due to the slow progress of the atrophic changes throughout the length of the nerve. I have had under observation for a year a patient having right-sided homonymous hemianopia, and at this time no indications of atrophy can be discovered.

Homonymous hemianopia the location of the cause of the visual defect is on the side of the brain corresponding to the blind half of the retina, and opposite the lost half of the visual field, e.g., in right-sided hemianopia the brain affection producing it is on the left.

3 Mauthner: Gehirn und Auge, 1881.
side, either in the cortex of the occipital lobe of the cerebrum, the optic tract, or the left side of the chiasm. If the sense of hemianopsia, instead of the lateral halves of the disks showing signs of atrophy, the paralyzed surface of one optic disk alone is affected, the other presenting a perfectly normal appearance. In right-sided homonymous hemianopsia, for example, the right disk becomes atrophic, while the left shows no change. The reverse is the case in left-sided hemianopsia. The explanation of this fact is obtained when we remember that the line of division between the normal and paralyzed surfaces of the retina is at the macula, and not at the optic nerve. Let us suppose, for example, that a tumor is pressing upon the optic tract of the left side. In this case, the nerve-fibres of the outer half of the retina are affected, and the outer half of the optic disk, we will imagine, shows signs of atrophy. The right half of the inner half of the retina of this (left) eye, however, comes from the tract of the opposite side, and on their arrival at the surface of the disk, a part of them go to the internal half of the retina, while the other part bend toward the macula, and in this manner cover over the external or atrophic half of the disk. At the macula, these again bend toward the brain, and the optic fibers layer over the disk. On ophthalmoscopic examination, the papilla of this eye would be perfectly healthy in appearance. The internal half of the right eye is supplied by a part of the paralyzed fibres of the left tract. The other set of these paralyzed fibres supplies the external half of the retina, and in their course to the macula they cover over the sound fibres of the right tract. Here, turning upon themselves, they form a second layer over the disk. An ophthalmoscopic examination of this eye shows that the entire surface of the disk has undergone atrophy. Then, while both nerves are alike atrophic, the nerve opposite the affected side of the brain alone gives evidence of such a condition. If a tumor is found that the anterior fibres of the chiasm are pressed upon, paralysis of the internal halves of the retina is the result, with blindness over the external half of the visual field (heteronymous temporal hemianopsia). In such a case the entire surface of both disks would finally show signs of atrophy. One part of the paralyzed fibres of the nerve is distributed to the internal half of the retina, which borders the macula, covers over the sound fibres of the nerve. Schöller reports a case of heteronymous temporal hemianopsia in a person aged twenty-five years, with normal vision, and without any apparent cause other than heredity. No brain symptoms. Iodide of potassium was given, and after a time some change was observed in the borders of the right disk, which became clearer, and the other side, incipient atrophy of the optic nerves was discovered.

If tumors were so situated that pressure would be simultaneously produced on the lateral fibres of each optic nerve, no signs of atrophy would be exhibited at the disk, because the atrophic fibres would be covered over by the healthy fibres of the inner side of the nerves. In superior or inferior hemianopsia, also, atrophy of the optic nerves occurs. Griffith reports the case of a man who had horizontal hemianopsia of the left eye, folowed by atrophy of half the disk. The visual field, at twelve inches from the blackboard, was absent below the line of division, being wavy, and from three to six inches below the fixation point. It is not essential that a brain-tumor, blood-clot, etc., be in direct contact with the optic nerve in order to produce primary atrophy. It may be in some other part of the brain, and give rise to this condition from an increase in the volume of the contents of the skull. Manifestly, the farther such a growth or blood-clot is removed from these nerves the less the opportunity to produce such results. An affection of the optic nerve in such a con-

cases of monocular pressure-atrophy the cause of the atrophy is in the orbit, and not within the cranial cavity.

The ophthalmoscopic appearances of primary atrophy of the optic nerve are generally very marked. The surface of the disk is pale or dead-white, having perhaps also a bluish or greenish shade. It may be level, but very frequently it is excavated, the excavation differing from the normal or physiological excavation in the fact that it is apt to extend over the greater part of the surface of the disk. Its edges are not abrupt, but slanting, so much so that oftentimes no dipping of the blood-vessels on the surface of the nerve is observed. The disk has lost its transparency, so that the vessels cannot be traced beyond the surface into its structure, as in health. Its outline may be irregular, but is sharply defined, and is readily to be distinguished from the surrounding choroidal ring. The small blood-vessels of the disk are hardly observable, or have entirely disappeared. The retinal arteries are much attenuated, oftentimes being thread-like in size. The veins are smaller than in health, but, as a rule, are not so small as the arteries. The above represents the nerve in an advanced stage of atrophy. Less marked changes are, of course, to be observed in cases wherein the cause is slight, of short duration, or slow in its progression.

SPASMODIC INTERNAL STRABISMUS.

By J. FERGUSON, M.A., M.D., L.R.C.P.,
TORONTO, CANADA.

So far very little attention has been paid to the condition of spasmatic strabismus. There are not many cases recorded to which one can refer for information as to the causes, prognosis, termination, and treatment of such a condition. No doubt it is a rare affection; yet perhaps if it once received a fair share of attention a larger number of examples might be detected than at present is thought to exist.

The following case which came under my notice, and which I purpose making the text for a few remarks, occurred in a young man aged nineteen. His health has always been good. When he came to me he stated that about a year ago he had entered the service of a watch and clock maker and repairer, and as a consequence was steadily engaged in work requiring close visual application. From this time on he noticed his left eye becoming affected, this eye would turn inward at times and look across the nose, and that he was becoming shortsighted with the left eye. This condition gradually grew worse until the internal squint came on frequently, and often from becoming excited in any way. When he consulted me first the eye would at times turn inward to such an extent as almost to hide the cornea from view. His family history gave evidence of spasmatic nerve trouble. His mother had never suffered from any disease of the nervous system, although she was very excitable and impulsive. One sister, older than the patient, had an attack of chorea some two years before the date at which I was consulted, while another and younger sister was greatly troubled with startings during sleep.

On examination with the ophthalmoscope nothing could be detected at all abnormal with the fundus. Light did not affect the eye. The eye was myopic. Print which could be read at eighteen inches by the right eye could only be read at six inches by the left. On steady application to fine work the left eye fatigued much more quickly than the right. The upper lid was occasionally twitched and convulsively upward. If the patient was not at work for a day or two the twichings of the eye became less severe and less frequent, and the myopia improved.

Such being the condition of the patient, what was the trouble, and where situated? It was clearly not a para-

lytic affection of the external rectus, as the squint was only of occasional occurrence; neither could it be due to a shortness in the internal rectus, as this would cause a permanent deflection of the eye. Moreover, from the spasmodic and occasional nature of the attacks, it was clearly of a nervous character.

As has been said, it could not be one of paralysis of the sixth nerve, as this would lead to permanent internal squint. The superior oblique, which directs the eye downward and outward, if paralyzed would allow the eye to roll slightly upward and inward. Hence neither this muscle nor the fourth nerve was at fault.

Turning now to the muscles supplied by the third nerve, we find that all the conditions existing in the eye could arise from contraction of these muscles. During and for some time after one of the spasms, the pull of the affected eye was more or less contracted according to the severity of the attack. This can be readily accounted for when we remember that the circular fibres of the iris are under the control of the third nerve. The third nerve, in addition to the circular fibres in the iris, supplies the levator palpebrae superioris, the internal rectus, the superior and inferior recti, and the inferior oblique.

Now, a spasm of these muscles would cause the upper eyelid to twitch upward and the eye to turn inward. In this latter action—namely, the internal squint— we have several factors to consider. The first and principal one is the internal rectus, which directs the eye inward; then the superior oblique and inferior oblique, which, when they act together, cause the eye to turn upward and inward, the latter downward and inward, while both acting together would carry the eye directly inward along with the internal rectus. The last muscle under the control of the third nerve which we have to notice is the inferior oblique. This muscle, when in action, turns the eye upward and outward. Now, from the superior, inferior, and internal recti it would be quite impossible for the eye to move outward under the action of the inferior oblique, while there is nothing to prevent the upward motion. Thus, three muscles would carry the eye strongly inward, while one would carry it feebly upward; and all together would carry it inward and a little upward, as in the case of the young man under consideration.

The myopia can be accounted for on the following principles of the composition of forces. The superior and inferior recti when contracted would compress the eye. Again, the inferior oblique carries the entire globe inward and would press it against the contracted internal rectus. From the above it appears that the axis of the eye would be elongated and myopia ensue.

The treatment adopted was to procure a pair of glasses with a plain glass for the right eye and a concave glass over the left eye. The patient was put on a mixture containing fl. ext. ergotis, M. xv.; pot. bromidi, gr. xx.; and liq. arsenicalis, M. v., four times a day. At the end of two months the spasm had ceased and only a slight myopia remained.

Milk Diet in the Treatment of Gastric ulcer.

—Dr. Deboeuf has lately lifted up his voice against the common practice of putting patients with ulcer of the stomach upon an exclusively milk diet. He argues that the quantity of fluid required is so great that a dangerous dilatation of the stomach is produced, thereby leading to hemorrhage, and cites one case of death so caused. His plan is to give about six drachms of beef powder with two and a half drachms of bicarbonate of soda. This, he found, is passed directly into the intestine, uncharged, with no change in the stomach contents. In addition, about a quart of milk with saccharated lime is allowed each day. M. Deboeuf states that this mode of treatment has given him great satisfaction in a number of cases.—Gazette des Hôpitaux, April 29, 1884.
Progress of Medical Science.

The Motor Nerves of the Stomach.—Having performed nine experiments for the purpose of determining the influence of the motor nerves of the stomach, Dr. Giliberti reaches the following conclusions: The motor innervation of the stomach is derived chiefly from the vagus, partly from the sympathetic, and to a slight extent from certain medullary nerve-fibres. The great sympathetic system does furnish motor fibres to the organ in spite of the negative results obtained by Chavasse from a stimulation of the cervical sympathetic in experiments of Adrian, who produced movements in the organ by exciting the solar plexus, must be accepted as exact. The sympathetic motor fibres enter the semilunar ganglia by way of the great splanchnic nerve, and participating in the formation of the solar plexus they pass to the gastric parietes. It still remains to discover the course pursued by the medullary motor fibres, which probably pass through the greater or lesser splanchnic, and to discover whether, after section of all the gastric motor nerves, contractions of the organ will still occur in virtue of the activity of possible intramural ganglia analogous to those of the heart. Ramier has demonstrated such ganglia in the frog's stomach.—Archivio per le Scienze Mediche, vol. vii., No. 3, 1884.

The Possibility of Syphilitic Reinfection.—The question of the possibility of a second attack of syphilis occurring in an individual who has previously suffered from the disease seems to be still held sub judice by many writers, despite the fact that instances of a true second attack have been reported by numbers of competent authorities. Dr. J. Neumann records, in the Wiener Medizinische Presse, Nos. 1, 2, 3, 4, and 5, 1884, a series of cases of secondary syphilis in which he had observed the development of sores resembling very closely in their general characteristics hard chancre. They healed, however, very readily under indifferent treatment, and were followed by no symptoms of general infection, nor even by indolent buboes. He concluded, therefore, that they were soft chancre or gummatia, which had assumed the characteristic induration from the fact of being syphilitic based on the probability that the greater number of cases of alleged syphilitic reinfection would fall in this category, and that the instances of a true reinfection are very rare, though that a second attack may occur hardly, in face of recorded facts, be doubted. Neumann ranks syphilis next after measles and scarlet fever in respect to the frequency of a second attack.

Sulphate of Copper in Obstetrical Practice.—At a recent session of the Académie de Médecine, Dr. Charpentier advocated the employment of sulphate of copper in injections after childbirth (Bulletin Général de Thérapeutique, April 30, 1884). He had used it with satisfaction in a one per cent. solution as a wash for the vulva, and in vaginal and intratracheal injections. This solution is absolutely innocuous, and joins to its antisep tic properties that of being a hemostatic but little inferior to the perichloride of iron.

The Effect of Mental Activity upon the Temperature of the Body.—M. Gley recently communicated to the Société de Biologie the results of a series of personal observations made to determine the fluctuations in the temperature of the body under various conditions. For this purpose he had a thermometer made in such a way that the rectal temperature could be easily observed and its variations followed. He found that when sitting perfectly still, with the mind not actively employed, the temperature of the brain, the muscles of the face, and the intellectual work this descent was interrupted and partially arrested. In an hour and a half the fall was 1.0° F. when the mind was at rest, but during the same length of time, with mental labor, there was a descent of but 0.4° F. In another series of observations, conducted while lying in bed, the intellectual faculties being meanwhile active, there was a slight rise. M. Gley seeks to account for this phenomenon by the influence of psychic activity on the brain caused by psychic activity, though it would admit of other, perhaps more satisfactory explanations.—Gazette des Hôpitaux, April 29, 1884.

Vomiting of Pregnancy.—Dr. Torino has found that during pregnancy there are often points of tenderness along the spinal column. He attributes the vomiting to spinal irritation and anemia of the cord. In support of this theory he addsuces the satisfactory results often obtained by the administration of phosphite of zinc and nux vomica. Under the influence of these drugs the vomiting is frequently controlled and the points of spinal tenderness disappear.—L'Union Médicale, April 29, 1884.

Resection of the Astraiguus in Ankle-Joint Disease.—In an article of some length on this subject Dr. Robert sums up as follows (Archives Générales de Médecine, May, 1884): 1. A spain of the ankle is often followed by chronic osseous lesions which are very prone to become localized in the astraiguus or at the articular surfaces of the astragalus and os calcis. 2. These lesions may remain for a long time limited to this part of the os tarsus, but are often very intractable to treatment. Even évidemment, scraping, and deep cauteryization may fail to remove all the diseased bone, and sometimes cause such an aggravation of the disease that the amputation becomes imperative. 3. The removal of the astraiguus is an operation which facilitates the exploration of the articular surfaces attacked by caries. Practised according to Vogt's method it is easy of execution, attended with but slight mortality, and leads to a permanent cure, with often the preservation of excellent joint motion. 4. As is the case in all resections, the removal of the astraiguus should not be attempted when the patient is affected with pulmonary tuberculosis or is of an advanced age, or, finally, when the disease is very extensive.

Carcinoma and Syphilis.—In a thesis upon the relations of cancer and syphilis, Dr. E. H. Orenne states his belief that the latter favors the development of carcinoma by creating points of feeble resistance. It, however, modifies the physiognomy of cancer, acting upon the functional troubles, particularly the pain, which it lessens or entirely abolishes. After having provoked the inception of the neoplasm, syphilis seems for a time to retard its progress. By provoking the disease and removing it from the scene, leaving the field free to the carcinoma, which then at once resumes all its usual features.—La France Médicale, April 29, 1884.

The Etiology of Croupous Pneumonia.—In January, 1882, an article appeared in the American Journal of the Medical Sciences from the pen of Dr. A. Seibert, of this city, in which it was sought to establish the dependence of croupous pneumonia upon meteorological influences. The conclusions of the author were as follows: 1. The development of croupous pneumonia is greatly favored by certain conditions of the atmosphere. 2. This meteorological influence is identical with that which forms the development of catarrh of the respiratory mucous membranes. 3. It is especially in the sudden occurrence and long duration of damp, cold weather that this influence is manifested. In these conclusions were called in question by a German writer, who asserted that whatever the fact might be in America, the experience of European observers was that pneumonia occurred with greatest frequency during a period of dry, cold weather. In a paper recently read before the Society of Physicians to the German Hospital and Dispensary of New York, Dr. Seibert returns to the question. He criticizes a series of four observations made within the last two years by Köhnborn, Post, Kel-
a slight degree of deviation of the head, painless and easily corrected by apparatus. Dr. Schwartz, who reported this case to the Société de Chirurgie of Paris (Revue de Chirurgie, May, 1884), related the results obtained in eight other instances of torticollis treated by stretching, section, or resection of the spinal accessory nerve. The conclusion arrived at was that the operation of resection gave promise of the best results. But the speaker thought that a preliminary stretching might be resorted to with advantage, the procedure being perfectly safe if not carried beyond moderate limits.

Anuria of Ten Days' Duration.—Dr. Eger reports the case of a man, fifty-two years of age, who was troubled with gravel, who had an absolute suppression of urine for ten days. The attack began with some pain, but this soon passed away, and up to the tenth day the patient felt well and complained of nothing. On this day, however, he was seized with uremic convulsions and died. The autopsy showed marked hydropneumothorax, both urines being plugged with calculi.—Centralblatt für Klinische Medizin, April 26, 1884.

Idiopathic Ascites.—Dr. Toulze defines this affection as an ascites occurring suddenly in a previously healthy individual, continuing for a variable time with perhaps one or more relapses, but terminating finally in recovery. Its cause is found in a sudden chill, either from external influences or from the ingestion of very cold fluids, or it may come on after the sudden suppression of a substernal pain or the recession of an acute inflammatory inflammation. It may exist as an acute, a subacute, or a chronic condition. The acute form is accompanied, as a rule, by a rather intense pyrexia. The abdomen is more or less distended with fluid, which gives rise to the usual functional troubles. The subacute form is of longer duration and presents the same symptoms, but without the less prominent, less pronounced ascites. This variety is characterized especially by the frequent relapses. The course and duration of essential ascites are naturally very variable, but that which characterizes all the different forms is the favorable termination. A spontaneous cure almost always obtains by crisis at the end of a month or two, sometimes more, sometimes less. The fluid is carried off by way of the kidneys, the skin, the intestines, or even, in some cases, by the mammary glands. Instances have been noted in which an increased secretion took place from accidental wounds or from ulcerated surfaces, the ascitic fluid finding vent in this way. The treatment consists in favoring development of spontaneous removal of the fluid. Dietetics and drastic ingurgitives are especially indicated. The liver should be preserved for those rebellious cases which seem to resist the action of internal remedies.—Journal de Médecine et de Chirurgie Pratiques, May, 1884.

Treatment of Pleurisy with Effusion.—Professor Picot, of Bordeaux, writes concerning a new procedure, suggested to him by Dr. Cayla, of considerable value in the treatment of pleurisy. After the thorough evacuation of the fluid by aspiration, he makes a number of punctate cauterizations covering all of the region affected, using for this purpose the thermo-cautery. The points of cauterization are very numerous and are placed close together, not more than a centimetre apart, but are very superficial, seldom involving more than half the thickness of the skin. They are very well borne by the patients. Professor Picot has used this method a number of cases, and has never met with one in which a reaccumulation of fluid took place.—Journal de Médecine et de Chirurgie Pratiques, May, 1884.

Diphtheritic Arthritis.—In an epidemic of diphtheria occurring in a school, Dr. Pauli observed some cases of multiple joint disease existing as a complication. He explains the occurrence of this arthritis as due to specific virus acting in the same way as that of gonorrhoea, pyemia, etc.—Centralblatt für Klinische Medizin, May 10, 1884.
LEGALIZED PROSTITUTION.

To those who, as a remedy for the public prostitution in New York City and elsewhere, have advocated a regulation by law, a close perusal of the work on Prostitution by Yves Guyot, member of the Municipal Council of Paris, will be both instructive and suggestive. M. Guyot has exhaustively reviewed the operation of the regulation system in France especially, and the other Continental countries in general. He also devotes some space to the working of the special provisions of the Contagious Diseases Acts in the military stations of England. M. Guyot, though plainly showing his antagonism to the license system, has not contented himself with mere phrases of rhetoric in displaying his opposition, but calmly and dispassionately has marshalled the incidents of years in order to support his enmity to a system which he deems illiberal, cruel, and unjust.

M. Guyot should be listened to with all the more consideration, owing to the fact that he has shown by his willingness to face the anger of the police de maurs, and even accept imprisonment for his opinions, that he has been actuated by naught except a sincere desire to overturn laws which bring discredit on a people enforcing them. He shows that the practice of making prostitution a source of revenue to the State is not French in origin, but dates back to the period when Solon was the law-giver of the Athenian Republic. From that time to the present the whole history of the attempts made to restrict or confine the carnal appetite has been a dark calendar of brutality and wrong to the unfortunate who, either from choice or unfortunate circumstances, have engaged in sexual commerce. To the minds of those who are disposed to be favorable to a form of regulation the rehearsal of the indignities suffered by fallen women prior to the nineteenth century may seem uncalled for, and not a fit method of rationalization. But when it is considered that these repetitions are but links in the long chain which is still being forged, M. Guyot can be pardoned for bringing up the past.

The arbitrary way in which women are compelled to submit to the enforcement of the police regulations is sufficient to cause a glow of shame to come to the cheek of every man who assists in sustaining a code which compels a woman to submit to an examination as if she were a diseased animal. A woman shows herself on the pavement after a certain hour. She may be a wife and mother about to obtain some necessary for her family. She may know of the laws governing prostitution, but lulled by the security which innocence always feels she is unconscious that any of the provisions may be twisted in such a manner as to apply to her. A member of the "Morals Police," anxious to make an arrest and moved by innate brutality, has the power to confine her in prison among abandoned women of all degrees of degradation, and when at last the unhappy woman is enabled to produce the testimony substantiating her assertions at the time of the arrest, she is discharged with the admonition to be more discreet in future and not mislead the virtuous police. She is no doubt happy to be relieved from bondage; but can it be supposed that a refined gentlewoman will ever forget the horrible nightmare of her incarceration?

Frightful as this may be, how much more incredible the situation of a young girl who from untoward circumstances finds herself in the hands of the supervisors of prostitution? Unable to communicate with friends, she undergoes the hellish ordeal of the speculum in the hands of men who disgrace the profession of medicine, and when, too late, her virginity is known she has the alternative of taking her ticket and becoming a registered prostitute, or bearing with her forever the thought of the horrible indignities to which she has been subjected.

A man becomes tired of the woman with whom he has lived, and bound by no ties of either Church or State, too cowardly to face the woman's tears or anger if he breaks off the connection, communicates with the police de maurs. They arrange it for the recreant lover, and the woman is forced to be examined and registered or leave the country. A girl lives in furnished rooms. She may have nothing in common with prostitutes, or may even be a respectable woman. The police de maurs, however, have observed her and she must accede to their demands or report for examination. The requirements of the police vary at times. They may ask individual fees or the satisfaction of private lust. At others they act as procurers for favorite or well-paying establishments protected by law. At all times they stand between the keepers and actual procurers and the law, and operate as stop-gaps whenever a person through philanthropy or curiosity attempts to discover the inner workings of legalized houses.

Never do these models of the "Morals Police" miss a chance to levy tribute from the miserable women whose masters they are, and from long experience becoming satisfied that they have immunity from punishment, force the chattels of the State to become the concubines of the enforcers of the law. These phases of the question, however, might be remedied if the law itself was a true solution of the problem, but it is not. Statistics which cannot be disputed prove that but a small percentage of prostitutes are registered in any of the countries where the regulation system is in vogue. This is the result after years and years, and when the non-registered know they are running the risk of imprisonment. The theory M. Guyot advances to account for this is, that no matter how mercenary and vile a woman may appear, there is still left a beginning spark of womanhood and shame, which fills her with horror at the thought of being examined by men who boast of the speed with which they
dispose of women. One inspector prides himself that he examined 120 subjected women in an hour.

As a safeguard against venereal complaints the inspection has also proved a decided failure. The statistics of the Paris hospitals in which records have been kept show that the percentage of venereal cases contracted from registered women is much larger than from those who have declined inspection. M. Guyot in commenting on this point mentions the unreliability of statistics of this nature, owing to the many peculiarities of syphilitic infection, but at the same time calls attention to the fact that from its very rapidity the inspection is never thorough and very often a genuine case of syphilis may be overlooked. While on the other hand, taking into consideration the virulence of the syphilitic poison and that the speculum is not thoroughly cleaned after each inspection, it may be naturally inferred that many women who enter the inspecting rooms absolutely free from venereal taint leave with the dried syphilis implanted in their systems, the poison having been transferred from a diseased woman by the medium of the speculum. The same thing has been noticed at the military and naval stations in England. Cases of a venereal nature have increased since the Acts of Contagious Diseases have been put in force, although the freaks of statistics are again illustrated in Portsmouth harbor, where two naval vessels anchored beside each other showed the most remarkable variations, one vessel having a percentage of syphilitic cases threefold as much as the other. But, leaving out all these disturbing factors, M. Guyot seems to make an almost unanswerable argument against the continuance of these provisions.

The work of M. Guyot bears the impress of honesty. He has not avoided ridicule of those who think differently, but if he had he would be a paragon. One thing, however, is to his credit, and that is in his figures and tables he has not attempted to twist everything into arguments for his side. As a whole, however, M. Guyot does not make his crusade upon the question of the success or failure of the laws, but bases it upon the sacred feeling of humanity and justice to women. As to syphilis, looked at from a hygienic point of view, M. Guyot well says, to cure it we must first get rid of the old prejudice which looks upon it as a shameful disease. Against it we employ police regulations, restraint, and annoyances, as prophylactic means—and forget only one thing—to care for it properly. To bring about the eradication of the disease, all hospitals should look upon it the same as any other disease and make the patient comfortable. The readers of M. Guyot's work when they reach the last chapter may be surprised by his plan to weed out prostitution. It may be a wild and chimerical method which he advances, but it must be admitted that it seems to be the only remedy. It is that the morals of the day undergo a complete transformation, and that instead of a woman being damned by social laws for the least trip she will in time be measured by the same gauge as man.

SECUlRINg A DIPLOMA BY SPECIAL MANDAMUS.

Information has reached us concerning a certain somewhat novel method by which a female medical student in the Woman's Medical College of this city succeeded in getting her diploma against the will and wishes of the Faculty. The story is interesting, and carries a moral for other medical colleges in this country. It appears that the student in question, though no doubt artless herself, was the wife of a lawyer, and was also a shorthand reporter. Throughout her medical course she had ranked as low as possible at the quizzes, but had surprised her instructors by getting sufficiently good papers at the final examinations to enable her to pass all the examiners but two, viz., the Professor of Obstetrics and the Board Examiner on Materia Medica and Therapeutics. Having failed before these two, however, she was, by the rules of the Faculty, not recommended for a diploma. But, anticipating trouble, she had kept a copy of her examination paper before the Professor of Obstetrics.

Copies of this were sent to Dr. L. A. Sayre, Dr. J. W. Ranney, Dr. T. Gaillard Thomas, and Dr. Byrne. These gentlemen all certified that the paper was a correct and a good one, showing perhaps unusual intelligence. Upon the authority of these names, a mandamus was issued, and the Dean of the Faculty was ordered to decide in half an hour whether the College would grant a diploma or stand a suit. Upon taking legal advice it was found that technically the student had the advantage and the College had no case. Medical colleges, it was argued, were not arbitrary bodies, and could not refuse a degree to a student without reasonable ground. This student was refused a degree by one Professor whose judgment was based not alone upon the examination papers, but upon personal and verbal examinations extending over a long time. Practically her judgment was overruled, and the College compelled to confer a diploma through the interference of the physicians above named. We have no doubt that these gentlemen passed upon the papers in ignorance of their real nature, but their action is not to be regretted the less on that account.

But the main lesson to be drawn from this incident is one of warning to medical colleges who desire to confer degrees only upon those whom they believe to be fit. If the tests are entirely written, it may be possible for an ignorant student, by industrious "cribbing" to get papers upon which the court will issue a mandamus for a diploma.

It is only fair to say that the examinations of the Woman's Medical College are conducted with more than usual care and strictness; for the students have to pass not only the Faculty, but subsequently must go before an independent Examining Board.

RECTAL ETERIZATION AND DR. AXEL YVERSEN, OF COPENHAGEN.

We have noticed that several of our contemporaries, in speaking of rectal etherization, refer to it as Molière's method. This is we think an injustice to the man to whom Molière owed the suggestion, and one that should be corrected at the outset. For although it is too soon to speak of anaesthesia by the rectal method as an innovation of real value, it is nevertheless not at all improbable that it may in time come to be recognized as a procedure of practical utility in certain cases. It is now on trial in several cities throughout the country, but time only can determine whether it will be adopted finally as
June 7, 1884.] THE MEDICAL RECORD. 643

a safe and convenient mode of inducing anesthesia. Should it be so adopted the procedure must receive a name, and that name should be one by which credit is given to the one to whom credit is due. Molière was indeed the first to call attention publicly to this method, but he did not claim the merit of the invention. As was pointed out in The Record of April 26th, his experiments were undertaken at the suggestion of Dr. Axel Yverson, of Copenhagen, and it seems only right, therefore, that this method of etherization should be called Yverson's or the Danish method, rather than Molière's or the French. It too often happens that the men who make discoveries remain unknown, while the credit for their work is bestowed on others who possess the faculty of presenting these discoveries to the world in a striking and attractive light. In the event, therefore, of Yverson's method becoming established as a practical and useful way of inducing anesthesia, we hope that the originator may not be deprived of the honor due him.

THE UMBRELLAS AND CHAIRS OF LULU HURST.

For several months Southern papers have been describing the wonderful performances of a young girl known as Lulu Hurst. These reports have stated that she possessed a unique and extraordinary "force."

We were pleased, therefore, to receive recently a very careful and conscientiously written account of this phenomenon from Dr. Seth N. Jordan, of Columbus, Ga. Dr. Jordan states that, in company with Drs. George Grimes and Carlisle Terry, he examined Miss Hurst, and that they are all agreed that she is not a fraud, but possesses some extraordinary and occult power. He writes that she is fifteen years of age, five feet four inches high, weighs one hundred and twenty-five pounds, is of moderate muscular development, in good general health, has menstruated regularly, is of an intelligent and amiable disposition. She first became aware of the possession of her "force" last September, and it has continued ever since, with the exception of a brief interval when she had a "cold."

Drs. Jordan, Terry, and Grimes, having purchased a new umbrella, experimented with her for four hours in the room of a hotel. The phenomena developed were somewhat as follows: Two or three scientific persons take hold of the handle of an open umbrella, and hold it fast; Miss Lulu then touches it with her open palm, when, presto! the umbrella is turned inside out, or snatched away despite every effort. Meanwhile other persons find that no muscular contractions have taken place in Lulu's arms.

Three strong and scientific men lift up a chair and hold it in the air. Lulu places her hand upon it and it sinks to the floor despite every effort. Dr. Jordan and others took hold of a long stick, the phenomenon touched the other end and it rapidly revolved, or pulled the three experimentalists roughly about the room. Miss Hurst's "force" seems to have a peculiar "penchant" for umbrellas and canes, so that she cannot carry the former article at all, the mystical something snatching it away and leaving her out in the wet.

With the exception of the production of knocks and raps, the above are the chief phenomena exhibited and described.

We fully believe that Dr. Jordan has described them correctly, and that Miss Hurst is a remarkable girl. But there is one feature in all her performances which no one, not even Dr. Jordan, seems to have noticed, or, at least, carefully studied. This is, that all the exhibitions of her wonderful force are exhibited in opposing voluntary muscular effort in others. This force has no power over dead matter, but only over living, conscious, muscular exertions. This fact explains, we believe, the mysterious energy which the Georgian phenomenon appears to develop. It is the experimenters, not the subject, who knock themselves and the umbrellas about. At any rate the matter ought to be investigated from this standpoint. It will probably be found that Miss Hurst's exhibitions are only another phase of the hypnotic phenomena.

News of the Week.

ARSENIC IN COFFEE.—The New York City Health Board found about one-twentieth of a grain of arsenious acid in two ounces of certain specimens of coffee examined.

THE KENTUCKY STATE MEDICAL SOCIETY met at Bowling Green this past week.

THE WISCONSIN STATE MEDICAL SOCIETY met on the same day.

THE NATIONAL BOARD OF HEALTH.—The Committee on Public Health of the House of Representatives has agreed to report adversely on the bill recommended by the National Board of Health for renewing the Quarantine Bill of 1879, taking the ground that it is not expedient to give the Board control of quarantine matters, and that the Treasury Department is managing that matter sufficiently well. It recommends that $200,000 be appropriated as a contingent fund, to be drawn at the discretion of the President, for preventing or checking epidemic disease, and it is to be presumed that the intention is that this fund shall be expended through the Marine Hospital Service. It also recommends that $25,000 be appropriated for the salaries and expenses of the National Board of Health, $18,000 being for scientific investigations. This action may be looked upon as a defeat for the Board, although it is better supplied than it was a year ago. Certainly the sum of $18,000 ought to bring forth some scientific work. The final settlement of the question, however, does not occur until the Sundry Civil Appropriation Bill comes up.

A CONFERENCE OF THE HEALTH OFFICERS OF THE GULF STATES was held this week at New Orleans. A committee was appointed to formulate a uniform system of quarantine for the entire Gulf coast, and another committee was appointed to consider the question of inter-State quarantine. Dr. Thornton, of Memphis, offered a resolution to memorialize Congress to invest with authority and means the National Board of Health as a medium of inter-State quarantine. Dr. Thornton's resolution was defeated by the votes of Alabama, Florida, Louisiana, and Texas against it, with only Tennessee and Mississippi in its favor.
THE ONTARIO MEDICAL ASSOCIATION held its fourth Annual Meeting at Hamilton on June 4th and 5th. A large number of papers were read.

THE CELEBRATED CHEMIST, Prof. C. A. Wurtz, died in Paris on May 12th, in the sixty-seventh year of his age.

PRESTBYTERIAN HOSPITAL, NEW YORK.—The recent annual election of officers of the Medical Board of this hospital resulted as follows: President, Dr. Alfred C. Post; Vice-President, Dr. Alexander Hadden; Secretary, Dr. Frederick A. Castle.

St. Luke's Hospital, New York.—Dr. Robert Abbe has been appointed surgeon to St. Luke's in place of Dr. W. T. Bull, resigned and appointed consulting surgeon in place of Willard Parker, deceased.

PROLONGED REPRIEVE AGAINST COMMUTATION.—The Governor of Delaware is not allowed to commute the death sentence of a criminal, but he can grant reprieves. In a recent case, where the circumstances seemed to warrant clemency, the present Executive devised a method of circumventing the law, for he granted a reprieve for fifty-six years.

PRIVATE HOSPITAL FOR EYE DISEASE.—Dr. Thomas R. Pooley has opened, at his residence, 107 Madison Avenue, a private hospital for eye and ear diseases.

THE ELEVATED RAILROAD CASE AND DR. TAYLOR.—Dr. Charles Fayette Taylor and Dr. Thomas L. Christie sued, some time since, the Manhattan Elevated Railroad for $25,000, estimating this to be the damages to their hospital for nervous diseases, at Fifty-third Street and Sixth Avenue, resulting from the noise caused by the cars of the company. At the first trial the jury disagreed, at the second a verdict was rendered in their favor for $20,000. This verdict has now been reversed on appeal by the General Term of the Superior Court. In the opinion directing a reversal, it was said that the use of the street for railroad purposes was consistent with other uses, and that the damage to property owners must come from the blockading of the street. The estimate of damage must depend upon the lowering of values and loss of rental. The loss of patients resulting from the noise are remote consequences and cannot be taken into consideration. The physicians might have removed to another location, and the loss of patients would not have occurred. As the verdict was largely based on the last consideration, it was held that it must be reversed and a new trial ordered.

A PECULIAR CASE, of much interest to medical men, has recently been decided in the English courts. The plaintiff was the father of a child who suffered from "croup." It being necessary to insert a tube in the child's throat to relieve it from threatened suffocation, the operation was skillfully performed. After the insertion of the tube the physicians requested the father to free it from the accumulated matter with his lips, which he instantly did, the doctors neglecting to tell him that he incurred any risk. The child died, and its disease proved to have been diphtheria, by which the father, in turn, was soon attacked. He sued the doctors for damages. The case was tried twice and was much discussed in the English press. Upon the first trial the jury disa-}

[June 7, 1884.]

greed. But Lord Coleridge told the second jury that the doctors were right in telling the father to free the tube, and a verdict for the defendants was found.

PUBLIC COMMENTS UPON DR. KOCH.—The Berlin correspondent of the Pall Mall Gazette writes: The hero of the hour at Berlin at present is Dr. Koch, the President of the German Cholera Commission, who has just returned from India, where he has discovered the cholera germ. In appearance he is described as of medium height, very thin, with a serious, energetic, spiritual student's face. His beard is brown, but his hair is becoming gray, and this, together with his glasses, makes him seem to be older than forty or forty-one. He studied medicine at Göttingen and afterward pursued his microscopic studies of bacteria at Breslau, under Professor Cohn. Geheimer Rath Koch has been known to the scientific world for some time as a conscientious and accurate observer, but to the non-scientific world his name was unknown until his discovery of the cholera germ. It now promises to be as famous as that of Jenner or Harvey.

PROFESSOR BURT G. WILDER has resigned his position as Professor of Physiology in the Medical School of Maine.

A DOCTOR'S SEMI-CENTENNIAL JUBILEE.—It is the custom in Germany for physicians who reach the fiftieth year of their medical practice to celebrate it. Dr. Bernard Segnitz, of this city, introduced this very pleasant custom into our city by celebrating his own medical semi-centennial last week. The doctor was the recipient of many congratulations and valuable presents. Dr. Segnitz is seventy-four years old, but is in excellent health. He came to this city as a political refugee in 1851, and has practised here ever since.

MORTALITY IN THE STATE OF NEW YORK.—The State Board of Health has commenced to issue a bulletin of mortality for the whole State. Though confessedly imperfect at present, especially for the smaller towns, the returns given are of much interest. Of the cities of over 20,000 inhabitants which are given, the order of healthfulness, as indicated by these returns, was, during the month of April: 1, Troy, with a rate of 6.6; 2, Kingston and Binghamton, 10.8; 3, Watervliet, 12.42; 4, Oswego, 15; 5, Yonkers, 13.9; 6, Rochester, 14.3; 7, Albany, 15.10; 8, Long island City, 15.43; 9, Brooklyn, 19.66; 10, Newburg, 19.95; 11, Utica, 20; 12, Syracuse, 20.11; 13, New York, 22.36; 14, Albany, 25.88. We doubt if the above figures are as yet sufficiently accurate to base any safe inferences as to comparative healthfulness on. At any rate, it seems incredible that Troy should really have so extraordinarily small a death-rate as 6.6, while Albany, its neighbor, has 25.88.

THE LEGAL STATUS OF THE MEDICAL DEPARTMENT OF NIAGARA UNIVERSITY.—Dr. A. A. Hubbell, of Buffalo, Secretary of the Medical Department of Niagara University, sends us a copy of a bill, recently become a law, which gives to the University in question full power to confer degrees in medicine. This law seems to settle definitely the question as to the legal status of the medical school.
THE WILL OF THE LATE PROFESSOR GROSS.—The will of the late Professor Samuel D. Gross has been admitted to probate. He bequeaths his medical library, museum, and diagrams to one of the following institutions: The Jefferson Medical College, or the Philadelphia Academy of Surgery, or the College of Physicians of Philadelphia, the choice of said institution to be made by his executor. If the institution so chosen does not accept this bequest, then it is to go to the University of Pennsylvania or the New York Academy of Medicine. He also bequeaths the sum of $5,000 to provide a prize every five years for the writer of the best original essay illustrative of some subject in surgical pathology or surgical practice founded upon original investigation.

THE WOMAN'S MEDICAL COLLEGE OF THE NEW YORK INFIRMARY held its annual Commencement on May 29th, at the University Club Theatre, Degrees were conferred upon nine graduates. Dr. Emma Ward Edwards delivered the address to the graduates.

DEATH OF A NOTABLE PHYSICIAN.—Dr. Samuel Fiske Green, of Worcester, Mass., died on May 28th. Few physicians have the capacity or inclination to accomplish what he did, and his life deserves more than ordinary recognition. He was graduated from the College of Physicians and Surgeons in this city. He began the practice of medicine in Worcester, but after a brief experience abandoned it to enter, from a sense of duty, the service of the American Board of Missions, and to go as a physician to the island of Ceylon, in the Indian Ocean. He soon mastered the Tamil language and established a school at Jaffna for the education of the Tamil youth in the European system of medicine. Having spent ten years in this service he ventured to this country after visiting England and the Continent of Europe on the homeward journey. He subsequently went back to Ceylon and devoted eleven additional years to his work. But the climate of Ceylon injudiciously affected his health, and finally compelled him to return to America. He then took up his residence at his native place, Green Hill, but instead of resuming the practice of his profession devoted himself to the compilation of medical works in the Tamil language. The manuscripts of these works he sent to India to be put in Tamil type, and the proofs were sent back to him for correction. His works in Tamil are now recognized as standard authorities. They are on obstetrics, surgery, anatomy, physiology, physics, and chemistry. He had also completed a pharmacopoeia of India, which is now in the printer's hands, and prepared the vocabularies of medical jurisprudence which he was about to undertake. In the preparation of these works he expended a vast amount of labor and fully twenty-five years of his life. They were executed with discriminating ability and painstaking fidelity, and with but narrow means at his disposal. The British Government, of which the island of Ceylon is a crown colony, in recognition of his services, made an appropriation, out of which he received a small stipend for the furtherance of his work. The students trained by Dr. Green are sought by the British Government for its Tamil service, and the doctor's name has become a household word among the people of the island. There is on record no more distinguished example of the beneficial results of a life of self-sacrificing devotion to the cause of humanity. Dr. Green possessed a singularly felicitous and pointed diction, and the pages of his works are filled with annotations on the different shades of meaning of words commonly accepted as synonymous. His life was a conspicuous example of self-denial, and of modest and unassuming worth. In his disposition unvarying gentleness and cheerfulness were united with dignity, independence, and firmness. His leisure time was spent in comforting and aiding those about him.

A PHYSICIAN INDICTED FOR MURDER.—Dr. S. G. Allen, Jr., a finely educated and promising young physician, and son of one of the leading physicians of Vermont, is in jail in Boston charged with murder. Dr. Allen, Jr., came to Boston on a visit, and while there went on a spree. While engaged in an altercation in a bar-room he shot and instantly killed an unfortunate man with whom he had been talking. The act was a drunken freak, but its perpetrator is now in jail charged with murder.

AT THE AMERICAN MEDICAL ASSOCIATION.—When the Association was in session in Washington last week a bright Vermont doctor introduced an innocent Indiana physician to the Vermont Senators. The Indiana man was particularly pleased with Senator Morrill because he looked so much like Sumner. "But," said the Vermonter, "Edmunds is the greater man. Besides, he thinks a great deal of doctors." "Why is that?" asked the Indiana man. "Because," replied the Vermonter, "he is an owner of one of the largest tombstone factories in Vermont."

SMALL-POX IN LONDON.—Cable reports state that small-pox is very prevalent in London, and that the city authorities are intending to erect another small-pox hospital.

THE RETURN OF KOCH AND HIS ASSOCIATES.—Dr. Koch and his associates Gaffky and Fischer, reached Berlin on May 3d, and were warmly welcomed by their scientific and medical brethren. A banquet was given them on May 13th. The Government has awarded them the sum of 135,000 marks, and the Emperor has bestowed upon Koch a decoration.

THE AMERICAN NEUROLOGICAL ASSOCIATION holds its annual meeting in this city on June 18th, 19th, and 20th.

THE NEW JERSEY STATE MEDICAL SOCIETY meets at Cape May on June 10th and 11th.

VACCINE AGAINST HYDROPHOBIA.—M. Pasteur claims now to have twenty-three dogs which he has made susceptible to hydrophobia by inoculating them with attenuated virus. The virus has been modified by passing it through several animals, especially monkeys and rabbits.

MEDICAL WOMEN ABROAD.—Forty young women have matriculated with the Faculté de Médecine of Paris. Two women from California have recently received their degree from that Faculty. A young woman, a graduate of Berne, has just passed the examinations and been admitted to practise in Belgium. This is the first time a woman has passed these examinations in that country.
THE MEDICAL RECORD. [June 7, 1884

A DOCTOR IN THEOLOGY.—Dr. William H. Thomson, of this city, has written a work, published by Harpers, entitled "The Great Argument." It is said to be an able and learned contribution to Christian apologetics.

GOLDS' DOG.—Professor Golds has a dog which he evidently wishes to become historical. He showed it before the Congress of Internal Medicine last month as an argument against the present cortical localization theories. He claimed to have removed a large part of the cerebral cortex without producing any permanent paralysis or severe symptoms. Dr. Gustav Fritsch has written a letter to the Berliner Klinische Woehenschrift in which he denies the argument of the dog. The whole of a recent issue of the Journal of Physiology has been taken up with the subject of Golds' and Ferrier's dogs, and the proper interpretation of their encephalic losses. Vide op. cit.

VACCINE AGAINST YELLOW FEVER.—Medical science has been treated lately with the announcement of two new protective "vaccines," one against rabies, the other against yellow fever. The discoverer of this latter virus is Dr. Domingo Freire, of Rio Janeiro. He avers that the virus of yellow fever is a vegetable parasite which he names cryptococcus xanthogenius. It possesses great vitality and can be inoculated in some of the lower animals. Having alternated this plant, Dr. Freire inoculated four hundred persons with it and rendered them refractory to the fever. Dr. Freire, it will be confessed, must have had persuasive powers of an extraordinary character, whatever may be his scientific attainments. The medical world will await a second bulletin before it accepts the cryptococcus.

THE SIMS MEMORIAL FUND.

To the Medical Profession and Others throughout the World:

The great achievements of Dr. J. Marion Sims call for some more lasting testimonial than obituary and eulogies. To him medical science is indebted for much brilliant and original work, especially in gynecological surgery. Those who have been benefited by his teachings and new operations, and such as have had the direct advantage of his personal skill are among the first to recognize and acknowledge this debt.

To him is due the honor of giving the first strong impulse to the study of gynecological surgery in America.

It is believed that the medical profession everywhere, the vast number of women who owe their relief from suffering directly to him, and those who realize the benefits he first made possible, will gladly unite thus to honor the man through whose original and inventive genius such blessings have been conferred upon humanity.

At the suggestion of many friends, therefore, the subjoined committee has been organized, and it is proposed that a suitable monument be erected to his memory in the city of New York.

To this end the active co-operation of the medical profession and the many other friends of Dr. Sims throughout the world respectfully solicited. Contributions of one dollar and upward may be forwarded to the journal which has been constituted the treasury of this fund—THE MEDICAL RECORD, New York.

Hooper's Physician's Vade Mecum: A Manual of the Principles and Practice of Physic; with an Outline of General Pathology, Therapeutics, and Hygiene. Tenth Edition. Revised by William Augustus Guy, M.B. Cantab, F.R.S., Fellow of the Royal College of Physicians; Late Professor of Forensic Medicine and Hygiene in King's College, London; Consulting Physician to King's College Hospital, etc.; and Harvard, M.D. Lond., F.L.S., Fellow of the Royal College of Physicians; Honorary Fellow of King's College, and late Physician to the London Fever Hospital; Lecturer on General Anatomy and Physiology at, and Physician to, St. Thomas' Hospital. Volume I. New York: William Wood & Co. 1884.

It is unnecessary to do more than refer to this standard work, for a book which has maintained an authoritative position for over half a century, and which has been studied and consulted by several generations of physicians, speaks for itself and needs no words of commendation from us. The original work of Dr. Hooper was published in 1831, but it has been revised and practically rewritten many times, to keep pace with the advance of medical knowledge, that the author, were he to revisit the earth, would find some difficulty in recognizing it as his own. The plan and general arrangement of the subject are his, and as it is here that the practical value of the book resides, it is very justly called by his name. But the matter is the editors', and we have in this a sufficient guarantee that the high standard of the Manual as an authority is fully maintained. This first volume appears as the May number of Wood's Library, and though we think it would be better were original works only published in this series, we must nevertheless confess that it would be difficult for any writer of the present day to produce a book of such real practical utility as Hooper's Manual.

Eczema and its Management: A Practical Treatise Based on the Study of Three Thousand Cases of the Disease. By L. Duncan Bulkley, A.M., M.D., Physician to the New York Skin and Cancer Hospital; Attending Physician for Skin and Venerable Diseases at the New York Hospital, Out-Patient Department; Dermatologist to the Hospital for Ruptured and Crippled; Anatomy Professor and Pathologist, Manhattan Hospital; Late Physician to the Skin Department, Demilt Dispensary, New York; Late Editor of the "Archives of Dermatology;" Translator with Notes of "Neumann's Hand-book of Skin Diseases;" Author of "The Skin in Health and Disease;" Permanent Member of the American Medical Association; Fellow of the American Academy of Medicine; Fellow of the New York Academy of Medicine, etc. Second edition. New York: G. P. Putnam's Sons.

This is the second edition of Dr. Bulkley's now well-known work on eczema. The data from some five hundred additional cases are incorporated in the tables, but no changes of importance have been made, the numerous alterations and additions which are found being merely the expression of the author's endeavor to simplify the subject as far as possible. By so doing he has in no way taken from the value of the work, but rather added to it by adapting it more perfectly to the wants of the general practitioner. We are surprised to see the author, who certainly needs no such bolstering, giving countenance by his example to the growing, but nevertheless foolish and dangerous, custom of tackling on to his name a long list of titles and positions, now so generally held, some of which can be had by anybody for the asking and the payment of the necessary dues. It is very proper to append to an author's name, on the title-page, such titles as may be of themselves an honor, or which may show that he has a right to speak authoritatively on the subject treated of in his book. But a declaration of membership in the Academy of Medicine, the only recognition for admission to which is a professional age of three years, can serve no such purpose. No one can accuse the author of this book of seeking to advertise himself by the use of a row of meaningless titles, but in the case of some less known and less honored man that would be the, perhaps, uncharitable conclusion arrived at.

In this book are presented short abstracts of the most important journal articles treating of surgical subjects which appeared during 1883. The selections are well made and embrace a variety of subjects, showing the advances made in surgery during the year. The book itself is printed in clear type, on good paper, and is neatly bound. But in the presence of Braithwaite and the Quarterly Epitome, the series of Year-Books of Medical Progress, of which this volume forms a part, it can hardly be said to meet a long-felt want, for so much want exists.

Mr. Power has given us a clear, concise, and altogether very interesting and valuable presentation of the subject of human physiology. Like many other English writers, he has drawn very freely upon Landis; but the book is original in some of its arrangements, and especially in the lucidity with which it deals with many intricate physiological problems. As the present volume is one of a series, the author has omitted such details in histology, chemistry, and practical experimentation as would be found in the other works.

While Mr. Power's work is unquestionably a success, it is a mistake to suppose that it can supplant in any way the standard text-books. It is rather a work for refreshing the student and for instructing the physician who wants to learn modern physiology.

The most unsatisfactory part of the book is that devoted to the nervous mechanisms of the different organs. A considerable part of the chapters on the nervous system is condensed so directly from Landis, that it would seem but justice to give that author some credit.

This little book is compiled for the express object of enabling parents to keep a record of the diseases their children have passed through. The object aimed at is a good one, though it may seem to the lay mind rather laborious. The book consists of tables and pages for menenoranda, suitably arranged.

The Hospital de Bicêtre contained, in December, 1881, 297 patients, of which 119 were epileptic adults, 76 epileptic children aliénés, 26 epileptic non-aliénés, and 71 idiots and imbeciles. The present volume is a clinical history of the service during the year. The chapters include "notes and observations upon epilepsy;" hystero-epilepsy in a boy cured; observations upon epilepsy. Much space is given to the history of an epidemic of measles which broke out in the Asylum. The most in
teresting portions are the cases of epilepsy, microcephaly, and idiocy, in which careful post-mortem were made. These are illustrated with several beautiful colored lithographs.

Erbstein's views upon the treatment of corpulence are familiar to the profession. He believes in a prolonged dietetic treatment of meat and fat, with green vegetables. He proscribes sugar and starch. The treatment is based on Voit's theory that human fat comes chiefly from the albuminates, a theory, which, though widely accepted, may yet be overturned. Erbstein's method as yet stands chiefly upon theoretical considerations.

There has long existed, in both the medical and legal professions, a demand for the practical codification of information bearing upon the medico-legal relations of a large number of lesions, involving more or less extensively the nervous system. Now that we have worked out treaties which have for their object the elucidation of the legal application of the medical sciences—such indeed we have. But while some of these works are explicit with regard to the medico-legal aspects of mental diseases, they fail to give adequate prominence to the forensic questions liable to arise in cases of spinal injury, epilepsy, and many neurotic affections. The consequence of this state of things is, that where special information is required upon individual points, it must be sought after in the files of journals, or in the pages of inaccessible monographs. In the work before us we find these deficiencies in a great measure remedied. The modest table of contents affords, indeed, but a meagre idea of the amount of information which Dr. Hamilton has been able to compress within the compass of about three hundred and eighty pages. It is only when we examine the excellent index and carefully con over the leaves, that we become aware of the exhaustive manner in which these disorders of the nervous system, which give rise to the treaties, have been treated.

We do not agree with the author, that the two definitions of insanity "that are the most satisfactory are those of Bucknill and Maudsley. " Nor do we believe that "a man who declares himself an agnostic is apt to injure his case and render himself ridiculous," when called to the witness stand to testify as a medical expert. As well might it be affirmed that, because a man's hair is black, or his eyes blue, he is therefore debared from the confidence of the community at large. This is certainly poor logic and narrow philosophy.

Dr. Hamilton cannot countenance the views of Kraft- Bing and others regarding the more delicate shades of mental disorder (primâre and originaire verücktheit). On this point he says (page 62): "I regard many of these delicate distinctions as founded upon a too sentimental plane, for, if we are to excuse men who are simply bad for the crimes they may commit, we shall open the doors of escape for all manner of wickedness." If Dr. Hamilton will examine the description given by Kraft-Ebing, he will find that there underlies what he terms "bad," a condition that is not a substantial—nor a mental condition as morbid as it is complicated. How are we to refuse to recognize—to repudiate this mental pathology simply because the outgrowth of the same is "bad?" As conscientious laborers in the cause of scientific psychiatry it is impossible.

The chapter on spinal injuries is excellent, as is also that which treats of cranial injuries. Taken as a whole, this little work must be regarded as an exceedingly practical contribution to medico-legal literature. Moreover, it has the distinctive quality of being written in such a manner as to be perfectly intelligible to the general medical reader.

As the author explicitly states in his preface, the chief object of the present work is to point out the pernicious uncertainty of verdicts in insanity trials, with the hope that by calling attention to the more prominent causes of that uncertainty, some of the more objectionable features of our medical jurisprudence may be removed.

By the aid of the physical media theory, our author hopes to accomplish this eminently desirable end.

As is well known to psychologists, the "physical media" theory maintains that mind is a "distinct, intangible, incorporeal entity," not dependent upon organized matter for its existence; but simply beholden to the latter for its manifestation "in this life." In other words, mind does not owe its existence to the disintegration of brain-tissue, but only to its manifestation. Upon the assumption that he has proven the validity of the "physical media" theory, the author states the following definition of insanity: "A diseased or disordered condition, or malformation of the physical organs, through which the mind receives impressions, or manifests its operations, by which the will and judgment are impaired, and the conduct rendered irrational." And as a corollary to this he offers: "Insanity being the result of physical disease, it is a matter of fact to be determined by medical experts, not a matter of law to be decided by legal tests and maxims." So then, since mind is only manifested through the brain, and since our author affirms that insanity is an abnormal condition of the physical organs, through which the mind manifests its operations, we are led inevitably to the sufficiently astounding inference, that insanity is not a pathological mental condition, per se, but simply a morbid manifestation of an otherwise healthy "intangible, incorporeal entity."

This is, indeed, a fantastic compromise between metaphysics and disjointed physiological conceptions. Such spavined logic will never do, either in court or out of it.

The author, however, deserves credit for the fearlessness and confidence with which he has boldly ventured. Moreover, he has contrived, in the discussion on the nature of mind, and in the subsequent chapter on "experts," to introduce much interesting information.

This book will prove an acceptable addition to the library of those interested in psychological matters.

Students who wish to gain an idea of the general principles of chemistry and of the composition of chemical compounds, will do well to consult this book. It is expository rather than didactic, and is more interesting on that account to the searcher for knowledge. It is a work which ought to supplement well the ordinary text-books.

With the present number this valuable compendium will be issued quarterly instead of half yearly. It furnishes a most excellent summary of medical progress, and we are glad to find that its work is to be made still more comprehensive.
Reports of Societies.

PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, May 2, 1884.

ROBERT F. WEIR, M.D., PRESIDENT, IN THE CHAIR.

DR. V. P. GIBNEY read a paper (see p. 639) on
THE TREATMENT OF SCIATICA.

DR. BEVERLEY ROBINSON had treated all of his cases of sciatica with familiar methods except one, in which he resorted to stretching the nerve with benefit. So far as his limited experience went he would say that the use of the actual cautery, latterly the thermo-cautery, had given the best results, especially in relieving the pain. Probably he had not pushed the use of galvanism and faradism as far as one would who had a special inclination toward that method of treatment, but he had used it sufficiently to convince him that it was not so successful as the use of the cautery.

He had relieved patients from the liability to recurrence of attacks by the use of deep hypodermics of morphone. Chloroform had acted unfavorably in his hands. He had treated sciatica with blisters and with trituration of iodine without notable effect, but with the actual cautery and deep injections of morphone he had obtained his best results.

DR. C. L. DANA said that he had notes of thirty cases of sciatica, some of which he had treated with electricity and others without electricity, at least in a systematic manner, the cases being selected by Dr. Gibney. So far as electricity was concerned, he had tried Dr. Gibney's method and had had the same experience; that is, some of the patients went out shaking the leg and feeling almost well for a time, but they generally got worse toward night, and on the following day again suffered from the pain; but by keeping up the application of electricity daily the pains were finally relieved permanently within a few days. He had, however, had some cases in which this plan of treatment had not done any good whatever. In the majority of his cases the patients had had rheumatic tendency, and perhaps that was the reason why they did not respond so well to the galvanic current.

He had not attempted to pay very much attention to the并列, and had had the same effects as those described by Dr. Gibney. He had also used the gravity cells. He would not advise any one to get the Leclanché battery, because it soon runs down and gets spoiled. Theoretically the best battery was the gravity because the internal resistance is about equal to the internal resistance of the body, and they balance each other. Theoretically, also, this was a practical point, and one which had already been referred to by Bartholow.

Aside from electricity he had used blisters, which had given more relief than any of the external applications which he had employed. He thought that if two or three blisters were placed along the course of the nerve, almost uniformly, the pain would be relieved.

Next to blisters came subcutaneous injections of morphone and atropine. He had used chloroform, but without good results. He had also injected the oleate of aconit in one case with marked benefit. He had given aconite internally without special results. The internal remedy which he had served him best was the oil of turpentine, a few drops administered three times a day in cases of pure sciatica, and also those with rheumatic pain. In the cases in which there was rheumatic pain the oil of gaultherium, with turpentine, was certainly very effective, and these remedies, with blisters, had, in his hands, produced relief within a short time.

Whatever the treatment might be, however, relapses were apt to occur, and, after all, patients did not get well much before the regular time in which the disease reached its natural termination. He had used the tincture of gel-selenium in one case, and it cured the patient quickly. Dr. Dana thought that what was needed most was some means of determining the pathology of the affection; whether or not it was a pure neuritis.

Dr. W. J. MORTON knew of scarcely any disease which he had treated more frequently, or which had given him more trouble in treating satisfactorily, than sciatica. He agreed with Dr. Gibney concerning the special form of treatment, but it did not seem to him that it would meet with success in all cases. He thought that the first thing to do in determining the nature of the disease, as there are so many forms of sciatic pain. An acute attack, which is generally referred to some form of exposure, is generally due to a neuritis, but this variety constitutes only about one-third of the cases. He first endeavored to make up his mind as to whether the case was neuritic from anemia and other causes, and if so the treatment must be pursued accordingly. The ordinary sciatica he saw frequently, and immediately proceeded to treat these cases by the use of internal remedies, such as cod-liver oil, iron, caffeine, perhaps stimulants, small doses of morphone, pushing the remedies as the patient could bear.

But as a rule, the cases with which he had to do had been either of the rheumatic or neurotic type from exposure, and in these two classes of cases he had restricted the treatment to the use of electricity and counter-irritation.

One of the first cases in which he stretched the nerve taught him a good lesson. It was a well-recognized case in Roosevelt Hospital, and the condition of the nerves was peculiarly striking. It was swollen larger than his little finger, red, congested, and covered by tortuous veins, and in a condition of active neuritis. He stretched the nerve and the man was cured, but he had not stretched a sciatic nerve since. He had been in the habit, in these cases of acute sciatica following some exposure, almost invariably of resorting to subcutaneous stretching of the nerve, which gives rise to very great pain; but as soon as working of the limb was over it was followed by very great relief, and following it up seven or eight days with another manipulation, these patients get well.

He had great confidence in counter-irritation, and the form he usually selected was the thermo-cautery applied in a hundred or a hundred and fifty places along the course of the nerve. He also believed in blistering, and had tried wet-cupping. Usually, however, he used dry-cups, applying a very large cup immediately over the sciatic notch, applying an air-pump so as to make a large ecchymotic spot.

As to treatment by electricity, he had been in the habit of using the faradic current, in rheumatic cases, in the shape of a brush. He had used static electricity, but would not think of treating the acute cases by this method. In those cases which seemed to be associated with rheumatic diathesis, with a great deal of stiffness and general soreness, he had found that static electricity had given relief, as had other remedies, lasting possibly for twelve or fourteen hours; but he did not see any special advantage in the use of static electricity in the treatment of sciatica.

There was one reason which would induce him, aside from what Dr. Gibney had said, to resort to the strong galvanic current, and that is the ease with which he had had three cases of neuritis in the distribution of the radial nerve, each with a tolerably similar history; that is, violent strain, a spot of extreme tenderness in the distribution of the nerve, swollen fingers, tolerably anaesthetic, and the seat of dull, aching pain increased on use, with a disposition to extend upward so that the pain had reached as high as the elbow. He had treated these cases with galvanism, and in one resorted to
what seemed to him to be a novel feature; that is, he applied the thermo-cautery at six or eight spots sufficient to break down the epidermis, and then applied a very strong current which could be passed directly in the line of the nerve. It was the additional advantage afforded by breaking the epidermis that enabled him to apply the electrical current to the actual point in which the neuritis was situated, and in these cases of neuritis of the radial nerve it was employed successfully. The patients seemed to be practically cured, although it was too soon to determine what the ultimate results were to be.

The President referred to two cases which he had treated by stretching the nerve subcutaneously, according to Nussbaum's method, in one of which relief was quite permanent, but in the other the pain returned in a short time.

Dr. Dana asked Dr. Weir if in any of his cases there was evidence that the function of the nerve had been impaired, as there is after a surgical operation.

The President replied that there was no evidence except burning sensation in the foot.

Dr. George F. Shrady had tried forcible subcutaneous extension in one case at St. Francis Hospital. He utilized the patient, but did not care to bring the tibia in contact with the chin or ear, because he felt something give way in the leg, and it seemed to him to be rather a heroic operation. The patient was relieved for a week, and at the end of that time he left the hospital.

Dr. Morton asked if any of the members had had any experience in breaking the skin before applying the current.

Dr. Dana had not tried it, but it seemed to him that removing the skin would make it more tender and would not admit of the use of the strong current.

Dr. Morton said the cautery simply charred the epidermis without breaking through the skin.

Dr. Sexton remarked that the conversation suggested a possibility of, namely, whether one current is more efficacious than the other.

Dr. Ginney remarked that, so far as his own cases were concerned, he had applied the descending current. He was not certain that one current was better than the other, but it had seemed to him that he had not obtained as satisfactory results with the ascending as he did with the descending current. Most of his cases were chronic, extending over a period of six or seven years; but he saw the patients during exacerbations, and thought that if the exacerbation could be relieved within a week it was good evidence that there was some relation between the treatment and the result. Of course general treatment had been adopted in rheumatic cases, or other general conditions put in the cases to which he referred especially, the treatment consisted in the use of galvanism alone. He had been able to follow the history of some of the patients, and he was quite sure that they had not had severe exacerbations after the regular course of treatment.

EUSTACHIAN CATHERETER.

Dr. Samuel Sexton presented a new flexible Eustachian catheter, manufactured by Ford, with which he had been able to relieve acute middle-ear trouble by drawing out the secretions into the pharynx. The method had been to introduce the catheter, apply a syringe, and draw the secretions from the middle ear into the mouth, and in that way he had succeeded in relieving all the symptoms entirely. He thought that in certain cases this procedure would be very desirable. While he thought it probable that the method had occurred to the minds of aural surgeons, he believed that no case had been previously reported in which it had been done. With a flexible catheter having a peculiar shape, he had been able, to his own satisfaction, to remove the secretions without difficulty, while, as was well known, it was frequently difficult to perform this operation with the metallic catheter. The Society then adjourned.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, May 14, 1884.

GEORGE F. SHRADY, M.D., PRESIDENT, IN THE CHAIR.

REPORT OF THE COMMITTEE ON MICROSCOOPY.

Dr. W. P. Northrup, from the Committee on Microscopy, reported concerning the specimen of broncho-pneumonia simulating tuberculosis which he presented at the last stated meeting. Microscopic examination determined that it was broncho-pneumonia, and not tubercle, although the specimen presented very much the gross appearance as that presented by the lungs which contained undoubted tubercles. The bronchioles were filled with pus, there was well-developed peribronchitis, and the alveoli in the immediate neighborhood contained pus cells with more or less fibrillated fibrin. The specimen, therefore, was one of broncho-pneumonia, or, as it had been termed by some, persistent broncho-pneumonia without tuberculosis. Dr. Northrup thought it impossible to determine in all cases, from gross appearances, whether or not tubercle is present.

DIPHTHERIC COLITIS OCCURRING IN THE PUPERAL STATE.

Dr. E. L. Partridge, presented, in behalf of Dr. Nelson H. Henry, candidate, a specimen, with the following history, by Dr. R. H. M. Dawborn, House Physician at the Nursery and Child's Hospital.

Lizzie C——, twenty-eight years of age, confined April 12th, 11.30 P.M., with her second child. The labor was entirely normal in all respects, and she did not until the night of April 18th, when, immediately following a vaginal douche, she was seized with a severe chill lasting twenty minutes. The temperature, taken directly after the chill, was 102° F., and there was at the same time some pain and tenderness in the left hypogastrum. A hot water bottle was applied to the left hypogastrum, and the next morning the temperature was 99° F. (coi removed at 100° F.). The abdomen no longer sensitive. Pulse 85, and good all this day.

Ten grains quinine, and a dose of compound licorice powder were given, as the bowels had not moved for thirty hours. She seemed well and cheerful as usual all this day, with the exception of the preceding night. She was not troubled with vertigo, nausea, or vomiting. About the patient's left side there was some moistness, and a thick yellowish exudation from the vagina. A hot-water douche (120° F.) was at once given, which checked the flow somewhat, but it required two more, at intervals of a few minutes, to entirely stop it. Amount of blood lost, probably between eight ounces and a pint.

There was with the second chill, as with the first, some pain in the hypogastrum, this time on both sides; temperature 102° F. Next morning the temperature was about 98° F. Early the following day the patient had a bloody movement from the bowels, with a little pain, but no tenesmus; and during the day had seven or eight discharges, each containing fluid blood in varying amounts from 5 sq. 5 to 5 j.

The abdomen was not sensitive a few hours after the chill, nor was it at any time tympanic. The stomach was in good order—no nausea. During this day, April 20th, the temperature was between 97° and 98° F., taken under the tongue.

The extremities grew constantly colder, notwithstanding that hot bottles were used. Four hours before death the tongue taken in the axilla was 105.8° F., but the tongue and breath were cold, and the temperature under the tongue was 97° F. At the time of death the axillary temperature was 104° F. The pulse, which was normal
THE MEDICAL RECORD.

June 7, 1884.

the evening before, went up to 120 on the morning of the 20th, and grew steadily weaker and more rapid until death, when it was about 180.

The respirations were normal throughout. Mind perfectly clear up to within an hour or two of death, which took place in a state of stupor. Secretion of milk continued up to the 20th of May. The patient was, however, ill-smelling. A vaginal examination made after the second chill showed the os to be patulous; the uterus in a condition of moderate depressant—the cervix being within two inches of os tum vaginae.

Stimulants (whiskey and carbonate of ammonia) were freely used. She died April 21st, at 4.15 A.M. N.B.: The times in this hospital are given twice in twenty-four hours. They are tepid and contain corrosive sublimate gr. iv. to Oj. (1 to 2,000).

Résumé.—Was confined on the 12th, late at night. Died well until the night of the 18th, when the first chill occurred. On the night of the 19th, at about the same time, the second chill set in, accompanied by hemorrhage from the vagina, which, however, was permanently checked in an hour. Early on the morning of the 20th bloody stools began, and continued till death. The temperature was normal on the day after the first chill, and normal and subnormal (under the tongue) on the day after second chill. But the temperature in the axilla four hours before death was 105.8° F. She died April 21st, at 4.15 P.M.

Autopsy.—Thirty hours after death. Well-marked rigor mortis. Body very well nourished. Lungs: a moderate amount of congestion and oedema. The pericardium contained about two ounces of bloody serum. The heart was normal in size, but its structure seemed soft and flabby; the valves were competent; the cavities contained small dark clots; the endothelium was distinctly stained. Spleen slightly enlarged, soft, and easily torn. Liver congested moderately. Kidneys normal. There was no distention of the abdomen; no evidence of peritonitis; the covering of intestines appeared of normal lustre. There was no cellulitis. The mucous membrane of the vagina was somewhat swollen and hyperemic, but showed no exudation. The cervix was flabby, with some edematous infiltration of the tissue, and evidence of slight contusion. The uterus had a firm feel, was of about normal size; the interior surface was thinly coated with a small amount of exudation, most abundant over the placental site. There were no clots, and no offensive odor. The mucosa of the region flaccid; the muscular portion of the small intestine was normal. The mucous membrane of the lower portion of the ileum was congested; Peyer's patches were swollen, and this condition increased quite rapidly toward the ileo-coccal valve. The mucous membrane of the entire extent of the large intestine was intensely congested and swollen; its color varied from a scarlet to a livid red or purple, and certain areas had a dirty chocolate color. The solitary follicles were swollen. This intense hyperemia was quite uniform, but most marked in the cecum and hepatic flexure, and again in the sigmoid flexure. In portions of the cecum there was a finely granular appearance. The large intestine contained a dirty, reddish-brown fluid, apparently blood and mucus, in large amount, and gave a peculiar offensive odor.

Dr. Levi presented, in behalf of a candidate, a specimen of tuberculosis of the endometrium. The specimen was referred to the Committee on Microscopy.

Dr. W. P. Northrup presented a single set of specimens which illustrated the history of two cases that were nearly alike.

(1) Double Pleuro-Pneumonia, with Pericarditis;
(2) Double Pleuro-Pneumonia, with Pericarditis and Peritonitis.

Two children, females, aged respectively seven and five months, inmates of the New York Foundling Asylum, were taken sick on the same day, and one lived eight days and the other nine days. At the time the children were taken sick there was an abrupt change in the weather, from warm to very damp, chilly, and raw atmosphere.

In both there were about four ounces of grayish, yellowish fluid, containing flocculi of fibrin, in the right pleural cavity, and a thick layer of fibrin upon the visceral and parietal layers of the pleura, somewhat encapsulated. In front there was a thinner layer of fibrin. In both, the left pleural cavity contained a somewhat smaller quantity of fluid of the same character, and the fibrinous exudation did not extend quite so far in front as upon the right side. The same fact held good with reference to the lung in each case; the left pleural cavity on the right side was a little more marked than on the left side. The second child, in addition to the double pneumonia, had well-marked pericarditis, much better marked than in the first child, and also well-marked peritonitis.

The specimen was of interest, because the children had neither had measles nor scarlet fever, were nursed children, inmates of the same ward, and were suddenly taken with pneumonia, which was due probably to change in the weather.

Dr. Levi remarked that one difficulty in accepting cold as the cause of the pleuro-pneumonia in these cases was the very fact that three of the serous membranes were affected in one of the patients.

GENERAL TUBERCULOSIS, INCLUDING THE UTERUS.

Dr. Levi presented, on behalf of Dr. C. G. Currier, candidate, a specimen with the following history: Miss A. M. — aged twenty-six, native of Ireland, servant, had a good family history, without any trace of tubercle or carbuncula in the family.

She was in perfect health until one year ago; then had pleurisy of the right side, from which she recovered completely. At New Year (1884) pain and swelling in the feet appeared at a menstrual epoch, since which she has not menstruated. At this time she first experienced pain in the abdomen, more or less constant, sharp, and cutting; the abdomen appeared to be increasing in size. She also lost flesh and strength.

On admission she was remarkably weak and emaciated, her appearance cachectic, and abdomen distended. To the right of the umbilicus there was a protuberance, three inches in diameter, with contents of semifluid consistency. Umbilicus did not protrude. Over the supraumbilical region fluid; percussion suggestive. In the central portion of the abdomen there was modified resonance, but at no point flatness. A needle inserted deeply just to the right of umbilicus withdrew no fluid. The liver dulness extended from just below the nipple to one inch above the costal edge. The splenic area not enlarged. Three days later, April 13th, the protuberance to the right of the umbilicus was more marked, slight fluctuation was felt, and on April 15th the abscess ruptured, from which several ounces of foul-smelling pus escaped. The patient was much relieved. Preadressing was employed. April 18th, the patient was better, but had much foul discharge. Ether was administered, and she was examined by vagina. The left labium was edematous; the cervix elongated and flattened, and uterus fixed. Rectal examination revealed a doughy mass, of the size of a fist, close to the left of the rectum. Parts otherwise normal.

The opening of the abscess through the abdominal wall was enlarged two inches in each direction and found to communicate directly with the peritoneal cavity. The intestines were not exposed to view. In the visceral and parietal surfaces of peritoneum were covered with a thick membrane. The cavity contained much foul pus, mixed with sloughs and masses of decomposing membrane. The intestines were firmly matted everywhere. A probe could be passed downward toward either ileum for a distance of about six inches. The cavity was thoroughly irrigated with a solution of corrosive sublimate.
was split bilaterally, and the internal os was divided sufficiently to give space for working, and then the tumor was grasped with the vasa and drawn down. While held in this position Dr. Lee endeavored to insinuate the scoop between the surface of the tumor and the inner surface of the uterus, which he found exceedingly difficult to do on account of the anteversion. The house-surgeon, who assisted while making counter-pressure, constantly informed him that he could not pass the end of the scoop. It seemed quite evident to Dr. Lee that he had not reached the uterine wall, yet he continued to work, but unsuccessfully, and he finally determined to cut the tumor away piecemeal. He therefore removed several pieces, cutting away only the portion embraced in the forceps, until he finally reached the base of the tumor. Then came the procedure which led to the woman's death. Although the instrument when it deals with pedunculated fibromata is an admirable one, it, in this case, cut through the uterine wall in two places, and led directly to the patient's death by intraperitoneal hemorrhage, and this occurred without Dr. Lee being able to determine that he had left the neoplasm and entered the uterine wall itself.

He ends his report on the operation because of the practical lesson which it taught. He had notes of six cases in which he had removed large tumors from the uterus with this instrument, and with no bad effect. He had supposed it impossible to do damage with the serrated scoop. Since the unfortunate result in his case he had found upon the report of the Woman's Hospital two cases in which a fatal result had followed its use; one case under the care of Dr. Thomas, and the other under the care of Dr. Hunter, and in both the uterine wall was perforated by the instrument and produced a fatal termination. In his case the patient never fully reacted, and died twelve hours after the operation. At the autopsy the pelvic cavity was found filled with blood and clots, the uterus was intact in the region of the cervix, but at the fundus there were found two openings, evidently made by the instrument, which were jagged and filled with clots. Within the uterus was a mass of the tumor which he had failed to remove.

Dr. Lee deemed it impossible by any method yet devised to operate for the removal of these tumors without some danger to the life of the patient, and he thought that the result in this case and the others which had occurred at the Woman's Hospital should be known in order that patients afflicted with this disease might be warned more fully than had heretofore been done of the danger attending operations for their relief. He was emphatically for the cure, and, unfortunately, the cure seemed to be the death wall. The malposition of the uterus probably had very much to do with the occurrence of the accident.

CEREBRAL HEMORRHAGE—ANOMALY OF THE AORTA.

Dr. Frank Ferguson presented specimens removed from the body of a man, aged twenty, a native of the United States, and a clerk by occupation. He had to attend to business, and was entrusted with the keys of the store in which he worked.

When the head of the firm arrived at 10 A.M., on the morning of the 11th inst., the door was found locked, and the man whose duty it was to attend to the business was found in a water-close, unconscious, paralyzed on the right side, both hands clenched, breathing heavily, and frothing at the mouth.

On examination at the House of Relief the pupils were found equal, and not responsive to stimulus; there was paralysis of the entire right side, less marked in the right upper limb; unconscious; urine negative; respirations shallow and stertorous; pulse regular, and sixty-four beats to the minute.

He continued in this condition until the following day, when the right pupil became much dilated, the left side became paralyzed; his temperature rose from nor-
mal (his condition on admission) to 108° F. just before death, which occurred at 5 A.M., May 14, 1884.

Autopsy.—All the organs were normal except the brain, which was the seat of hemorrhage. The hemorrhage on the surface involved the island of Reil, all the convolutions were completely flattened, and it also involved the white matter of the tempo-sphenoidal lobe. The hemorrhage had destroyed the large ganglia at the base of the left hemisphere.

The case was of considerable interest in view of the fact that with cerebral hemorrhage the blood-vessels are diseased in a majority of cases, and associated particularly with renal affections. But in this instance the kidneys were perfectly normal, and there was no evidence of disease of the blood-vessels. The heart showed small hemorrhages beneath the pericardium, not infrequently observed in connection with high temperature.

The anomaly in the case was in the condition of the aorta, which was at least one-third smaller than it should be, and the diminution in size was throughout. The vessels given off from it were rather smaller than normal, but were large as compared with the calibre of the aorta itself. Why he attached any importance to this fact was because he had seen another case of cerebral hemorrhage, occurring in a young woman, twenty-two years of age, within three months, whose aorta was a tripe larger than the one presented, but the cerebral hemorrhage occurred independently of jaundice or disease of the vessels. Whether in these two cases the occurrence of cerebral hemorrhage, independent of pachymeningitis, or disease of the vessel, was a coincidence, he had not been able to determine. He felt quite sure that the hemorrhage was not due to thrombosis of embolism.

Dr. Northrup remarked that it seemed to him the aorta was certainly diminished one-third in size, and it was quite probable that the average aorta would measure twice as much in diameter as the specimen presented.

Dr. Ferguson remarked further that the iliac vessels were nearly of the normal calibre.

Dr. W. H. Porter had seen one case of cerebral hemorrhage in a young man of twenty to twenty-five years of age, who had suffered from malarial poisoning. In that instance there were multiple hemorrhages into the brain and spleen. He thought it possible that the chronic malarial poisoning might have produced some effect upon the walls of the blood-vessels and given rise to the hemorrhage.

Dr. Amidon remarked that the gross appearance of the hemorrhage was of that due to miliary aneurism, but the patient was too young for the occurrence of this lesion.

Dr. Van Santvoord thought it possible that the lack of development in the aorta indicated a general lack of arterial development throughout the body, and therefore the blood-vessels were more liable to give way than when the normal condition of the arteries existed.

Dr. Levi thought the condition of the aorta was well taken, and that the small aorta went far to explain the occurrence of the cerebral hemorrhage, from the fact that the normal elastic coil had no time to take place, and the circulation in the capillaries was interfered with, which, in connection with straining, would subject the capillaries to a greater amount of pressure than they would be subjected to in the normal condition.

Dr. W. H. Porter said that the rate of pulse (64) indicated that the pressure was less than it would be in a normal case.

Dr. Levi thought that with the absence of elastic coil the quantity of blood sent forward would be increased.

Dr. J. C. Peters referred to a case of apoplexy occurring in a man forty-five years of age, well developed, and apparently due to very great mental emotion, the patient restraining himself under provoking irritation. Before the seizure he was apparently perfectly well, and had not been guilty of any impropriety. The patient died within four hours after the attack.

Dr. Carpenter asked Dr. Ferguson if he had seen a small aorta without cerebral hemorrhage.

Dr. Ferguson said that he had not, and that at one time he made observations in six hundred cases with reference to anomalies of the circulatory system, but did not encounter the condition exhibited in the specimen presented.

Dr. Carpenter remarked that he had seen a case in which the aorta was very much below the normal size, not so small, however, as the one presented by Dr. Ferguson, and the patient died of disease other than cerebral hemorrhage.

FATTY LIVER WITH CIRRHOSIS AS A COMPLICATION.

Dr. George R. Elliott presented a specimen, with the following history furnished by Dr. H. J. Boldt: "Male, aged forty-eight years, married; butcher by occupation. He claims never to have indulged to excess in alcohol, and gives no history of syphilis. He was perfectly well up to September 1, 1883, when he had an attack of chills and fever, after which he noticed his stomach increasing in size and his breathing growing more and more difficult. His case was diagnosed by the physician who saw him at that time as cancer of the liver. In April, 1884, I saw him for the first time, and withdrew by aspiration thirteen pints of fluid from the abdominal cavity. I aspirated twice subsequently. Urine at no time contained anything except urates. He died May 12, 1884, from apparent exhaustion." Autopsy was made by Dr. Boldt, twenty-four hours after death.

Dr. Elliott had examined fresh microscopic sections of the organs and found the heart in a moderately fatty condition—the striations of the muscular fibres being in many places obliterated by fat. The kidneys were very large; capsules non-adherent; surface smooth; considerable connective tissue increase, and the epithelia are very granular both in the cortical and medullary portions. The liver weighed ten pounds. The surface presented a slight granular appearance. Upon microscopic examination an excessive amount of fat was found, appearing to replace entirely the hepatic cells; also, distributed very generally throughout the organ a moderate amount of foreign connective tissue—the latter was mostly in the form of round and spindle cells, very little being fibribilated. He regarded the fatty condition, the primary lesion, and the cirrhosis as a complication; the large size of the liver was undoubtedly due to the great excess of fat. He did not consider it an example of what is known as hypertrophic cirrhosis; in that condition we have a very large amount of young connective tissue, while here that tissue is not at all abundant. The spleen was but slightly increased in size.

Dr. Porter said he had an opportunity to examine specimens from the liver presented by Dr. Elliott, and was of the opinion that the primary change was fatty infiltration.

The Society then went into executive session.

THE PHYSICIAN’S PRAYER.—Dr. W. W. Hewlett, of Babylon, L. I., writes: "Your number of May 24, 1884, contains a form of prayer which I B states was found among the prayers of the late Dr. C. F. Couch, of Petersburg. Permit me to inform your correspondent and other readers of THE RECORD who may be interested, that that beautiful supplication was composed by Dr. John Mason Good, and may be found in a sketch of the author’s life which is prefixed to the stereotyped edition of the 'Book of Nature,’ published by the Harper's in 1831."
Correspondence.

RECTAL ETHERIZATION.

TO THE EDITOR OF THE MEDICAL RECORD.

Sir: In view of the recent interesting articles in The Record on the subject of etherization by the rectum, and believing that the value of this novel method of inducing anesthesia can only be effectively determined by the profession at large in their manifold and diverse experience, I think it might not prove uninteresting to present succinctly an account of the two following cases in which etherization was induced by this method.

I was first enabled to employ this method (May 10th) through the courtesy of Dr. Hazen, the visiting physician, in a case of senile cataract, in which I operated by von Graefe's method.

My apparatus consisted of a common four-ounce, wide-mouthed bottle (with scratches on it indicating ounces and half-ounces), through the perforated cork of which the distal extremity of an ordinary Davidson syringe, the valves of which were temporarily removed, was passed; to the proximal end an ordinary vaginal tube was attached.

The bottle, containing three ounces of Squibb's ether, was immersed in water at 150° F. In a few seconds the ether was freely evolved from the vaginal tube; the syringe and attachments had previously been immersed in hot water in order to obtivate condensation of ether.

The patient, a negro, aged sixty-five years, was debilitated from fasting for seven hours before the operation. Shortly before operating the lower bowel was emptied by an enema. A subcutaneous injection of ergotine was also administered to obtivate ocular hemorrhage. He was placed on his right side for the administration of the ether.

It was fifteen minutes before the patient was completely anesthetized, and five ounces of ether were consumed.

During the first ten minutes the only effect of the ether (three ounces) was to cause the patient to exclaim frequently, "Oh, my belly! my belly!" (there was slight distention of abdomen) and to expel "wind" almost continuously, and with loud and prolonged noise, filling the bowel. Judging that this was thus being by this vis à targe more ether than he was absorbing, I pressed the nates tightly together (which had previously been neglected) and replenished the ether bottle with two ounces of ether. In five minutes the patient was thoroughly anesthetized, and the odor of ether could easily be detected in the breath. There was only a very slight and transitory stage of excitement. The administration of ether was continued for thirty minutes. The pulse and respiration during this time were excellent. During the patient's recovery from the effects of the ether he was quite boisterous, singing religious songs. He vomited slightly twice, at short intervals. There was for a short time a slight "pain in the stomach." He had one profuse slightly diarrheal stool, no blood. Throughout the whole process there was only slight distention of the abdomen. During the latter part of the administration of the ether the flow of saliva was considerably stimulated.

My second case was on May 18th. It was necessary to make a counter-incision for the purposes of drainage, and the patient urged me to give him ether. The patient, a negro, claims that he was "twenty years old when the British war (1812) broke out." His condition was such as made me hesitate somewhat before inducing anesthesia. The heart was weak, irregular, and rapid (fatty heart). But this very unpromising condition made me all the more eager to test the value of rectal etherization. Four ounces of ether in eight minutes occupied in inducing complete anesthesia. The administration of ether was continued five minutes longer. The stage of excitement lasted three minutes and manifested itself by loud singing (religious). In four minutes the flow of saliva was profuse, as in etherization by the ordinary method.

Very slight abdominal distention. No diaphoresis. Vomited slightly twice. Complained of "sore belly." Respiration was slightly accelerated. The point of special interest in this case was the action of the heart. As stated above, the pulse symptoms were ugly; but under the influence of the ether the pulse approached a normal basis, it became quite regular, slow, full, and strong, and maintained this condition throughout the period of anesthesia. It appears that this last case illustrates very emphatically the safety of rectal etherization. Respectfully,

D. K. SHUTE, A.B., M.D.,
Lately Resident Physician Children's Hospital, D.C.
WASHINGTON ASYLUM HOSPITAL, D.C.,
May 19, 1884.

LARGE CALCULI.—THE PATIENT OR THE SPECIMEN, WHICH?

TO THE EDITOR OF THE MEDICAL RECORD.

Sir: Medical journals frequently contain notices of very large calculi removed, and no surgeon's cabinet seems to be complete without more or less large, fine, and rare specimens.

Not long since I witnessed an operation for the removal of a stone, that set me thinking whether possibly some cabinet specimens may not have a history, which, truthfully told, would detract much from their apparent value as curiosities.

The patient in the instance I refer to was a man past middle life, and the case and all its surroundings were not very promising at the best. Whether or not lithotomy was the proper operation under the circumstances need not be discussed.

The ordinary lateral incision was made and nothing worthy of note occurred until the surgeon had reached the bladder and grasped the stone with the forceps. When it was discovered that the stone was an exceedingly large one, the operator appeared to be seized with a frenzy to secure so fine a specimen. He tugged and pulled and pried for a long time, and in a most brutal manner. The mucous membrane and the tissues were shamefully bruised and lacerated in trying to drag a large, rough stone through an insufficient opening. The incision was extended to the utmost bounds of safety. Much was said about the prospective choice specimen, not a word respecting the safety of the patient. Some of the bystanders protested against the reprehensible procedure; others, however, sided with the "calculus feud." Finally, the unseemly struggle was abandoned from sheer necessity—the stone was crushed and removed in pieces. Thus a fine specimen was sacrificed. Thus also was sacrificed whatever chance of recovery the man may have had; for, sad to relate, the perverse patient, within a very few days, actually died of pyemia.

It is to be hoped for the credit of the profession that performances like this are very rare indeed.

BENJ. EDSON, M.D.
8 St. Mark's Av., Brooklyn.

CHROMATIC PHARMACY.—Dr. J. C. Neal, of Archer, Fla., writes: "Allow me to suggest to manufacturers of granules, pills, and powders the propriety of coloring their products, rendering it easier to avoid mistakes, and much better for the practitioner in giving directions among the illiterate. For example, color purgatives and laxatives, yellow; carminatives, black; stimulants and tonics, red; diuretics and diaphoretics, white; narcotics and sedatives, blue."
Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from May 25 to May 31, 1884.

WRIGHT, J. P., Major and Surgeon. Directed to perform temporarily, in addition to his other duties, those of Medical Director, Department of Missouri. S. O. 107, par. 2, Headquarters Department of Missouri, May 28, 1884.

MIDDLETON, PASSMORE, Captain and Assistant Surgeon. Granted leave of absence for one month on surgeon's certificate of disability. S. O. 107, par. 2, Headquarters Department of Missouri, May 28, 1884.

HALL, WILLIAM A., Captain and Assistant Surgeon. Assigned to duty at Fort Stockton, Tex. S. O. 63, par. 1, Headquarters Department of Texas, May 19, 1884.

BAILY, JOSEPH C., Major and Surgeon, now on leave of absence, is relieved from duty in Department of Texas, and ordered to report to General commanding Department of the East for assignment to duty at Fort Monroe, Virginia, to relieve Lieutenant-Colonel Charles Page, Surgeon, on July 1, 1884, from duty at that station.

PAGE, CHARLES, Lieutenant-Colonel, on being relieved by Major Baily, will proceed to Fort Leavenworth, Kansas, and report to General commanding Department of Missouri for assignment to duty as Medical Director of that department. S. O. 125, par. 12. A. G. O., May 29, 1884.

Official List of Changes in the Medical Corps of the U. S. Navy, during the week ending May 31, 1884.

BEYER, H. G., Passed Assistant Surgeon. Detached from Coast Survey Steamer Blake, and ordered to Smithsonian Institute for special duty.

RUSH, W. H., Passed Assistant Surgeon. Detached from U. S. S. Despatch and ordered to Coast Survey Station.

JONES, M. D., Passed Assistant Surgeon. Detached from Naval Hospital, New York, and resignation accepted June 15, 1885.

WISE, J. C., Surgeon. Detached from Academy and ordered to U. S. S. Constellation.

No Small-pox in Easton, Pa.—Dr. Traill Green, of Easton, writes: “In The Medical Record of April 26th, page 474, it is reported that there is a present outbreak of small-pox at Easton, Pa. We have no knowledge of the existence of that disease in Easton, our Board of Health have no report of its presence.”

Dr. MILLARD’s Paper.—Dr. H. B. Millard writes: “In my paper published in your issue of May 31st, page 603, twenty-seventh line from the bottom, an oxemia should read anoxemia.”

The American Climatological Association.—The first annual meeting of the American Climatological Association was held in Washington, D. C., May 16th. In the absence of Professor Loomis, the President, Dr. F. I. Knight, of Boston, First Vice-President, occupied the chair. The first day was occupied in adopting a suitable constitution and by-laws. The second day was devoted to the reading of papers, as follows: Address by the presiding officer, Dr. Knight; “The Etiology of Pulmonary Phthisis,” by Dr. F. B. West, of Brooklyn; “The Effects of Sea-Air upon Diseases of the Respiratory Organs,” by Dr. Boardman Reed, of Atlantic City; “The Relation of Laryngeal Disease to Pulmonary Diseases,” by Dr. F. H. Bosworth, of New York; “Dryness,” by Dr. Charles Dennison, of Denver, Colo., in which he dwelt on the following points: “Visibility of object, required role for classifying climates as to dryness and desirability, based upon low, absolute, and relative humidities and preponderance of sunshine; the influence of elevation, sunshine, cold, etc., in producing desirable dryness; the physical effect of dryness on man; “City Life and City Air Injurious to Consumptives,” by Dr. Donaldson, of Baltimore; “The Use of Compressed and Rarefied Air as a Substitute for Change of Climate in the Treatment of Pulmonary Diseases,” by Dr. J. Solis Cohen, of Philadelphia. The following officers were elected for the ensuing year: President—Prof. A. L. Loomis, New York; First Vice-President—Dr. F. I. Knight, Boston; Second Vice-President—Dr. W. H. Geddings, Aiken, S. C.; Secretary and Treasurer—Dr. J. B. Walker, Philadelphia.

The Effect of External Influences upon the Product of Conception.—A curious illustration of the influence upon the child of the circumstances under which conception takes place is afforded by some observations made by M. Legrand du Sauleau, which we find reported in the Progrès Médical. He has seen 92 children who were conceived in Paris at the time of the siege, 64 of whom (nearly seventy per cent.) were deformed in mind or body. He divides these 64 into three groups. In the first, numbering 33, he found children with scrofula, treating foreheads, strabismus, epilepsy, deafness, stammering, hemiplegia, club-foot, incontinence of urine, and rachitis. The 21 children comprised in the second group presented intellectual peculiarities, such as a want of psychical activity, moroseness, apathy, inability to fix the attention on any one thing, semi-imbécilicity, and idiocy. The remaining 18 exhibited various mental deformities. He found them egotistical, self-willed, vicious, quarrelsome, and prone to strike their companions on slight provocation, and several were obscene in their actions and habits. A very large proportion of the children conceived at this time were either still-born or died in early infancy. The number of deaths and the frequency of mental and physical deformities in the survivors were so noticeable that the term enfant du siège has come to be popularly applied to any sickly and deformed or otherwise unfortunate child.

Some Consolation for Smokers.—Tobacco does not deserve all the anathemas that have been hurled against it by the followers of Trask and Decroix, if we are to believe Professor Pécoulier, whose views we find quoted in Et Dictamen. He assures us that tobacco is a powerful microicide, destroys intestinal worms, cures the itch.
and salt rheum. It is a prophylactic against certain contagious diseases, and inveterate smokers enjoy a wonderful immunity from tuberculosis. These and many others are the vices of this comforting weed, according to the learned professor, and we quote them for the benefit of smokers, who are little accustomed to hear encomiums of their dear vice from scientific lips. Another of our Spanish exchanges, La Higiene para Todos, asserts that the Congress of the United States has passed a law similar to that in force in New Jersey, prohibiting the sale of cigarettes to persons under seventeen years of age. It is to be regretted that Congress has not the power to enact such a law, but there is nothing to prevent the other States following the example of New Jersey, and thereby rescuing our boys from a real evil, and at the same time going a long way on the road toward abolishing the cigarette nuisance.

STICK TO THE PHARMACOPEIA. — Said Sydenham: "The chief defect of physic proceeds not from a scarcity of medicines to answer particular intentions, but from the want of knowing the intentions to be answered."

THE TREATMENT OF EPISTAXIS.—Dr. T. O. Reynolds, of King's College, in the New York Medical Record several articles detailing as many methods of arresting this frequently troublesome disaster, has been induced to give his experience in a few cases: "Case 1: Mrs. B——, a widow lady, ninety years of age, was attacked with nose bleeding, which continued at intervals, notwithstanding minor attempts to stop it, for a week. I was called that, at each time when I visited her, on arrival the hemorrhage had ceased voluntarily, consequently I only deemed it necessary to leave with the attendant a pet prescription of mine, which had served me a good turn on several like occasions before, i.e., on the reappearance of any signs of hemorrhage, having ready some hot water, apply this immediately to the feet, ankle, and instep with a towel; at the same time on the second apply ice or cold water on napkins to the throat and cervico-spinal region. This treatment has always produced the desired effect in all moderate cases with me. A message having been sent to Boston, to a son of the patient, containing information that the mother was bleeding from the nose, and the party addressed thinking the case, no doubt, of a serious nature, brought his physician with him, an unexpected event to the family, who consequently could not notify me. When the consultant-to-be arrived, I was out of town. Going to the house and happening to find the patient bleeding, and arguing very naturally that something decided must be done, he very cleverly plugged posteriorly, etc., and left the patient to the care of the nurse. At the next visit the following evening the hemorrhage came on with vigor and oozed beside the plugs freely. Nothing was to be done but to remove and replug. The removal, in which I was assisted by the son who remained, took a long time. While thus employed I had time to think, and was possibly assisted by the expedient by the protestations of the patient as well as her son, that such a procedure should not be again resorted to. Having cleared out the nasal cavity, I directed the old lady to take a deep inspiration and hold it, when at once threw up from an ear-syringe a quantity of Monsel's solution 3 j to 3 j. aquae. Repeating the same for the other side, I left the patient a quantity of the preparation remaining. The son was directed to repeat the operation should occasion demand. We were never troubled again from hemorrhage in this patient. She lived four years afterward and died of pneumonia. Case 2: Lucius W——, attacked very severely during the last stage of convalescence from typhoid fever; he had lost over a pint of blood when I arrived; it was the night when he had once had the hot and cold water applied, and the blood which was flowing freely stopped in two or three minutes. During the succeeding ten days this patient was re-attacked several times with indications of violence, the same method controlled the bleeding completely each time. He subsequently went home to Boston, where he resides, and has since been free from epistaxis. Case 3: William G——, adult, twenty-seven years of age, was attacked severely and had become nearly pulseless, and still the flow continued. On arriving, I resorted immediately to the other method above mentioned, and injected the sol. ferri persulph. He had no more trouble till the next day, when I had to repeat the operation. Three days after I again repeated it, and since have had no occasion to use remedies, the patient having fully recovered."

VALERIANATE OF CERIUM IN THE VOMITING OF PREGNANCY is recommended by Dr. Blondeau in a communication to the Société de Therapeutique. He gives it in doses of 10 centigrammes three times a day.

ENLARGEMENT OF THE BURSA PELLICLÆ IN CLERGYMEN.—Dis. Wherry and Grosholz have written letters to The Lancet showing that what is ordinarily known as "housemaid's knee" is to be met with not infrequently among clergymen and priests.

SUDDEN DEATH AFTER PARTURITION, WITHOUT APPARENT CAUSE.—In view of the recent discussion upon the above subject, the following cases reported to us by Dr. R. Farries, of this city, will prove of much interest. He writes: "In May, four years ago, I was called in consultation to see a Mrs. C——, who had been in labor from about 7 A.M. to 5 P.M., and had delivered a healthy fourth child. She was about thirty-five years old, a medium-sized woman, and appeared to be in a good healthy condition, was not exhausted, and had only moderate pains. After a careful examination nothing was found out of the normal except a hand presentation which was protruding from the vulva. Nothing contraindicated the performance of the time. At 7 A.M. this was easily done, and the whole operation lasted about ten minutes. No chloroform was used. I left her in a cheerful, happy-looking mood, expressing herself as very comfortable, and stepped into an adjoining room while the attending physician relieved her of the placenta. In about five minutes the doctor called me to go back, as there was something wrong. I just got into the room in time to see her expire. There was no hemorrhage. The uterus was reduced to the usual size and was firmly contracted. On April 28th (last), at 4 A.M., I was called in consultation to see Mrs. H——, a very fat, thick-set woman about thirty-eight years of age, who had been in labor with her first child about ten hours. At about 3 A.M. the placenta was refused for many hours. All efforts had been made to deliver with forceps, but without avail, as they invariably slipped off. At 4 A.M., when I arrived, the patient was well under the influence of chloroform. No progress had been made since midnight. Otherwise she seemed in good condition, except the vulva, which was unusually swollen. The operation was normal, and the only obstacle in the way was an abnormal elevation of the promontory of the sacrum. We concluded, under the circumstances, the best thing was to turn and deliver. This was done with considerable difficulty. The operation lasted probably half an hour, and although difficult, no desperate efforts had to be made to effect delivery. In a few minutes after the operation, and while the attending physician was delivering the placenta, the patient revived so far as to ask a few questions concerning the event. The placenta arrived in due time and the uterus contracted to about the usual size. The patient was properly cared for and appeared very comfortable. At this stage (about three-quarters of an hour after delivery), I could see; in about three minutes, she sank into a state of collapse and died. There was no unusual hemorrhage and nothing in either case to indicate such a result. What did those women die of, or could anything have been done to avert such an unhappy termination?"

EXTENSION OF THE HIP AND ITS PRODUCTION.

By CHAS. F. STILLMAN, M.D.,
LECTURER ON ORTHOPEDIC SURGERY, WOman's MEDICAL COLLEGE, NEW YORK.

Extension of a joint is the condition produced by traction, exerted between points of attachments to the limb above and below the joint. The two terms are not synonymous, although an effort has lately been made to substitute the latter for the former, but the former is a state and the latter an active agent or force by which this state or condition is produced. A joint is in a state of extension when the tissues about it are stretched by traction and counter-traction, and extension should, therefore, not be considered identical with traction.

The extension may be incomplete or complete, but these are merely differences of degree. To produce incomplete extension the structures are embraced above and below the joint, and the traction force is exerted to separate these attachments. As a result the soft parts about the joint are "put upon the stretch" and are thus forced to exert circumferential pressure upon it. This is easily verified by having an assistant grasp a leg below the knee and pull it away from the thigh, while the operator encircles the thigh with both hands and pushes upward toward the origin of the muscles governing the joint. In such a case it will be seen that the tissues about the joint become rigid, and the joint appears stretched. The circumferential pressure thus produced by traction differs from the pressure of a rubber bandage, in that it does not compress the lax tissues about a joint, but instead forces the tissues themselves to compress the synovial sac.

Moreover, although hindered by the stretching of the traction, is not entirely prevented, and the angle of the limb may be changed without interfering with the extension; consequently motion is not incompatible with incomplete extension. Fixation of the joint is not produced by this degree of traction, except so far as it may be considered a partial result of the stretching of the tissues, which are thus made to form a splint about the joint. Another and prominent effect of this stretching is to diminish the interarticular pressure and prevent concussion, and if this pressure is unequal and reflex, and the cause of articular pain, the muscles are so stretched by the traction, if it is exerted in the axis of the limb, as not to transmit their contractile effect to the articular surface and the injurious results of spasm are thus prevented.

These effects, therefore—first, circumferential pressure; second, tension of all the soft parts about the joint; third, diminution of interarticular pressure, and fourth, prevention of muscular spasm—are the most prominent to be derived from the moderate degree of traction which best tends to produce rest; and these constitute the condition of extension (incomplete).

Complete extension may be defined as that condition of a joint in which there is separation of the articular surfaces. This is not attained during life by any traction apparatus without injury to the structures involved, for sufficient force would have to be exerted to first overcome completely the inherent contractility of the muscles, and this of itself would occasion so much pain to the patient as to be impracticable.

It is a well-known fact, which comes under the observation of all who use traction in joint disease, that while a moderate amount of stretching relieves pain, if it be increased ever so slightly beyond the comfort point the pain becomes intolerable, and long before the muscular contractility gives way entirely, rupture of the attachments of the muscular substance must take place; second, the ligaments would require to be stretched, and third, in the hip the atmospheric pressure must be overcome. This of itself has been shown to be sufficient to hold the articular surfaces together after all the muscles and ligaments have been divided and the capsule left entirely free from all appendages.

Bearing in mind, then, that only a moderate amount of extension is compatible with true rest in a joint, and that sufficient traction to draw articular surfaces apart is incompatible with true rest and injurious to the structures, it will be readily understood that incomplete extension is beneficial in such joint diseases as are attended with effusion into the joint, or tissues about the joint, or hypertrophy of the osseous or other tissues, or unequal and spasmodic pressure from the reflex contraction of muscles governing the joint.

The circumferential pressure of the stretched tissues tends to cause absorption of effusion and hyperplastic formation of tissue, and opposes a resilient force to the effusion of new fluid and the deposition of new plastic material, while their rigidity acts as a splint to protect the joint from sudden lateral movements and concussion and opposes the transmission of the effects of spasmodic muscular contractions. Bearing in mind, then, the swelling and reflex pains which accompany "chronic articular ositis" (Gibney) of the hip, it will be readily seen that extension of the hip in the incomplete degree will tend to prove beneficial if the traction be exerted in the proper directions. The separation of the two points of attachment—one above and one below the joint, for the production of extension in the joint, is effected by means of weight or traction ratchets.

* * *

1 It is unfortunate that the same word is also used to denote a motion and position of a limb, as contrasted with flexion. The confusion might be avoided by spelling the opposite of flexion with d, via, extension, and this plan the writer will follow in this paper.

2 E. H. Bradford, Boston Medical and Surgical Journal, November 11, 1860.
3 This is greatly assisted by the rubber bandage used in connection with the traction, and a much greater degree of pressure by the bandage can be tolerated without odema if they are combined, than if the rubber is used alone.
can be divided into two forms, adjustable and elastic. Adjustable ratchets oppose metallic strength to the elastic contractility of the muscles. The simplest of these is composed of slotted strips connected by clamps. Another form is the screw, and still another form the cog and key, which is very largely used.

The elastic ratchets are formed of coiled spiral wire, or of rubber cord or webbing. The latter was first proposed and used advantageously by Dr. H. G. Davis, and was of the form shown in Figs. 1 and 2. This has been modified by Dr. M. J. Roberts, as shown in Fig. 3, and the writer has still further modified the original form of Dr. Davis, as shown in Fig. 4. The screw clamp shown in the drawing permits the substitution of adjustable for elastic extension, by simply tightening it. Any of these various forms of ratchets are efficacious so long as they keep the points of attachment above and below a joint separated and thus keep the parts well stretched. One advantage which the adjustable possesses over the elastic ratchet is that it is not so liable to allow concussion when a false step is taken. Dr. Davis, recognizing this fault of the elastic, used to employ another strap made of leather as a guard, and this served to overcome the difficulty.

The elastic possesses the advantages over the adjustable ratchet of being simpler, cheaper, and more easily regulated by the patient, and is destined to become very largely used in surgical mechanics for the production of extension. The direction of the traction to produce extension of the hip should be considered first in relation to the deformity.

The hip, unlike the knee or other ginglymoid joints, has its governing muscles grouped around it in the shape of a cone, and not parallel with the shaft of the bone. The apex of this cone is the zone of muscular insertions about the head of the femur, while its base corresponds to their pelvic origin. For convenience this muscular cone may be subdivided into an inner and outer. The first is composed of the obturator internus and externus, the gemellus and pyriformis. When the disease is in its incipient stage, so that the patient merely evinces a stiffness of the limb and a tendency to favor it, these muscles, grouped as they are so closely to the head of the bone, are reflexly excited to hold it more firmly without having sufficient strength to produce deformity in flexion, rotation, or abduction. But the second or outer layer of the cone is composed of all the powerful muscles which combine to produce the characteristic deformity, and to create an extension of the joint it will be necessary for us to exert the traction force in more than one direction.

The hip-joint is capable of free movement, owing to its ball-and-socket construction, and its movements are either in flexion or extension, abduction or adduction, and inversion or eversion.

In chronic articular ostitis, during the first and second stages the limb is usually flexed and abducted and either inverted or everted. The traction must therefore be directed symmetrically against the cone of muscles in a threefold direction, and the tendency of his force will be to force the limb in the direction of adduction, extension, and either inversion or eversion, as the case may be.

Adduction, or the changing of the angle which the vertical axis of the limb makes with the transverse plane of the pelvis, from obtuse to a right or acute angle, is produced by traction exerted to separate the points A and C (see Fig. 5). It will be seen that as the distance A C is increased to A C', the limb is thrown inward into its normal angle with the pelvis and thus adducted. But to allow this traction force to be advantageously utilized the point A above the joint must be prevented from moving upward, and the point C from slipping downward.

The former is accomplished by a perineal band AB, which should be inflexible, and the latter is accomplished by means of an adhesive plaster, as used in all traction splints for the hip. The original Davis splint, in which traction was first utilized to produce extension of the hip, was formed partially upon this plan, although the point C was more effectually prevented from slipping by increasing the length of the splint to a point below the knee, to afford more surface for the plaster and better attachment of the splint to the limb. The point A has since been still further prevented from slipping upward by the addition of a pelvic band (with a second perineal band upon the other side), which affords better fixation, as in the Sayre short splint, and to prevent impingement upon the soft parts a hinge and screw, or other device for adjusting the adduction, is provided at this point. The perineal band, however, is the important feature, and should be made of firm material which will not stretch upon the application of a strong force.1

The point C has since been further aided in its fixation by an increase of length in the splint to an appreciable distance below the foot (as in the Taylor and Sayre long splints), so that the weight of the body in locomotion is transmitted to the ground by it, without vertical pressure upon the joint, the point A being prevented from slipping upward by the perineal band, which is thus forced to receive the entire strain, assisted, so far as displacement is concerned, by the pelvic band.

That the abduction of the limb is thus lessened by force exerted upward against the point A, and downward against the point C, or some inferior point of attachment to the limb, may be easily demonstrated by inspection of the action of any of the forms of traction apparatus which are constructed upon the principles just described. To overcome the flexion, the traction must be exerted against that portion of the muscular cone by which it is produced. By reference to the diagram (Fig. 6) it will be seen that in this deformity the thigh is flexed on the pelvis by muscles which have their origin somewhat above the hip, and exert their contraction in the line A C, the joint

---

1In the Davis splint the perineal band was elastic, guarded by an inflexible band, and was therefore not effective in preventing the point A from slipping upward entirely.
being at B. Therefore any traction force which tends to separate the points A and C will tend to decrease the flexion. But unless a pivot was so placed at some part of the traction ratchet as to allow change of angle in the line of flexion such traction force would cause the attachments to impinge upon the soft parts, and not only cause discomfort but would interfere with the effect of the traction in reducing the flexion, unless the traction was exerted in the vertical axis of the limb or trunk.

For this reason, if the traction was exerted in the line A C (which is the direction in which it is exerted in the Taylor, Sayre, and Shaffer splints) a freely movable pivot must be supplied either at A or C, preferably at A. These splints, therefore, are obliged to allow constant motion at A if traction is used. The direction of the traction force in hip-splints constructed with a flexion pivot at the pelvic band is in the line of the contraction, and not the line of the deformity, as enunciated so often by many authors upon the subject.

In Fig. 6 the line of deformity is represented by A B and C, and the extent of the deformity by the angle A B C (the term rectilinear deformity is usually used to describe the condition depicted in Fig. 6), and the line A C represents the axis of the contraction. In these splints the traction is exerted in the line of contraction A C, the two points A and C being pushed apart by it until the deformity A B C is effaced and the distance A C becomes equal to A B and B C combined. Therefore we must conclude that such efficacy as these splints possess is due to the traction force exerted by them to relieve abduction and flexion of the limb, the force being exerted in the line of the contraction, and that the various splints formed on this plan exert their traction in the line of contraction and act in the lines of deformity. Theoretically, therefore, it would seem that flexion is best overcome by traction in this line, but actually the intra-arterial pressure and lumbar incursion are increased by it, as the accompanying diagrams will demonstrate.

This tendency to curvation of the spine can be partially overcome by adding a back piece to the splint, which will

THE MEDICAL RECORD.

---

line of contraction A C is not only useless but really a cause of its increase. We must, instead of a single ratchet making traction in the line A C, make use of a double ratchet which will take a point over the centre of the articulation as a centre and make traction in each direction from the joint, the traction being exerted in the lines of the deformity. This is best illustrated by taking a strip of lead bent to an angle of 90°, corresponding to the degree of flexion of the thigh, and placing the apex upon the knee, bend it backward in each direction, at the same time drawing the extremities away from the centre (see Fig. 10). The arrow-heads in the diagram represent the direction of the traction. It will thus be seen that the force is exerted very much more conservatively than when in the line of contraction, as in Fig. 11.

---

This can be easily verified by anyone making the experiment. If the bracket shown in Fig. 11 be placed over a hip, the terminal plates being secured to the pelvis above and the thigh below by plaster-of-Paris and adhesive plaster, and the clamp connecting the two slotted strips is directly over the joint, traction can be exerted in each direction from the joint, and the tissues between the two terminal plates will be stretched. If at the same time, the clamp being loosened, the thigh is forced backward, the flexion is diminished (provided the attachment to the trunk is carried sufficiently high on the back and low on the pelvis to prevent lumbar cur-
of importance in hip-braces which was first insisted upon in this country by Dr. Judson, and still more lately by Dr. Roberts.

The limb attachment is of several kinds, depending upon the length of splint desired and the kind of traction ratchet employed. It may be short, which extends to the knee (Fig. 15), or long, extending below the foot, as is the Taylor, Sayre, and Shaffer braces, or above the ankle, as in the Bauer and other braces. Figs. 15 and 18 are examples of the short attachment to the limb, and in these figures the traction of the sector can be increased by the adjustable cog and key ratchet. This can also be effected by an elastic ratchet.

The joint division of the splint is made up of a sector flexion movement (see Fig. 15), with clamps for adduc-

---

1 This joint movement was devised by the writer in 1878, and presented to the American Medical Association, an account of it being in the Transactions for 1880, and is the first extension splint for the hip in which the pivotal centre is over the joint and the traction is made in the line of deformity.

2 The writer now uses a broadpad shown in Fig. 44 posteriorly, which presses against the back of the pelvis, opposes the hip-joint, and is attached by a strong slotted strip to admit of adjustment to the pelvic band, or by a bent slotted strip to the centre of the sector. This acts in place of the knee in Fig. 39 in reducing the flexion.
The traction is then effected by the ratchets, and the joint is placed in a state of extension. If fixation is desired, the clamps may be tightened, and in general the joint is placed under control of the surgeon.

Fig. 22 illustrates a form of brace which the writer uses to advantage, and in which the posterior pad is a prominent feature. This affords sufficient leverage behind the joint to overcome flexion and avoid lordosis without the use of the English bandage.

In this brace the extension is produced by an elastic ratchet, as in Fig. 4, in addition to that produced over the joint by the sector mechanism, and the splint is extended to the ankle. In some cases it is to be extended to the shoe, but this is not often necessary.

FLORENCE HOUSE, NEW YORK.

MANY DRUGS: FEW REMEDIES.

BY GEORGE T. WELCH, M.D.,

EASTPORT, N. J.

DISEASES are the same, but the armament of the physician has increased ten thousand-fold. Hippocrates with a few remedies and a wide and practical observation of the laws of health, wrested medicine from the domain of sorcery, and made it to shine as an art, and himself as a demi-god in the eyes of men; but the modern physician in his multitudinous drugs finds few remedies, and the tragedy of death is played all round him as he stalks behind the scenes. It is the boast of the profession that the death-rate is less and the average of human life is greater, but I might be pardoned the query if we have given due weight to other irresistible influences abroad. Exchange of commodities, increase of wealth, desire of luxury, culture of travel—all these have waved the magic wand over the penury of the past. The barber is better housed than ancient kings; the very charwomen have finery their grandmothers knew not of. The elements no longer beat upon and disintegrate the wandering populations of the world. Every war has been a civilization. Races have amalgamated, languages have blended, the hordes of the barbarians are the thriving citizens of to-day. Cities shine thick about the earth: the ocean is but a highway. Small wonder is it, then, that famine and pestilence are held at bay; that the fine art of the chemic treatment of the whole multitudes! Did medicine exorcise the demon, or did comfortable warmth and food, new thoughts, wider horizons?

The schools increase, the graduates swarm, the books emerge through printer's ink like bubbles on Avernus, but how many great physicians can you name, and which are the diseases borne under by the annual springwood of doctors! And yet where is the young doctor who does not believe in the magic of drugs, and the old doctor, if he be a wise man, who does not look upon the most of them as mischievous, and the minority as deserving of restriction? The pathologist is skeptical of them all.

With laborious zeal we study diseases. The magnificent eye of the microscope dilates above the smallest speck and gives it a local habitation and a name; we anatomicize and compare, and the professor awes with learned length while he discourses of the ills he cannot cure. Cripps tells us the death-rate from cancer has shown a pretty steady relative increase in England during the whole period of which we have any accurate returns, averaging about 1 in 56 of all the deaths that occur; and comparing the death-rate with the number of persons living, there is an annual average of 1 death from cancer in every 2,860. Comparison with the statistics of deaths from the reports of the Board of Health of New Jersey, during 1879 to 1883, inclusive, shows

---

1 Read before the New Jersey Medical Society at its meeting at Cape May, June 28th and 29th, 1884.
an average death-rate from cancer of 1 in about 51 of all the deaths that occur, and annually, taking the census of 1880, of over 3,475 living. Are we any nearer to the cure of malarial diseases? Although it might justly be urged that what is frequently called malaria is not malaria at all, and that where the ignorant or the indolent doctor of old, mildly puzzled by a disease relegated the cause to the liver and prescribed a mercurial, his son or his grandson, more glibly fashionable, ascribes all to malaria, prescribes quinine, and goes his way. Yet I am speaking of the veritable miasma; those that rise from unhallowed places, and, tangled in the veins, debauch the system and lower its morals. And do we, waiting behind the eye of Koch, know anything of tuberculosis, or believe that he does? Does not the ravage go on? And who has won eminence in curing yellow fever? Are men no longer in dread of the cholera? And the exanthemata—does not the gresnowes pendulum of disease sweep into and out of every neighborhood, about once in five years? Who cures rheumatism, or typhoid fever, or chronic Bright's disease? And where is the stout heart that never failed before a patient burning and blinding in the horrible slow flame of pneumonia? And yet who knows the purgatives? Yet why move one way about the cauldron, and we go the other; they throw in the drugs that brew the poison, and we throw in the counter-poisons. Stillé and Maisch's Dispensatory has a list of one hundred and fifty remedies for rheumatism, a disease which is as likely to become chronic with treatment as without it. Everybody has a specialty, from your grandaunt with tea, fomentations, and fiascol, to the last German doctor with his forty grains of salicylic acid to the dose. The extremes of treatment are one-and-thirty days, and relapses as frequently occur with the acid as without it, and the heart frequently becomes affected when the system is saturated with the drugs, and this surely. And then, as to typhoid fever, rarely exists a physician nowadays who does not feel called upon to reduce the temperature, though why, it would be hard for him to tell. Struggles the system against the fever with the ferocious strength of a man at bay in battle; oscillates every little cell with the glowing heat; by every avenue nature seeks to expel the invader. Suddenly an appalling dose of quinine paralyzes the fever and the patient as well. Almost gleefully the physician reads the figures on his clinical thermometer: the temperature has fallen four degrees! but the patient does not rally. He lies dazed in a stupor for hours, when the blood begins its ebulitions, the frenzy is renewed, the fever has asserted itself once more. And once more the physician gives it. This is the phenomena and not in the organic condition out of which they spring." It is the same old officious zeal that must be doing something, not remembering Milton's famous line,

"They also serve who only stand and wait."

The trouble is, medical thought runs too much toward specialists. It is the fashion of the time to achieve sudden honors, sudden wealth, easy learning, and why not rapid restorations to health? The journals teem with fortunate prescriptions, the nostrums of manufacturing chemists push braggit charlatanism to the wall. Our Pharmacopeia has but barely escaped from the jumbled thestics of old times when these monstrosities appear. Montaigne and some of his friends, all suffering from calculous disease, while comforted with each other's miseries, made merry over a new pill of a hundred ingredients, lately devised to cure their complaint. The antidote of Mithridates contained fifty-four ingredients, and the thersiac of Andromachus sixty. Warburg's tincture has about twenty, and the nostrums of every medical journal are flaunted the nostrums for the cure of the same diseases; and, most painful to relate, there is always appended the name of some professor in a medical college to lend the mixture. But the medical colleges are all over the land like mushrooms, and the professors are thicker than blackberries. There may be knowledge enough to go round, but there are few heads strong enough to take up thinking for themselves. Are we any closer to the cure of malarial diseases? Although it might justly be urged that what is frequently called malaria is not malaria at all, and that where the ignorant or the indolent doctor of old, mildly puzzled by a disease relegated the cause to the liver and prescribed a mercurial, his son or his grandson, more glibly fashionable, ascribes all to malaria, prescribes quinine, and goes his way. Yet I am speaking of the veritable miasma; those that rise from unhallowed places, and, tangled in the veins, debauch the system and lower its morals. And do we, waiting behind the eye of Koch, know anything of tuberculosis, or believe that he does? Does not the ravage go on? And who has won eminence in curing yellow fever? Are men no longer in dread of the cholera? And the exanthemata—does not the gresnowes pendulum of disease sweep into and out of every neighborhood, about once in five years? Who cures rheumatism, or typhoid fever, or chronic Bright's disease? And where is the stout heart that never failed before a patient burning and blinding in the horrible slow flame of pneumonia? And yet who knows the purgatives? Yet why move one way about the cauldron, and we go the other; they throw in the drugs that brew the poison, and we throw in the counter-poisons. Stillé and Maisch's Dispensatory has a list of one hundred and fifty remedies for rheumatism, a disease which is as likely to become chronic with treatment as without it. Everybody has a specialty, from your grandaunt with tea, fomentations, and fiascol, to the last German doctor with his forty grains of salicylic acid to the dose. The extremes of treatment are one-and-thirty days, and relapses as frequently occur with the acid as without it, and the heart frequently becomes affected when the system is saturated with the drugs, and this surely. And then, as to typhoid fever, rarely exists a physician nowadays who does not feel called upon to reduce the temperature, though why, it would be hard for him to tell. Struggles the system against the fever with the ferocious strength of a man at bay in battle; oscillates every little cell with the glowing heat; by every avenue nature seeks to expel the invader. Suddenly an appalling dose of quinine paralyzes the fever and the patient as well. Almost gleefully the physician reads the figures on his clinical thermometer: the temperature has fallen four degrees! but the patient does not rally. He lies dazed in a stupor for hours, when the blood begins its ebulitions, the frenzy is renewed, the fever has asserted itself once more. And once more the physician gives it. This is the phenomena and not in the organic condition out of which they spring." It is the same old officious zeal that must be doing something, not remembering Milton's famous line,
and tendency of the age. To this end a large body of pioneers, most attracted by lucre, a few by fame, are everywhere experimenting, or pretending to experiment, and seeking to demonstrate the miraculous utility of new drugs or recent compounds in the cure of the most diverse and lingering diseases; scarcely a chemist at his lurid flames, dissimulating or combining, discovers a rare crystal or a potent liquor, into which all things at some expansion will dissolve, but he begins to experiment with it on plants and animals, with a view, while it is yet crudely known, of heralding it as a specific for a score of human ills. If they threw physic to the dogs only, we might commiserate the unfortunate brutes; but when we think of the human, everywhere, down whose unsuspecting tal // at the potential dose must go, we fear well shrink aghast at the unrecorded mischief that is done.

We hear of the so-called cures, where we might shrewdly suspect nature would have remedied herself if let alone, but rarely do we hear of the failures. Where one physician is honest enough to publish the latter, a thousand will say nothing about it. It is positively painful to read the recent and eleemosynous poems that reach us. The most unconquerable diseases are found to have been cured by the most unreasonable medicines. The most unscientific writer has had no difficulty in subduing phthisis, diphtheria, albuminuria, or typhus fever with drugs that you and I have found no virtue in. Where you and I have failed, he has always cured about fifty per cent. of the cases, though only a part of the patients were cured, with less. But what are the means? As to the drugs, most of them are poisons. Solutions of the majority poured about the roots of plants destroy their vitality, and given to animals full often the horrid corroding torture begins that death cannot too speedily end. Given to men, corresponding effects are usually produced, if cautiously taken, but often having no effects from those produced in the lower animals is frequently an argument both fallacious and dangerous. The chemical action of the digestion in brutes would seem to be gross compared to that of man. Not seldom the toxic properties of plants are expelled undetected through the kidneys of the former, which would be speedily fatal to the finer human organization. As, for instance, birds and herbivorous animals eat the fruit of the belladonna without injury, the latter excreting the active principle with the urine. Two or three grains of atropia may be injected hypodermically in pigeons and dogs without causing more than a few hours' indisposition. Birds will tolerate the presence of morphia in the stomach to an almost unknown extent. A dog, says Strachan, has recovered from a dose of six grains of acetate of morphia.

While, on the other hand, where men find no evil result in certain drugs, brutes will rapidly succumb to unexpected toxic effects. Thus, citric and tartaric acids, camphor, cocculus, and dulcamara are fatal to most of the lower animals usually experimented on, destroying them with pain and violence. Thomas injected milk into human veins, and saved his patients from death by hemorrhage. Howe performed the same experiments on dogs, and all the animals died. And oil of thyme, acetate of ammonia, and potassium iodid act fatally on the lower animals, while they are fairly medicinal to men.

Besides the illustrations given there are many other drugs which act so diversely on different animals that no judgment as to even their probable action on man can in any way be gained. Falk and Guenstein administered berberia hypodermically to rabbits without observing any uniform effect, and tried with many animals such drugs as colocynth, cyclamen, eucalyptus, hyoscymus, and stramonium, and some others, which presented the most curious and remarkable, some slaying outright, some sickening grievously, and leaving others entirely unharmed.

Added to the cloudy comprehension of these might be added the uncertainty of the action of drugs which have been habitually prescribed for centuries. Calomel, so long used with superabundant faith as a cholagogue, though occasionally disputed, is at last believed to have no such effect, but to actually diminish the secretion of bile. Who does not remember when sarsaparilla was thought so potent, though now so unregarded. And it has been no long time since antimony was restricted, when before it had been of universal application.

Even to be liberal in a large sense, if certain drugs like opium, quinine, iodine, phosphorus, iron, ether, strychnia, and aconite were rescued, the whole nauseous bulk of the rest might be in the flat seas sunk, and the death-rate rise no higher. Medicine has achieved her most glorious renown in the prevention, not in the cure of disease; and in that domain lies her imperishable reward.

In dealing with the fortunes of a spirit so subtle and elusive as life, we should accept nothing as proven that has not stood the inquisitorial tests of time and innumerable applications. Lands and governments remain for the future craft of men; but life, that fades from before us today, to-morrow shall reillumine. Our art deals at once with all that is vital in the stupendous mysteries that surround and pervade us; the eagle is vouchsafed the forge, the wonder and the paragon of nature—is the exquisite sense at fault, the body languishing? Would we remedy it, we must be quick about it. And to be of seemly haste we must be convinced of the qualities and applicability of the medicines we are about to use. But how shall we be convinced? Certainly not through drug-gate circulars, nor through the unfrequented enthusiasm of a few professors; but if a carefully tabulated return of diseases treated and remedies used could be annually made from every physician to a responsible board of supervisors, who, in their turn, should sift and digest with rigorous criticism the mass of evidence before them, and report back again to the profession at large, progressive knowledge could be built upon foundations secure. As it is, we have no system; each works upon his own plan; our therapeutics is cloudy and foggy. The power that comes from thorough organization is squandered in individual groping.

There is no reason why medicine should not work toward a great end by machinery similar to a political government, provided you can make each physician responsible to all, and exact his best endeavors. But this we have tried for years in New Jersey, and having left it to the honor of medical men, their indulgence has made the end impracticable. There is one other way—the establishment of a college of experimental medicine, as recommended by Milton, with a system of registration for correcting errors of observation.

The Black Plague derived its name from the dark and livid color of the spots and boils that broke out upon the patient's body. It descended along the Carpathians to the shores of the Mediterranean, spread over the South, and only entered Russia after the rest of Europe was affected. It followed the caravans which came from China across Central Asia until it reached the shores of the Black Sea; thence it was conveyed to Constantinople by ships, because this was then the commercial centre between Asia, Europe, and Africa. In the year 1347 it reached Sicily, Italy, and Marseilles. The next year it spread to France, Germany, and England. It did not reach Russia till 1351, or four years after it was at Constantinople. Thus, like the cholera, it followed a regular route, which differed according to the lines of trade and commerce at the different periods. The plague was to water poisoned by the Jews, and persecuted them infamously: 1,500 Jews were burnt in Mayence; London lost 100,000 in one month; Avignon and Florence, each 60,000; Marseilles, 56,000; Paris and Norwich, each 50,000; Strasburg and Erfurth, each 16,000; Basle, 14,000; and Venice, 10,000 in one month.
Hospital Reports.

Presbyterian Hospital, New York.

Service of John H. Hinton, M.D.

(Rapport by Alfred Freeman, M.D., late House-Surgeon to Presbyterian Hospital, New York.)

Pistol-shot Wound of Stomach—Recovery.

The following case occurred in Dr. John H. Hinton's service at the Presbyterian Hospital during the month of February, 1884, and is particularly interesting for the favorable progress and satisfactory termination following an injury of such apparent gravity. It occurred as follows: The patient, a male, aged twenty-one years, and in good health, was shot in the back a few minutes after eating his breakfast. He experienced a sensation as if struck with some large heavy body, but walked immediately to a place half a block distant, and from there was conveyed in an ambulance to the hospital. When admitted, at 9.30 A.M., he presented no symptoms of shock, but was in very good general condition. Examination showed that the pistol had been presented sufficiently near to blacken his overcoat, and that the ball had entered over the left tenth rib behind, five inches to the left of the spine, while on the anterior abdominal wall a small hard body was felt beneath the skin three inches above the umbilicus, and two inches to the left of the linea alba.

The patient complained of no pain whatever, but expressed a great desire for sleep, so Magendie's solution were administered hypodermically, which quieted him for about half an hour, when he suddenly vomited about a pint of dark fluid and clotted blood with food intermixed. He vomited four times after this, about three ounces of dark fluid blood at each attack, but showed no symptoms of collapse, and nothing occurred to indicate that he was taking place of the peritoneal cavity. Cracked ice was given by the mouth, and a hypodermic injection of gr. x. of ergotin in solution.

In the afternoon, an incision being made over the bullet, it was removed, and found to be a conical 32-calibre ball in good shape. Flaxseed poultices were then applied to both wounds. The day after the injury found the patient sitting up in bed. No nourishment was allowed by the mouth, and he was fed entirely by enemata of milk every four hours. During the afternoon he vomited once, about a teacupful of dark fluid blood.

The evening temperature was 101° F., and the pulse being full, strong, and 120 to the minute, gtt. ij. of the tincture of aconite were given every two hours. The next morning there was another attack of bloody vomiting, followed shortly by a large, tarry, fecal passage. In the evening, the pulse having fallen to 107, and being less forcible, the aconite was discontinued. During the next four days there were no signs of peritonitis, and no important changes occurred. Eggs and beef juice had been added to the enemata, but on the fifth day he complained so much of hunger that milk in small quantities by the mouth was allowed and well borne. The temperature, which had never gone above 103.5° F., fell to normal on the ninth day and remained so. By this time the patient had become somewhat anemic and emaciated, and the allowance of food was gradually increased and the enemata stopped. Both wounds had begun discharging pus, and the poultices were changed for absorbent dressings. His general condition steadily improved after this, and on the twentieth day he was able to sit up and eat the regular house diet. By the thirty-fifth day the wounds had cicatrized and he was up and about, feeling perfectly well.

Eleven weeks of illness, although not suffering from pain, he was unable to sleep at night without morphine, and the nightly amount required was 3100 mg. of Magendie. There was no difficulty, however, in diminishing the dose, and when he became able to sit up through the day the restlessness at night disappeared. Having lost twenty pounds in weight during his sickness, he gained one pound daily for ten days on returning to a regular diet. No dyspeptic symptoms occurred, and he left the hospital feeling as well as ever and apparently cured. In this case it seems fair to suppose that the ball passed through both walls of the stomach, and probably above the food level. The wounds being small may have contracted rapidly, and one may have become closed by a flap being torn from the inner wall of the stomach acting as a valve, and preventing food and blood free escaping into the peritoneal cavity.

It was shown that this may occur by the following experiment on the cadaver.

After pumping the stomach about one-half full of water, the subject was shot in the back. Examination showed that the ball had entered about in the same situation as in the above case, passed through both walls of the stomach and lodged in the anterior abdominal muscles. The wound in the posterior wall was guarded by a valve-flap of mucous membrane, which completely prevented fluid escaping, and the other wound was almost closed, but had no protecting flap. No other vessels besides the stomach was injured.

Progress of Medical Science.

The Modus of Action of the Bromides in Epilepsy.

In a number of experiments upon dogs poisoned with bromide of potassium, Dr. Rosenbach found that the irritability of the cortex to electrical stimulation was diminished or entirely destroyed, while that of the subjacent white substance remained unchanged. From this the author concluded that the therapeutic value of potassium bromide in epilepsy was owing to its power of lessening the irritability of the cortical substance of the brain. —Norsk Magasin for Lægevidenskab, April 15, 1884.

Chloral in Chorea.—Dr. Mosler relates a case of very severe general chorea in a girl eighteen years old, in which a speedy cure was obtained by chloral. After morphine and arsenic had been given for two weeks without effect, chloral was exhibited in thirty-grain doses, at first four times, then twice, and finally once a day. On the very first day the patient slept soundly, and at the end of a week the choreic movements had ceased entirely. It is worthy of note that the onset of the chorea was preceded by a tooth ache, a circumstance which has been remarked by other observers. —Norsk Magasin for Lægevidenskab, April 15, 1884.

Mechanical Treatment of Hematemesis.—The difficulty of controlling hemorrhage from the stomach or esophagus by any of the ordinary means led Dr. Schlüll to employ an apparatus by which direct compression might be made against the inner walls of the organ. It consists of a flexible stomach tube with a rubber bladder at one end and a stop-cock at the other. The bladder is introduced and very slowly and carefully inflated until it is made large enough to excite contractions in the stomach. In this way the hemorrhage is controlled. The air should be let out again very slowly, so that the clots may not be loosened. If the bladder has been properly applied, the hemorrhage will be diminished to a point where the dressing to the esogaul will be lessened. If this procedure fail to arrest the hemorrhage, we may then conclude that its source is in the esophagus (usually it is at the lower portion of the tube), and recourse must then be had to the esophageal tampon. The author relates one case of repeatedly recurring hematemesis, which was permanently arrested by the use of this device, in twelve minutes. The inflation should be moderate, as the object is to excite contraction of the gastric walls and not to distend the organ.—Centralblatt für Chirurgie, May 3, 1884.
TRACHEOTOMY IN DIPHTHERITIC CROUP.

At a series of meetings recently held by one of the sections of the Academy of Medicine to discuss the treatment of diphtheritic croup, the large numbers in attendance and the close attention paid to the speakers showed the great interest taken by the profession in this subject. One noticeable feature in the discussion was the very general skepticism as to the utility of solvent inhalations in the destruction of the false membrane. There was exception taken to this sentiment, however, by a distinguished gentleman present, who thought that by a faithful use of the spray, about one in eight cases might be saved. There is apparently some uncertainty attending this mode of treatment. The pseudo-membrane is composed of several different elements which may yield relatively to different solvents; but as we do not know in any individual case which of the component parts of the membrane preponderate, we cannot be sure that the best inhalation is in use. This is possibly an explanation of the fact that good results have been claimed for such widely differing solvents in different cases. It is also uncertain how much of the inhalation actually reaches the larynx in a young child. The atomizers in common use do not throw a very strong spray, and few children can be kept near enough to receive the full benefit of what is thrown out. Most physicians agree that a moist atmosphere, in which fresh air is not excluded, is desirable in the treatment of croup. In one of the papers, the internal administration of corrosive sublimate in frequently repeated doses, was recommended as promising great results. These good results, however, have not as yet been fulfilled, and probably all will agree, that despite the best medicinal treatment most cases of diphtheritic croup will die if no operation is performed. The important question for the physician is, whether the operation itself affords enough chances of success to warrant its frequent performance. The oldest statistics are rather disheartening; but in the past two or three years much better results have followed the performance of tracheotomy. It is of some interest to inquire the cause of this improvement in results. Is it due largely to fortuitous circumstances, or has a more intelligent application of our art not been a factor in its production? Many observers consider that the type of diphtheria has changed somewhat in the past few years. There is less manifestation of septic blood-poisoning that produces heart-failure, nephritis, and so many fatal results after the ob-
in case of necessity, to perform a tracheotomy. Invaluable time is often wasted in searching for a surgeon. A few hours, or even minutes, may make the difference between life and death. We predict a brilliant future for this operation.

M. PASTEUR'S HYDROPHOBIA VACCINE.

It seems to be the fortune of M. Pasteur every now and then to put himself in such a bad light that serious people ask if there is not, after all, something of the charlatan about him.

We recall the peculiar way in which he announced his discovery of the chicken-cholera microbe and its vaccine, the exaggerated and untenable claims which he made for his anthrax vaccine, and the persistency with which he clings to obsolete and unsafe methods of bacteria-culture.

M. Pasteur's last performance is in keeping with some of the others. Several weeks ago, he furnished to a sensational paper the announcement that he had discovered a vaccine against hydrophobia. The exaggerated language in which his discovery was described might have been largely due to the expansive imagination of the reporter. Nevertheless, such a possibility should have been foreseen and guarded against. Though promising great things to the newspaper public, M. Pasteur, it seems, dares not yet actually put his "vaccine" to a practical test.

A cablegram from Paris says: "Numberless persons have applied to M. Pasteur, and expressed their willingness to be inoculated with the modified virus which causes rabies. All such applications the scientist has refused to avail himself of until he shall have completed his experiments upon dumb animals. The final test with animals will shortly be made before a Government commission."

M. Pasteur's method of obtaining the rabies virus has already been referred to in these columns. He finds that by inoculating monkeys with the virus from a mad dog that the intensity of the poison is gradually diminished. After passing the virus through a sufficient number of monkeys he inoculates rabbits. In passing it through rabbits, the strength is gradually increased again. When the proper intensity is reached, the animal to be protected is inoculated.

The test referred to in the above cablegram is likely to shock the sensibilities of every one, but it may, and we trust it will, be entirely justified by the results. Twenty healthy dogs are to be inoculated with the protective virus, twenty more control-animals are to be kept unvaccinated. The whole forty are then to be bitten by mad dogs.

THE CONSERVATIVE VIEW OF CREMATION.

We do not mean to assert by any means that cremation is a humbug, or that it is not a mortuary rite entitled to respect. Cremation is a legitimate and decent method of disposing of the deceased. Those persons who wish that after death their bodies should be put upon a crematory gridiron and slipped into a fiery furnace, ought to have opportunities for the gratification of such a harmless eccentricity, the proper medico-legal cautions being taken.

We have before expressed the opinion that, the novelty of cremation having passed away, it has ceased to encounter very much opposition or to receive very great encouragement. The English Parliament has, to be sure, rejected the cremation bill, but an English judge has affirmed its legality, and the Paris municipal council has voted to cremate the anatomical debris of the city's dissecting-rooms. But though cremation has been revived now for many years, the number of bodies burned is still counted only in hundreds.

The fact is that cremation is not a necessity, as is claimed, except possibly in certain localities. The alleged dangers of inhumation do not exist if the solid coffins are not used and the bodies are deposited in proper soils.

Much has been said and written concerning the purifying loveliness of fire and the mouldy putrefaction of the earth. Such arguments relate entirely to the individual feelings, and are not practically of much value. Most people really prefer to take the chances (post mortem) with the worms, to produce putrification, and other interesting chemical bodies, rather than be suddenly blown up through a tall chimney in the form of CO₂, the inorganic remainder being returned home by express. Yes, flame purifies; and, therefore, man is in the habit of casting all his rubbish into it. But most persons object to classifying summarily their beloved dead as rubbish, to be disposed of by bonfire, as is the custom in the country.

Let those who cremation who want it, let it be introduced into cities which absolutely need it, if such exist. But there is no need that sanitary jeremiahs should go about informing the people that inhumation is disgusting and that cremation is a hygienic and aesthetic necessity. This is truly humbug.

THE ILLINOIS MEDICAL PRACTICE ACT.

Recent decisions in two cases—one under the Act to Regulate the Practice of Medicine in Illinois, the other under the Dental Surgery Act—sustains the right of the State Board of Health to determine the status both of a college and of a practitioner. Under the latter act the Supreme Court refused the petition of Isaac N. Sheppard for a writ of mandamus to compel the State Board of Dental Examiners to issue him a certificate or license based upon a diploma of the Indiana Dental College. The Board refused the license on the ground that the college was not a "reputable" institution. It was argued that the law constitutes the Board judges of the standing of a college, and that there is no power of review vested in any other body. "If the Board should arbitrarily or unreasonably abuse their discretion, and refuse a license without any reason therefor, there is a remedy for such abuse of a discretionary power." But there was no ground for claiming that this was the case in the present instance. The Board, in its judgment, had decided that the curriculum of study and requirements for graduation of the Indiana Dental College were not such as to entitle it to be classed as a "reputable dental college," and there is no power in the law given to any person or body to review and set aside, or confirm, the exercise of the discretion by the Board. The petition for a mandamus was denied.
In the case of the State Board of Health against C. Buel Rice, of Cincinnati, a graduate of the Medical College of Fort Wayne, tried in the Sangamon County Court, the defence set up the plea that, being a graduate of a "legally chartered medical institution in good standing," the defendant was entitled to the certificate of the Board; and that it was not competent for the Board to inquire into the moral or professional character of such graduates. On the part of the prosecution it was shown that charges had been presented to the Board alleging that Rice was in the employ of, and associated with, the "K. & K. Surgeons," a firm of advertising quacks from Cincinnati and elsewhere, and that in various ways connected therewith his conduct was unprofessional and dishonorable within the meaning and intent of the Medical Practice Act. Upon these charges the Board had refused to issue Rice a certificate until he had disproved the same. Instead of making any attempt at such disproof, Rice continued to practise; whereupon he was arrested for practising without the necessary certificate. The facts were admitted by the defence; but, as already stated, the court was asked to dismiss the suit on the ground that it was obligatory on the Board to issue its certificate to the possessor of a genuine diploma of any "legally chartered medical institution in good standing," regardless of the moral or professional status of the individual. This the court declined to do, but found the defendant guilty, and assessed a penalty of $50 fine and costs.

STATE SOCIETY MEETINGS.

DURING the past week there has been more than the usual number of meetings of State medical societies, and in them the ordinary amount of interest has been manifested in scientific matters, local and general. As a whole, however, these organizations do not rise to their privileges of instruction to members or influence with communities as they should.

There are many difficulties to contend with in view of such desirable ends, which all reasonable lookers-on are willing to admit. Their plans of work are necessarily defective, their membership is not sufficiently representative, and the character of the papers read are not such as tend to bring out the best lines of practical thought.

At the bottom of the difficulty appears to be the dearth of papers, especially such as are calculated to interest general practitioners. The consequence is that the time is occupied in other ways, mostly by specialists, who almost invariably put the hay too high for the little horses. The few papers which are presented are generally devoid of interest, occupy the full time of the sessions, and narrow the exciting and interesting events to the election of officers, to the taking of an excursion or two, and the attendance upon a supper.

The annual addresses are delivered as a penalty to the greatness of the office which makes them necessary, are usually sadly weary efforts in the direction of patching up threadbare subjects, and have the only redeeming feature that they are slightly "more blessed to give than to receive." We are now speaking on general principles, and place ourselves above individual references. But why cannot these inflictions be dispensed with altogether, and the time occupied in their delivery be devoted to strictly scientific work? Or can we not get at matters pertaining to the prevention of disease, the value of sanitary reforms, the utility of vaccination, the necessity of advancing medicine, of checking quackery, and like subjects talked about ad nauseam, in some more practical way? This may be a question not easily answered, but in the interest of audiences yet to be, we ask it notwithstanding. Is it not possible to make the election of a president of a State society conditional with a promise by the candidate that he will eschew all such subjects in his address? This would certainly open the way to a little variety in topics which might prove refreshing and entertaining. In any event, we have certainly come to the point where new departures are in order.

In this connection we are glad to notice that in some instances the presidents have recognized a becoming fitness in things and have branched forth in new directions. It cannot, of course, be expected that in a session of a day or two very many papers can be read, but such as are read can be on practical subjects. There should be some arrangements made beforehand by the president to secure the proper material and encourage the every-day workers to come to the front and discuss every-day diseases. Let the papers be short and their subjects published beforehand, so that the members interested may be prepared for the discussions.

By all means let the collective study of disease be encouraged, and in no better way can it be done than by the distributed membership of a systematically organized State society. The material is always at hand for such work in every State society in the land. We want to know more of the commoner diseases, for we speak now in the interest of the country practitioner generally, who forms the backbone of every State society, and who attends the meetings that he may bring home with him something that will aid him in diagnostically more surely and in treating more efficiently typhoid, puerperal, malerial, and scarlet fevers, pneumonia, rheumatism, Bright's kidney, and the like. Just in proportion as all these things are done will the meetings be more prosperous, more profitable, more instructive, and more representative.

A QUESTION FOR OUR MEDICAL CENSORS.

The medical press of England occasionally comes out with some stringent criticisms upon the practice of advertising medical books in the daily papers. The general sentiment of the profession there is emphatically opposed to these public announcements of technical medical works with their authors' names and titles. A similar feeling prevails among the physicians in this country and has very generally been respected. We observe, however, that of late several medical works have been advertised in the city papers and on the sidewalks along with the other publications of the firms. Authors who allow this enlarge the circle of their readers, but they also weaken their own standing among their medical brethren. A good medical work cannot be made intelligible to general readers, and the very fact that attempts are made to secure such an audience stamps the work at once as of questionable authority and value.
Jews of the Week.

AMERICAN NEUROLOGICAL ASSOCIATION.—The tenth annual meeting will be held at the New York Academy of Medicine, June 18th, 19th, and 20th; afternoon and evening sessions.

ILLINOIS BOARD OF HEALTH.—Governor Hamilton, of Illinois, has appointed Dr. George N. Kreider, of Springfield, a member of the State Board of Health, vice Dr. A. W. H. Reen, of Peoria, resigned.

DR. WILLIAM PEPPER has been elected to the Chair of Theory and Practice of Medicine, in Jefferson Medical College, in place of Dr. Alfred Stillé, resigned. Dr. Pepper's father held the same position.

FAILURE OF THE DRUG COMBINATION.—As we at first predicted, the leading wholesale druggists who agreed some time ago that they would not sell drugs, medicines, or proprietary medicines to the retail dealers in this city and Brooklyn that cut rates, have cancelled their agreement, and they sell now to all customers as before the combination.

PHYSICIANS' MUTUAL AID ASSOCIATION.—Increased membership of the Physicians' Mutual Aid Association has enabled the trustees to increase the payment at death to $475, and it is confidently expected that the sum will soon be increased to $500.

THE NEW CHAIR OF PATHOLOGY AT CAMBRIDGE UNIVERSITY.—Dr. Charles Smart Roy has been elected to the new Chair of Pathology in the above-named university.

THE INTERNATIONAL CONGRESS OF HYGIENE meets this year at the Hague, August 21st. Dr. Van Overbeek de Meijer, Professor of Hygiene at Utrecht, is Secretary. The Dutch Minister of the Interior is honorary President. Drs. Koch and Pasteur will be present and read papers.

A NEW AND MORE CERTAIN METHOD OF ATTENUATING VIRUS has been discovered by M. Chauveau, and is described partly in the Lyon Medical. It consists in the use of compressed air acting upon the organisms in the culture-fluids.

PROFESSOR WEBER-LIEL, of Berlin, well known as an otologist, has accepted a call to Jena, where he has charge of a clinic. Professor Liel writes us that Jena, like other of the smaller German universities, has excellent advantages for the study of the specialties. Living and tuition are cheap. A short course is given by the Professors and docents in the summer months.

DR. THOMAS C. CHALMERS, one of the oldest physicians of this city, died at his residence, on June 4th, after a short illness. He was born at West Galway, Saratoga County, this State, June 18, 1810, and was graduated with high rank from Union College. He came to New York in 1834, and for many years was connected with the New York Hospital. For more than forty years he practised his profession with marked success, and was held in the highest esteem for his skill and devotion to his patients. He was a member of the New York County Medical Society, and was one of the original founders of the Academy of Medicine of this city.

THE ARMY MEDICAL RECORDS.—The U. S. Senate has passed a bill providing for the erection of a fire-proof building in Washington for the records of the army medical department.

THE FAITH CURE IN COURT.—The Rev. Clement T. Blanchet is an Episcopal minister who cannot be accused of not practising what he preaches. He is a firm believer in the faith cure, and tested it upon his six-year-old daughter until the Society for the Prevention of Cruelty to Children interfered in the child's behalf. The child in question broke one or both bones of her fore-arm. The parents both agreed to try the faith cure, and suitable prayers were offered. The child's arm did tolerably well, it being only a green-stick fracture. The neighbors interfered, however, the Assistant Bishop sent a letter of protest, and the Society for the Prevention of Cruelty to Children had the father summoned before a justice. A doctor was called, and the arm set. The faith cure has thus failed to encroach on the domain of surgery.

STATE MEDICAL SOCIETY MEETINGS.—The following State Medical Societies met during the past week: The Delaware State Medical Society; the Indiana State Medical Society; the Ohio State Medical Society; the New Jersey State Medical Society; the Maine State Medical Association; the Massachusetts State Medical Society; the Rhode Island State Medical Society; the Michigan State Medical Society.

Reports of Societies.

MASSACHUSETTS MEDICAL SOCIETY.

One Hundred and Third Anniversary, held in Boston, Mass., June 10 and 11, 1884.

(By Telegraph to THE MEDICAL RECORD.)

TUESDAY, JUNE 10TH—FIRST DAY.

In the morning the members of the Society availed themselves of the invitations of the officers of the various institutions to visit the Massachusetts General, City, Children's, and Lying-In Hospitals. At noon they met at the new Harvard Medical School building to listen to a communication by Dr. H. P. Bowditch on METHODS OF INSTRUCTION AND RESEARCH IN PHYSIOLOGY, WITH DEMONSTRATIONS.

The members of the Society were shown over the laboratories and lecture-room of the physiological department, explanatory diagrams being drawn on the blackboard, and the members of the Society were given an opportunity to examine for themselves the methods here employed in giving instructions in physiology, and to inspect the appliances used for original investigation. The blood-pressure in the dog, and the effect of irritation of the vagus nerve; methods of studying the vasomotor nerves of the cat and frog by plethysmograph; effect of temperature on rate of heart-beat of frog; the force of ciliary action; the action of the semilunar valves, as shown by those of the ox so arranged in a current of water that their movements could be observed; some optical illusions of motion (subjective complementary motion), as shown by a revolving spiral figure; and the pendulum photograph for determining the reaction time of muscle were shown.

DR. ERNST explained the methods and apparatus for the cultivation and study of the tubercle bacillus, showing specimens obtained by culture up to the fourth generation.
The members then adjourned to the anatomical lecture-room, when Dr. Dwight presented a communication on

**MODERN METHODS IN ANATOMY, WITH DEMONSTRATIONS.**

Dr. Dwight spoke of the intimate relation of the Professor of Anatomy to the museum, which is the monument that the anatomist raises to science, and which perpetuates his own name, being indeed a criterion of the anatomical merit of the institution which owns it. He mentioned the work of the great anatomists of this and the past generation as seen in the great museums of Europe. Turning to the museums of Harvard University he mentioned the great Agassiz collection; the beautiful collection of comparative anatomy by Harvard's great anatomist, the lamented Jeffries Wyman, which is now diffused through a larger collection; and the Warren Museum at the Medical School, founded by John C. Warren, Professor of Surgery and Anatomy, and devoted to both morbid and normal anatomy.

Anatomy should not be spoken of as a science without a future. It is true that man is still made of the same bones, ligaments, muscles, etc., as of old, and that they have been, on the whole, fairly described; but without speaking of the acknowledged great advances in minute anatomy, what great progress has been made in embryology, which with comparative anatomy throws much light on mammalian morphology, embryological structure, and which theorists would have the foundation of anatomical teaching. Anatomy has to do also with the movements as well as the relations of the various organs, and the subject-matter of the anatomist's knowledge should be the breathing, moving man. Dr. Dwight spoke of the great advance in the methods of presenting the different subjects in anatomy—the advance in topographical anatomy marking an era in the science. The reader called attention to certain grave errors only lately pointed out; as, for instance, the shape and position of the stomach, whose lesser curvature has only within a few years been recognized as practically vertical. His has recently shown, by means of livers hardened in situ, that the description of that organ given in Gray and most text-books is wrong, and only in the last edition of Quain is it corrected. The relation of the mouth, pharynx, and esophagus, as pictured by Bougeray and others, is shown by Braune to be incorrect. The position of the ovaries is, even to-day, a matter of doubt.

The reader spoke of the great value of frozen sections in connection with other methods of study, showing specimens of the head, thorax, abdomen, and various joints. A series of recently prepared corrosion preparations was exhibited, a part of them being in colored wax and resin, according to Rudinger, prepared by Dr. Dwight; and others, of vessels and cavities, such as the air cavities of the head, in fusible metal, prepared by Dr. Mixter, assistant in anatomy. The wax preparations have the advantage of giving two or more systems together of different colors, while with the fusible metal can be made finer injections, and at the same time they are less easily affected by the heat. A large number of thin sections of bone were also shown as demonstrating its internal structure.

At three o'clock the Society met in Huntington Hall, to listen to a paper by Dr. G. W. Gay, on

**THE PLASTER POSTERIOR SPLINT IN THE TREATMENT OF FRACTURES OF THE LEG, WITH ITS PRACTICAL APPLICATION.**

Dr. Gay described the method of applying the splint, which is as follows: The leg is first surrounded with cotton batting, and a layer of crinoline is then placed beneath it, wrapped about the leg, and cut so as to envelop the whole leg from the toes to above the knee, with the exception of about an inch on the anterior surface. This piece serves as a pattern by which six or eight layers are cut. Plaster mixed with warm water is rubbed into each layer, and the whole applied to the limb and secured with a roller bandage. When dried, the outer bandage is removed and the tray is complete. The advantages of this splint are, that it holds the fragments firmly in position, it does not interfere with circulation, seldom requires readjusting, allows the patient to move and be moved, allows easy examination, and is very comfortable. It is also easily removed and reapplied.

It is especially adapted to cases of simple fracture of the leg not attended with extensive injuries to the soft parts and not requiring great force to retain the fragments in a proper position. It may also be used in certain cases of compound fracture, in which the wounds can be exposed through apertures in the splint. It is of especial value in children, as, when once properly applied, it requires very little readjusting.

This splint has been in almost constant use at the Boston City Hospital for several years and has given great satisfaction. Not infrequently cases of fracture are put into this bandage within twenty-four hours of the accident, and are not interfered with for six weeks or until recovery is complete. Cases of Pott's fracture give more trouble than almost any other form, and require a longer period of confinement. A patient weighing one hundred and fifty pounds should not, in Gray's opinion, be allowed to bear his weight on a Pott's fracture for three months, and the heavier the patient the longer should be the confinement.

At four o'clock an adjourned meeting of the Society was held. After a long and animated discussion the Society voted to amend the by-laws so as

**TO ADMIT WOMEN TO THE SOCIETY.**

This action to become effective must be concurred in by the Councillors, and a committee was appointed to present the wishes of the Society to that body in the evening.

**EVENING RECEPTION.**

At 5 P.M. a reception and collation were tendered to the members of the Society by the Medical Faculty of Harvard University at the new Medical College, and the new building was exhibited. In the evening the annual meeting of Councillors was held at the Medical Library, and the question of the admission of women was discussed and acted upon. The action of the Society in the afternoon session was sustained, and in the future women will be admitted on the same terms as men. This ends the struggle that has been going on for several years.

**WEDNESDAY, JUNE 11TH—SECOND DAY.**

The meeting was called to order by the President at 9 A.M., when the Secretary's report was presented, followed by that of the Treasurer. The presentation of medical papers being next in order, Dr. F. Nickerson, of Lowell, related a case of chylous discharge in the abdomen.

The patient, a man forty-five years of age, in good health, was suddenly attacked with pain and swelling of the abdomen. On examination a tumor was discovered, which, on aspiration, yielded two quarts of milky fluid. During the next two years the patient had repeated attacks of pain and swelling, sometimes accompanied by vomiting of milky fluid, and once by a discharge from the rectum of the same character. During this time the tumor was aspirated several times, always giving the same kind of fluid, the quantity, however, each time becoming less. Specimens of this were examined by Drs. Eades and Wood, of the Harvard Medical School, the result being as follows: reaction, alkaline; specific gravity, 1,018; is fat emulsion.

**THE PITCH OF THE PERCUSSION SOUND**

was the title of a paper by Dr. L. Huntress, of Lowell.

The reader claimed that sufficient stress had not been laid on pitch of percussion-note, though some writers
mention it. It is probably of greater value than intensity, though not as great as quality. He had carefully examined over two hundred healthy persons, and found that there was slight or well-marked difference in pitch on two sides of the chest in more than two-thirds of the cases. The pitch of tympanic percussion-sound depends on the volume of air and the tension of the walls. Flint spoke of it as higher than normal, while Loomis holds that it is probably due to different degrees of tension of the walls of the cavity.

Dr. Bowditch spoke of the importance of recognizing the fact that there may be variations in pitch in different parts of the same healthy chest.

Dr. Garland spoke of changes of pitch in the organ-pipes as depending on the length of the air-column until the length becomes equal to, or less than its width, when the rule ceases to apply. This probably explains the difference in pitch of the tympanitic note.

Dr. J. F. Adams read a paper entitled SANITARY FOREST-CULTURE.

It had been only recently recognized that the presence of forests has a marked effect on the flow of streams, moderation of climate, and prevention of malaria. Forests act as reservoirs and distributors of moisture by allowing more water to fall up into the snow-falls and thus preventing freshets, and extremes of high and low water. In Europe it is noticed that the variations in the rise and fall of rivers are much greater than formerly. Forests also serve to break the force of winds and distribute moisture. It had been repeatedly shown in this country and Europe that cutting away forests had, in many places, increased the prevalence of malaria, while many malarial districts are rendered habitable by planting rapidly growing trees. The reader recommended that the State take measures to awaken a knowledge of the importance of the subject in public minds, pass laws to protect existing forests, and establish a school of forestry in the University in Europe. Many waste lands in the country could be made to yield a good interest if properly planted.

Dr. H. O. Marcy spoke of the importance of steps being taken for the preservation of the Middlesex fields. An excellent opportunity was there offered for the systematic cultivation of forest trees.

Dr. Millett spoke of the manner in which forestry is taught and applied in Germany, where in certain districts, forming water-sheds to important streams, no trees can be cut without permission from the government forester.

On motion of Dr. Millett the Society passed an unanimous vote referring the subject to a committee, with instructions to present it to the Legislature, and urge the passage of suitable laws on the subject.

WEIGHT AS AN INDICATION OF THE CHARACTER OF RISKS FOR LIFE INSURANCE, was the title of a paper presented by Dr. J. Seaverns, of Roxbury. Some very interesting points were brought out in reference to the condition of weight and its bearing upon health and hereditary predisposition. Being under the usual standard weight was always a matter of more concern than a slight over-weight. Extremes in either direction were hazardous as to life risks, as each was known to have its diseases, and excited a direct influence upon life expectation.

The reader presented a careful analysis of a large number of cases of deaths found in the records of an insurance company, with especial reference to the limit of safety risks on whose weight was generally accepted life insurance tables of normal standard weight. He concluded that twenty per cent. is too great a margin for those whose weight falls below the standard, while it may be increased for those who are heavier, providing, of course, that examination shows no defect. He would put the limits of safety at fifteen per cent., below and twenty-five per cent. above. Outside these limits all persons should be rejected.

The President, Dr. John Crowell, of Haverhill, delivered the ANNUAL ADDRESS.

He spoke of the duties of the physician as a teacher of the public, especially in sanitary matters, calling attention to the prevalence of bad drainage and ventilation in even our best houses, and especially in summer resorts and old farm-houses in the country. There has been great improvement in this respect since the formation of boards of health in 1877, but much remains to be done. In the matter of food there is opportunity for great advances. Much is to be learned from economical and healthy dishes, French and Scandinavian. We do not do as well as we should with the materials at hand.

In the conduct of the sick-room much improvement is needed, especially in the country. The attitude of the public to contagious disease and its prevention, especially in cases of diphtheria and small-pox, is not wholly as it should be. The speaker closed with an eloquent appeal to the profession to educate the public so that they may be freed from quacks and vendors of nostrums and specifics, and that the rising generation of the poor may be better fitted for their struggle with vice and ignorance.

At the close the Society unanimously voted its thanks for the able and eloquent address.

THE ANNUAL DINNER.

After the delivery of the President's address, and the introduction of Dr. Homans, President-elect, the delegates and invited guests repaired to the Skating Rink in Clarendon Street, where a dinner was served for seven hundred physicians.

The hall was handsomely decorated with banners and long tables tastefully spread. The Germania band furnished music for the occasion. Nearly seven hundred Fellows of the Society were present.

Dr. George B. Shattuck, of Boston, Anniversay Chairman, presided with a quiet dignity befitting the occasion, and happily and gracefully introduced the speakers of the day. Upon the platform were his Excellency, Governor Robinson, Dr. Mackie, of New Bedford, Surgeon-General Holt, Rev. Frederick Courtney, Samuel Elliot, Dr. George C. Shattuck, Dr. J. O. Green, of Lowell ; Dr. Jarvis, Dr. Henry L. Bowditch, Mr. H. O. Houghton ; the President-elect of the Society, Dr. Charles D. Homans ; the retiring President, Dr. Alfred Homser, of Watertown ; the Orator, Dr. John Crowell, of Haverhill ; ex-Mayor Dr. F. A. Gage, Dr. Ira Russell, of Winchendon, Dr. H. P. Wolcott, of the State Board of Health, and Dr. George F. Shrady, of New York.

In calling the assembly to order after dinner, Dr. Shattuck welcomed the members and guests to the Eighty-third Annual Dinner. The Society has fairly begun on its second century of work, and there is reason to hope that it may prosper even more than during the first. He then introduced Dr. Homans, the new President.

Dr. Homans responded briefly. He stated that in 1879 there were but sixty-eight members of the Society against one thousand five hundred and twenty in 1884. This was certainly a wonderfully gratifying increase. There had been ninety-four new members added during the present year. Dr. Homans alluded to the action of the Society in admitting women, and remarked that perhaps twenty or thirty years hence the present scene might be a ball-room.

Dr. Alfred Homser, of Watertown, retiring President of the Society, spoke of the value of the new Code of Ethics last established by the Society. On every Fellow of the Society owes to the profession, to the Society, and to himself. No one could become a physician deserving the name unless he first was a man.

Governor Robinson on being introduced spoke of the intimate relation of the State to public health and
State medicine so called. Everyone can contribute to our knowledge of this subject, which is of the most vital importance. He referred to the present system of expert witnesses, and suggested that if paid by the State it would be a better system. He spoke of the appointment of medical examiners that he must make in a few days, and expressed his desire to appoint the men best fitted. The Governor then congratulated the Society on its action of the day before in admitting women, and wished that the next century should be as useful as the last.

After listening to remarks by Rev. Fred. Courtney, Mr. Justice Field, Dr. John Crowell, Dr. Samuel Eliot, and Professor W. T. Sedgwick, of the Massachusetts Institute of Technology, the meeting adjourned.

WEDNESDAY, JUNE 11TH.—SECOND DAY.

KENTUCKY STATE MEDICAL SOCIETY.

Twenty-ninth Annual Meeting, held at Bowling Green, June 3, 4, and 5, 1884.

(Special Report for The Medical Record.)

TUESDAY, JUNE 3D—FIRST DAY.

The Society was called to order at two o'clock P.M., by the President, Dr. J. N. McCormack, of Bowling Green, who introduced Dr. T. J. Townsend, the Chairman of the Committee of Arrangements. Dr. Townsend in behalf of the President, introduced the Hon. G. U. McElroy in behalf of the people, welcomed the Society to the city. The President then delivered the annual address.

Dr. A. Morgan Vance, of Louisville, read a paper upon "Local Anesthesia by the Ether Spray," and demonstrated the method as applied in his hands. He claimed that the best application of this method is not to carry the spray to the point of contact of the tissues, but to operate at the moment of application, following with the knife the spray as it touches and obtunds the surface. He detailed a number of operations in which this plan had been observed, and in every instance the patient escaped pain and shock. The instances cited were tenotomy, excision of fibrous tumor of foot, and enucleation of eyeball. He deemed it of the utmost importance that the spray be applied by an assistant so directed by the operator that the line of incision be instantly consequent upon the touch of the spray.

Dr. J. P. Thomas, of Pembroke, made the annual report on "Materia Medica and Therapeutics," which was for the most part devoted to a consideration of penicillin. In the discussion which followed, Dr. Stone, of the Western Lunatic Asylum, gave the result of his observations upon the comparative merits of various hypnotics in treating the sleeplessness of the insane. After commending the use of choral hydrate and the bromides in various conditions, he claimed that opium is superior to all other agents for this species of insomnia. He recommends its use in small doses frequently repeated.

Dr. R. Maupin Ferguson, of Louisville, read a paper on "Glaucoma." After detailing the most advanced views as to the nature of this affection, he gave an interesting account of the methods of treatment as recently observed by him in London, Paris, Berlin, and Vienna.

At an evening session of the Society, Dr. J. W. Holland, of Louisville, read a paper upon the "Cause of Consumption," giving a detailed account of modern pathological investigation into the origin and nature of tubercle. The paper was discussed by the Society.

WEDNESDAY, JUNE 4TH.—SECOND DAY.

After the transaction of miscellaneous business, Dr. L. S. McMurtry, of Danville, made the annual report upon the "Progress of Surgery." This paper was devoted
to a study of the comparative safety and value of the anesthetics used in surgical practice, and to recent improvements in abdominal surgery. The speaker gave in résumé the results of experimental investigation into the comparative safety of the several anesthetic agents in common use, and described the method and results of etherization by the rectum, as recently practised in France and America. He believed this method exceptional in applicability and dangerous, yet deserving full and fair trial. Taking up the subject of wounds of the intestines, he advocated their treatment by the application of the advanced principles of abdominal surgery. To avoid fecal extravasation and peritonitis, to control hemorrhage and prevent septicemia, the abdomen should be opened, the wound of the intestine closed with sutures, and the abdomen then resutured carefully. The greater portion of the report was devoted to the diagnosis of abdominal tumors, the speaker giving illustrative cases from practice.

This paper was discussed by Dr. D. W. Yandell, Dr. A. Morgan Vance, and others.

Dr. Stone, of the Western Lunatic Asylum, made a written communication on a case in which pregnancy was mistaken for an ovarian tumor.

Dr. J. M. Harwood, of Shelbyville, read a report on "Epidemics."

Dr. Pinckney Thompson, of Henderson, opened a discussion on the "Treatment of Typhoid Fever," with a paper, which elicited remarks from Drs. Wm. Bailey, J. L. Larrabee, and D. W. Yandell, of Louisville, and others.

Dr. W. M. Fuqua, of Hopkinsville, read a paper entitled "Civilization and Sanitation," and Dr. A. W. Johnson, of Danville, on "Bigelow's Operation."

Dr. Dudley S. Reynolds, of Louisville, made a clinical report upon "Iritis; its Etiology, Pathology, and Treatment," and discussed the subject with special reference to the early recognition and treatment of the disease on the part of general practitioners, and the prompt application of essential remedies.

Dr. Wm. Cheatham reported a series of cases of catarrh, with remarks upon the operation.

Dr. T. D. Finck, of Louisville, read a paper on "Phlyctenular Conjunctivitis," which was discussed by Dr. Reynolds and others.

THURSDAY, JUNE 5TH—THIRD DAY.

Dr. J. W. Holland, of Louisville, read a paper on "Diphtheritic Paralysis."

Dr. J. M. Mathews, of Louisville, made some remarks upon hemorrhoids, with special reference to operation during the inflammatory state. He reported a series of cases from his own practice, in which the operation for radical cure was performed while in a state of acute inflammation, with most satisfactory results. At the suggestion of the President he discussed the comparative value of the ligation and injections of carbolic acid and other agents in the treatment of hemorrhoids, and gave preference to the ligature.

Dr. A. Morgan Vance, of Louisville, read a paper on "Tetanus in Childhood.

Dr. W. M. Fuqua, of Hopkinsville, offered the following, which was adopted:

Resolved, That whatever measures shall be proposed by this committee shall be submitted to this Society, in its next meeting for discussion, revision, or stricture, and if, upon a majority vote, this proposed enactment be passed, then it shall become the duty of this committee, together with the President of this Society, to present a suitable bill to the Legislature of Kentucky and urge its enactment.

The President then appointed the following standing committees: Practice of Medicine—Dr. William Bailey; General Surgery—Dr. J. M. Mathews; Orthopaedic Surgery—Dr. A. M. Vance; Abdominal Surgery—J. H. Letcher; Surgery of the Genito-urinary Organs—Dr. A. W. Johnston; Gynecology—Dr. L. S. McMurtry; Obstetrics—Dr. Andrew Sargeant; Ophthalmology—Dr. D. S. Reynolds; Otology—Dr. William Cheatham; State Medicine—Dr. J. W. Holland; Vital Statistics—Dr. J. W. Harwood; Materia Medica—Dr. T. J. Townsend; Pharmacy—Dr. J. F. Thomas; Susceptibility of the Infective Diseases—Dr. J. G. A. Stewart; Infecciones of Children—Dr. J. A. Larabee; Necrology—Dr. L. B. Todd.

Drs. W. M. Fuqua, J. F. McElroy, and T. D. Fink, of Louisville, were appointed delegates to the International Medical Congress of Copenhagen.

Dr. L. S. McMurtry, of Danville, Chairman of the Committee on the Prize in Surgery, made a report, stating that the condition of the treasury was not equal at the close of the last annual meeting to the constitutional provisions for offering a prize, and hence no advertisement had been made by the committee. He then moved that the Society subscribe through the Secretary, and in the name of the Society, the sum of one hundred dollars to the Sims Memorial Fund. This motion was unanimously adopted.

The following officers were elected: President—Dr. Pinckney Thompson, of Henderson; Senior Vice-President—Dr. O. D. Todd, of Eminence; Junior Vice-President—Dr. L. S. McMurtry, of Danville; Secretary—Dr. S. M. Letcher, of Richmond; Assistant Secretary—Dr. F. Dunlap, of Danville; Treasurer—Dr. Edward Alcorn, of Hustonville; Board of Censors—Dr. Dudley S. Reynolds, of Louisville, chairman; Dr. James H. Letcher, of Henderson, secretary; Dr. A. Sargeant, of Hopkinsville; Dr. R. F. Floyd, of Lebanon; Dr. J. M. Harwood, of Shelbyville; Dr. R. C. McCord, of Lebanon.

The Society adjourned to hold the next annual session at Crab Orchard Springs.

MAINE MEDICAL ASSOCIATION.

The Thirty-second Annual Meeting held at Portland, Me., June 10 and 11, 1884.

(By Telegraph to THE MEDICAL RECORD.)

TUESDAY, JUNE 10TH—FIRST DAY—MORNING SESSION.

The meeting was called to order in the Common Council chamber, City Hall, the President, Dr. Oren A. Hoit, of Lewiston, occupying the chair.

Prayer was offered by the Rev. John A. Bellows, of the Park Street Unitarian Church.

The reading of the records of the last meeting was omitted. The printed volume of Transactions had been distributed to the members.

The Treasurer, Dr. Aug. S. Thayer, of Portland, presented his report, which showed the Society to be in a prosperous financial condition.

The report of the visitors to

THE MEDICAL SCHOOL OF MAINE,

at Brunswick, was made by Dr. Sumner Laughton, of Bangor. Ninety-nine students were in attendance during
the term which has just closed, and one-third of these received the doctor’s degree, after passing a severe examination. The teaching was stated to be sound and eminently practical. The amount of clinical material is much greater than can be satisfactorily exhibited to the class. The school is worthy of the entire confidence of the profession of the State.

Dr. S. F. Warren, of Portland, reported a case of acute pulmonary edema in labor, with death from heart-cot—a very rare complication of parturition; and a case of labor at seven months, complicated by subserous, intramural and submucous fibroid tumor, eclampsia, sloughing of fibroids, septicemia, and death. The subjects thus introduced were discussed by a number of members.

First Day—Afternoon Session.

Dr. How, of Newburyport, and Dr. Nichols, of Cambridge, delegates from the Massachusetts Medical Society, were welcomed and invited to participate in the scientific discussions.

President Horr then delivered his inaugural address.

He reviewed the principal features of the first decade of the life of the Association, calling attention to the efforts for the elevation of the profession which were made by the founders of the Society, most of whom are dead, and showing that their successors owe them deep gratitude. Numerous recommendations were made for the improvement of the Association and the benefit of the community and the profession, particular emphasis being laid on the necessity of obtaining legislation for the registration of practitioners of medicine and surgery. The desirability of having the Medical School of Maine removed from Brunswick to Portland was also enforced.

Dr. Frederick H. Gerrish, of Portland, read a paper on the recording of cases, insisting upon the importance of keeping complete records of all cases, and recommending the envelope system, in which the notes are made at the bedside of the patient, and preserved without copying. The chief merit of the plan is that it is so easy of performance that one is induced to pursue it who would shrink from the labor of writing out an account of the day’s work every night.

Dr. Gerrish also read some notes on etherization, the result of the observation of a large number of cases. He had found that ninety grains of bromide of sodium, administered during the twenty-four hours just preceding the etherization, furnish a considerable protection against vomiting, a point of importance in abdominal and ophthalmic surgery; but that the time required to anesthetize is considerably increased by this medication.

Dr. Hampton E. Hill, of Saco, reported six ovariotomies, with five recoveries. The cases were all difficult, being complicated with adhesions and otherwise.

First Day—Evening Session.

Dr. Daniel O. King, of Pontiac, was introduced as the delegate from the Rhode Island Medical Society.

Dr. Stephen H. Weeks, of Portland, reported a case of phosphorus necrosis of the inferior maxillary bone, on which he had operated by removing more than half the bone. The specimen was shown, and also the patient, who is already getting a somewhat serviceable jaw, though but a few months have elapsed since the surgical procedure.

Dr. Weeks also reported a case of Tait’s operation.

The patient recovered, and was saved from insanity by the operation.

Dr. S. C. Gordon, of Portland, reported four cases of Tait’s operation which have recovered and have experienced much benefit from the operation. A fifth case is now recovering from the operation.

Dr. S. Laughton, of Bangor, read an essay on micro-organisms, their pathogenic relations. The discussion which ensued was participated in by Drs. Dana, Smith, Fuller, and others.

Wednesday, June 11th—Second Day.

The committee to whom was referred the revision of the by-laws reported that no revision was necessary.

A paper on the induction of premature labor in a case of albuminuric ketinitis was presented, the obstetrical portion by Dr. Sarah Ellen Palmer, of Portland, in whose practice the case occurred, and the ophthalmic portion by Dr. James A. Felling, who was called in consultation. The patient recovered her sight, which was almost destroyed by the disease. The necessity of an ophthalmoscopic examination of the eyes in all cases of pregnancy was insisted upon.

Dr. Charles W. Bray, of Portland, reported a fatal case of apoplexy in a girl of fifteen years.

Miscellaneous Cases.

Dr. J. A. Donovan, of Lewiston, reported three cases. The first patient was a boy who had suffered at one time fracture of one parietal bone, comminuted fracture of the left femur, and compound lower epiphyseal fracture of the right femur. A large piece of the right femur just above the epiphysis was removed. The patient, who walks very well, was shown. The second case was one of fatal meningial inflammation of the brain originating in chronic non-suppurative inflammation of the middle ear, and the third one of tumor of the kidney.

Professor Alfred Mitchell, of Brunswick, read a paper on the “Treatment of the Perineum in Labor.” An animated discussion followed, participated in by many members.

Second Day—Afternoon Session.

The committee to whom was referred the suggestions in the President’s address reported, recommending that a committee be appointed to confer with the trustees of Bowdoin College and urge the removal of the Medical School of Maine from Brunswick to Portland. The report was accepted, and Drs. M. C. Wedgwood, of Lewiston, J. B. Walker, of Thomaston, and F. C. Thayer, of Waterville, were appointed as the committee.

Officers elected.

The following officers were elected for the ensuing year: President—Thomas A. Foster, Portland; First Vice-President—Summer Laughton, Bangor; Second Vice-President—Abiah Libby, Richmond; Corresponding Secretary—S. W. Johnson, Belfast; Censors—George H. Cummings, Portland; B. F. Sturgis, Auburn; E. Adams, Litchfield; H. E. Hill, Saco, and A. L. Hersey, Oxford;
Recording Secretary, ex-officio—C. O. Hunt, Portland; Publication Committee—C. A. Packard, Bath; C. G. Adams, Portland; J. O. Webster, Augusta; Business Committee—J. E. Kimball and C. D. Smith; Recording Secretary—Charles D. Smith, Portland; Treasurer—A. S. Thayer, Portland.

Dr. A. L. Hershey, of Oxford, pronounced

THE ANNUAL ORATION.

He dwelt at length on the general subject of the etiology of disease, argued for greater diffusion of sanitary knowledge, and declared his conviction that the greatest hindrance to the elevation of the standard of medical education was the encouragement given to incompetent students by individual practitioners. The medical schools are not as much to blame as the profession at large.

Voluntary papers were read by Drs. Cammell and Crandall, of Portland.

THE COMMITTEE ON NECROLOGY reported the death of four members during the past year, namely: Drs. John Taylor Gilman and J. S. Goodwin, of Portland, William Swazy, of Limerick, and C. W. Whitmore, of Gardiner.

SECOND DAY—EVENING SESSION.

A case of monocular diplopia was reported by Dr. Stephen H. Weeks, of Portland; and Dr. J. A. Spalding, of Portland, who had seen the patient in consultation, read brief accounts of the cases which he had been able to find in the literature of the subject.

Dr. Israël T. Dana, of Portland, made some extended remarks on doubtful cases of typhoid fever, which were succeeded by a long and interesting discussion.

THURSDAY, JUNE 5TH—THIRD DAY—MORNING SESSION.

Dr. Alonzo Garcelon, of Lewiston, as delegate to the American Medical Association, gave an account of the meeting in Washington. He reported that many gentlemen from various sections of the country had expressed

A DESIRE TO HAVE THE NATIONAL ASSOCIATION MEET IN PORTLAND,

and he suggested that this Society consider the feasibility of extending an invitation for 1886.

On motion of Dr. Weeks, of Portland, it was voted that a committee of five be appointed to consider the propriety of extending an invitation, through our delegates, to the American Medical Association to hold its meeting in Portland. The same committee was also directed to have power to act after conference with the President and Chairman of the Board of Censors.

Dr. Weeks and Gerrish, of Portland, A. J. Fuller, of Bath, Laughton, of Bangor, and Garcelon, of Lewiston, were constituted such committee, with power to add to their number at discretion. The sentiment of the Association was strongly in favor of the movement. Portland has ample facilities for accommodating the Association in every way, and is so situated with reference to popular summer resorts as to offer extraordinary attractions to physicians from other parts of the Union.

The Board of Censors made their annual report. In addition to many details of small general interest, it appointed Dr. S. H. Weeks, of Portland, orator for the next meeting. Also delegates to other medical societies, and fifteen members to report on various subjects.

RESOLUTIONS WERE PASSED EXPRESSING SATISFACTION AT THE ENERGY OF THE DIRECTORS OF THE MAINE GENERAL HOSPITAL IN THE MATTER OF ERECTING AN OPERATING AMPHITHEATRE.

By a rising vote the Association unanimously adopted resolutions of respect to the memory of Dr. John Taylor Gilman, of Portland.

Dr. F. H. Gerrish, of Portland, was appointed chairman of the committee to secure legislation establishing a State Board of Health. The usual resolutions of thanks were passed, and the Association, after a most successful meeting, adjourned to meet in Portland June 3, 1884.

THE MEDICAL SOCIETY OF NEW JERSEY.

One Hundred and Eighteenth Annual Meeting, held a Cape May, N. J., June 10 and 11, 1884. (Special Report for The Medical Record.)

TUESDAY, JUNE 10TH—FIRST DAY.

The meeting of 1884 was called to order in the Stockton Hotel, on Tuesday, June roth, at 4 P.M., by Stephen Wickers, M.D., of Orange, N. J., President in the chair. After prayer by Rev. G. F. Bishop, of Cape May, the Committee on Organization reported the number of delegates present.

ENTERTAINMENTS.

Dr. H. Genet Taylor, Chairman of the Committee of Arrangements, stated that the prominent citizens and cottagers had generously responded and offered a banquet, to be given at the Hotel Lafayette on the evening of June roth, to be followed by a hop at the New Columbia Life-saving Service. The West Jersey Railroad manifested their liberality by placing at the disposal of the Society a complimentary train from Camden to Cape May and return. The

ADDRESS OF WELCOME on behalf of the county of Cape May was tendered by Dr. James McRary. He stated that since 1876, the date of our last meeting at Cape May, a destructive conflagration destroyed all of the largest hotels except the Stockton. But Cape May had risen from its ashes, and now has as fine hotels as can be seen in any watering place in the world. Its sewer system is laid in almost every street, having a sufficient fall to quickly carry all effete matter far away from the town, thus giving such a sanitary condition that the mortality of both city and county is the lowest of any in the State. The water-supply of the town is in excellent condition, furnishing about one million gallons daily, and distributed through all the most thickly settled portions of the town, giving an abundant supply of excellent potable water from the very bowels of the earth and stored in three large tanks. From these it is distributed through mains to every part of the city. To a city having these and many other advantages he gave us a most cordial welcome. He was followed by Hon. F. G. Melvin, Mayor of Cape May, who in a very happy manner expressed the satisfaction it gave him to welcome the Society to the city.

The minutes of the last annual meeting were then read and adopted.

The committee appointed to examine

THE ACCOUNTS OF THE TREASURER reported as follows: Total receipts from 1874 to 1883, $12,721.38; total disbursements from 1874 to 1883, $10,627.16; balance on hand, $1,644.22; assets, $1,550 which in U. S. four per cent. bonds, and a balance of $182.81 remaining in the Newark Savings Institution and $88.99 in hands of Treasurer.

REPORTS OF DELEGATES TO OTHER STATE SOCIETIES.

Dr. D. C. English, delegate to the Connecticut State Medical Society, reported a very interesting session held at New Haven.

Dr. Benjamin also reported that as delegate to the Pennsylvania State Medical Society he was deeply interested in the Society's proceedings.
The Standing Committee, acting as a Committee on Medical Ethics, reported in the case of appeal of Dr. Warman, from the Mercer County Medical Society, that there is no ground for appeal.

PRELIMINARY STUDY.

The Committee on Judicial Business then presented the following:

Resolved. That this Society approve and adopt the recommendations of the special committee on the curriculum of the preparation to be required by persons contemplating the study of medicine in this State, as contained in the report presented at the last meeting of the Society. That to carry out the recommendations of said report, regard to a censorship, as therein contemplated, the Society is of opinion that two Boards of Censors be appointed, consisting each of five members of this Society, one for the northern and one for the southern part of the State, to whom should be presented for approval the credentials of all persons proposing the study of medicine, and in case of the insufficiency of such credentials to cause the applicant to be rejected. The branches of science and learning indicated in the report of the committee. That the Standing Committee prepare and report to the Society, for its adoption, such amendments to its by-laws as are necessary to carry out the plan and recommendations of the committee. That the Corresponding Secretary communicate the action of this Society to the different medical societies in this State, with instructions to adopt such regulations as shall effectively secure the observance of the measures adopted by this Society in their several localities. That the Corresponding Secretary communicate the action of this Society on the subject to the State medical societies of the several commonwealths of the Union, and respectfully request that the State societies elevate the standard of medical education throughout the country.

Dr. E. M. Hunt spoke in favor of the resolution, and Dr. Benjamin opposed it on the ground that it failed to express the aim of those who favored a very high standard of medical excellence on the part of those who are to enter the profession. It was finally decided to defer consideration of the resolution till the following morning.

Adjourned till 7,30 P.M.

FIRST DAY—Evening Session.

On motion the REASON OF THE CORRESPONDING SECRETARY (Dr. Elmer) was first listened to. He stated that 'Transactions' had been received from the following State medical societies: Maine, New Hampshire, Massachusetts, Connecticut, Pennsylvania, Delaware, Maryland, Virginia, South Carolina, Georgia, Mississippi, Louisiana, Texas, Tennessee, Ohio, Indiana, Illinois, Michigan, Wisconsin, Minnesota, Arkansas, Colorado, California, and Oregon. Also from the New York Academy of Medicine, and from the College of Physicians and Surgeons of Philadelphia. A copy of the report on "Preliminary Education" as presented by the committee, Drs. Pennington, Elmer, Jr., and Rogers, at the last meeting of the Society, was forwarded to the American Medical Association at its recent session in Washington. No special action was taken upon it.

The President then read his address on LIVING AND DYING, THEIR PHYSICS AND PSYCHICS. He said that life is an infinite mystery. The genesis of life is obscure only to the theophobe and agnostic. It is written with the pen of iron and with the point of a diamond in the rock forever. Man in his normal state when created and before he fell was deathless. His physical constitution was complete and its vital functions perfect, without liability to pain or sickness, and it may be to anything we call decay. It is only from the days of the flood that the lives of men in general have been reduced to their present limits. Before the flood men retained health and vigor of body through many centuries, and as far as we know sickness was unknown! Buffon says that one hundred years is the period Providence has allotted to man. Haller has collected one thousand instances of persons who have reached the age of one from one hundred to one hundred and ten years.

Roger Bacon says that every man would be able to remedy his own decay if he would subject his health, from youth up, to a complete regimen, embracing food, drink, sleep, waking, motion, rest, evacuation, construction, climate, and habit of mind. For if any one would follow these rules from birth, he would live as long as that nature derived from his parents would permit. The fixed law which regulates the number of our years is that in the animal economy the duration of life is regulated by the duration of growth.

Fluorins claims that a man lives five times his period of growth; therefore, if the period of growth be twenty years he will live five times twenty years, or one hundred years. The doctor then spoke of the signs of impending dissolution, showing also how the mind may be so influenced by excitement and indigence as to be unaffected by dangerous exposure. In concluding, he said that when a man, in addition to his scientific attainments, cherishes a devout and abiding purpose to meet the claim of the God of nature upon his reverent personal service, he meets the claims of his profession, does good in his day, and commands the loving respect of his fellowmen. When such a life is finished its memory is blessed.

WEDNESDAY, JUNE 11TH—Second Day.

The first order of business was a consideration of the resolutions of the special committee on the CURRICULUM OF THE PREPARATION TO BE REQUIRED BY PERSONS CONTEMPLATING THE STUDY OF MEDICINE IN NEW JERSEY.

Dr. E. M. Hunt urged their adoption. Dr. Kipp was opposed, stating that there already existed provision for the same object. Dr. Godfrey favored their adoption.

Dr. Welch spoke at length, stating that the medical profession of to-day is much in advance of the point reached one hundred years ago. It is therefore a mistake to be too stringent in the matter of fixing a medical standard higher than that already established by the best colleges. Dr. Watson stated that medical literature shows a decided advance in medical knowledge since one hundred years ago. Dr. E. M. Hunt then moved the consideration of the resolutions seriatim. Carried.

The first resolution was read and adopted. The second resolution was amended by Dr. E. M. Hunt, by the insertion of a Standing Committee to be appointed each year, and the resolution as amended was adopted. The third and fourth resolutions were adopted. The fifth resolution was amended by the substitution of "State" for "Commonwealth" and adopted. The resolutions were then adopted as a whole.

THE REPORT OF THE STANDING COMMITTEE was then given by Dr. T. J. Smith. He stated that there had been MUCH LESS SICKNESS AND FEWER DEATHS IN THE STATE THAN FOR MANY YEARS.

It was also recommended to give much larger doses of quinine in malarial fever than are now employed. The report on medical jurisprudence was by con-
sent made by Dr. Garrison. The report urged the necessity of having

EXPERT WITNESSES

recognized as such in the eye of the law, and to have such compensation made as was deemed just by the judge in a given case. It also urged that expert witnesses be employed by special selection.

Dr. E. M. Hunt offered the following resolution in this connection:

Resolved, That this Society recognize the importance of some legislation as to the best modes of securing expert witnesses. Adopted.

Dr. Benjamin moved that the report be referred to a committee of five, and that they report any modification at the next annual meeting. Not carried.

Dr. Hunt moved that the matter be referred back to the original committee, and that they, in co-operation with the Standing Committee of the Society, make such changes as they deem best, present the bill to the Legislature, and urge its acceptance.

The report of the COMMITTEE ON THE ARMY MEDICAL MUSEUM

and Library of the Surgeon-General's office was then presented by Dr. B. A. Watson. He stated that a fireproof building was much needed for the Army Medical Museum, and also urged that the State Medical Society of New Jersey present to Congress a request that the Library and Museum be suitably cared for and protected by an annual appropriation.

Dr. Parrish gave the report on lunacy, saying that the FACILITIES FOR THE CAREFUL STUDY OF NERVOUS DISEASES

in the majority of the insane institutions of the State are very few. The various appliances to restrain the insane are still used to some extent. It is to be hoped that these will soon become relics of the past.

Drs. T. A. Emmett and I. E. Taylor, of New York, were made honorary members.

Dr. C. J. Kipp then read an essay ON THE PREVENTION AND TREATMENT OF PURULENT CONJUNCTIVIS.

He said that the most frequently observed and most important variety of the disease is the purulent ophthalmia of the new-born. The prevailing idea that the disease is produced by the diphtheria bacillus is not correct, and that in many cases, at least, the disease can be prevented by the employment of prophylactic measures. In 1854 Wm. Mackenzie wrote as follows on this subject: There is reason to believe that the disease is not infrequently an inoculation of the conjunctiva by leucorrhoeal fluid during parturition, and therefore it might often be prevented by the use of injections of tepid water or a weak alkaline solution into the vagina in the first and second stages of parturition, and by carefully washing the eyes of the infant as soon as it is removed from the mother. The former precaution is scarcely ever, and the latter too seldom, attended to. He urged the necessity of every practitioner acquainting himself beforehand with the fact whether the mother is affected with any vaginal discharge. If the vaginal discharge is not removed, or if on the child being born nothing is done to it for perhaps half an hour or longer, every chance is given for inoculation of the eyes. It generally follows that when the child becomes affected with this ophthalmia, the mother had leucorrhoea or gonorrhoea, and that the eyes were not cleaned for some time after birth.

Alfred Graefe recommends irrigation of the everted lids with a two per cent. solution of carbolic acid immediately after birth. He also advises that the lids and surrounding parts be thoroughly cleansed with the same solution, and that, if possible, a compress wet with the solution be left constantly on the lids between the irriga-

tion in all cases where the mother is known to have a vaginal villenorrhoea.

Credé has for years used a drop of a two per cent. solution of nitrate of silver in the eyes of all children born in hospital under his charge, and it is claimed that since this treatment was adopted only four cases of purulent ophthalmia have developed.

Dr. Kipp, however, does not favor the use of the carbolic acid and nitrate of silver solution, as they are too irritating and may do more harm than good. He thinks it better practice to carefully wipe from the eyelids any vaginal secretion which may adhere to them, and to wash out the conjunctival sac with plenty of clean tepid water. In England and other parts of Europe measures looking to the dissemination among the people of knowledge regarding the cause of the ophthalmia of the new-born, and the means to be resorted to for its prevention, have lately been under discussion in medical societies, and steps have been taken to distribute among all classes of society cards of instruction drawn up in the simplest possible language. The same might be done here by our State Board of Health, which has already done so much to enlighten the people with regard to the causes and prevention of disease. Dr. Kipp emphasized the importance of instructing the attendant of the patient with reference to the contagiousness of the discharge from the eyes, in order that proper care should be observed not to spread the disease.

In speaking of the treatment the doctor says that the disease varies considerably in severity, the difference probably depending upon the quality and quantity of virus introduced into the eyes. He recommends: 1. Cleanliness, as in this way all discharge is removed and the parts have a chance to heal. Of 156 cases of ophthalmia neonatorum treated by Dr. Kipp, the cornea was damaged in 38, or 24.3 per cent. Briefly stated his treatment is as follows: Scrupulous cleanliness, the application of cold to the lids in the early stage, and the application of the nitrate of silver to the conjunctiva during the pyrocystic stage. a. During the first few days of the disease, while the lids are hot and shining, the conjunctiva is tense and smooth, and the secretion consists of straw-colored water, he has found it best to do little more than to apply cold compresses to the lids, and to clear the eyes at short intervals. He prefers absorbent cotton to sponge for wiping away the discharges and for the purpose of removing the secretion from the conjunctiva. He believes that the lids should be kept slightly opened. The eyes should be opened and cleaned at least every hour. Compresses applied continuously. A reliable attendant is a great help in these cases.

When there is a very profuse discharge from the eyes, and when the conjunctivae are a good deal swollen, he uses at first a one per cent. solution of nitrate of silver, if necessary a two per cent. solution, the indication being the presence upon the conjunctiva and cornea of shreds of nerve or less firmly adherent fibrin. To apply this caustic solution it is wise to so place the child upon the lap of the nurse that you can hold the child's head face upward between your knees. In this way the head can be firmly fixed. Conical complications are most easily subdued by local delection, leeches to the temples, and application of cold to the lids.

Dr. T. G. Welch followed with an essay on "Many Drugs: Few Remedies." (The paper will be found on page 661 of the Medical Record.)

The following officers were then elected: President—P. C. Barker, M.D., Morristown, N. J.; First Vice-President—J. Parrish, M.D., Burlington, N. J.; Second Vice-President—C. J. Kipp, M.D., Newark, N. J.; Third Vice-President—J. W. Ward, M.D.; Corresponding Secretary—William Elmer, M.D., Trenton, N. J.; Recording Secretary—William Pierson, Orange, N. J.; Treasurer—W. W. L. Phillips, Trenton, N. J. Adjourned.
NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, June 5, 1884.

Fordve Barker, M.D., LL.D., President, in the Chair.

The Statistical Secretary, Dr. Francis V. White, announced the deaths of Dr. Thomas C. Chalmers and Dr. Gilbert L. Newcomb.

Dr. Alfred Mitchell, Professor of Midwifery in the Medical School of Maine, was introduced to the Academy, and invited to a seat upon the platform.

After the admission of twenty-four new Fellows The President made the following remarks on the death of the Senior ex-President,

DR. WILLARD PARKER,

and Honorary Fellow

DR. SAMUEL D. GROSS.

Having welcomed each of our new Fellows individually, I assume the privilege of congratulating both them and the Academy on this accession to its numbers and its strength, with the full conviction that the benefit will be reciprocal. We count upon our new Fellows to cooperate with zeal and earnestness in the objects of the Academy, "the cultivation of the Science of Medicine," and in furthering the work for the advancement of the character and honor of the profession, and we cannot doubt that every one who has now joined us will find their individual gain and personal advancement in this work.

But I will not detain the meeting by repeating truths which must be obvious to all, as otherwise they would not be with us. In connection with the death of two of our most eminent and distinguished Fellows, I have learned certain facts in regard to the history of our Academy, which struck me as interesting and curious.

This Academy was founded thirty-seven years ago, and the roster published in 1880 gives the names of 118 original Fellows. One hundred of this number are now dead. I find that 7 died between the ages of 80 and 90, the average of this 7 being 83; 18 died between the ages of 70 and 80, the average being 73; 47 of the number died between the ages of 55 and 70, the average being 64.5. Of eight ex-presidents, who were original Fellows, the average age at time of death was 78.5. Only two of this class died under 70, Dr. John Watson at 55, and Dr. H. D. Bulkeley at 67. Our present senior ex-president, George Peabody, reached his eighty-sixth birthday, and is still erect and mentally active, and nearly all the others of the eighteen living are, so far as I know, in vigorous health, mentally and physically, and still more or less in active professional life, and I but give expression to the sentiment of all in the prayer that they may long continue with us.

This history of the founders of the Academy seems to me remarkable, and I know not where its parallel can be found in any other class of one hundred and eighteen men, as to duration of life, who have been brought together without selection as to the probabilities of long life. There must be some explanation, which I leave for others to ascertain. I believe that it has been demonstrated that notwithstanding the hard life of medical men, their incessant toil, the frequent impossibility of regular hours for food and sleep, the burden of anxiety and responsibility as to the happiness and lives of others, their longevity as a class compares most favorably with other professions.

May we not ask whether the influence of this Academy has not been a factor in bringing about this result? The stimulus of such an association of educated men to lead an active, useful, regular, and honorable life; the incitement to constant mental and physical activity; the interchange of social feeling; the promotion of kindly sympathies and its influence in suppressing "envy, hatred, and malice, and all uncharitableness," or, in other words, in repressing all those emotions and passions which are so unfavorable to longevity, may have contributed more to this result than a careless superficial observation would suspect.

All are called upon to bear those sorrows and trials which are common to humanity. But I cannot forbear a reference to a recent loss which has befallen one of our founders, who has the high respect and warm esteem of all the profession, who has ever been an efficient friend and supporter and a faithful office-bearer of this Academy, in the death of a most promising son, who had but recently entered the profession, and lost his life by disease contracted in the performance of his duty in Bellevue Hospital. In such a sorrow it may be some consolation, slight though it be, to reflect that the death was that of a most promising young man, a graduate of the College of Medicine, and the result of an ordinary and uneventful graduate course, and the assurance that the afflicted parents have the sincere condolence of all in this Academy.

Within a few weeks the profession has lost two of the best known and most distinguished men in this country, both belonging to this Academy.

I shall not now repeat any of those biographical details which have been so generally published, but shall only refer to their connection with us and their personal qualities which seem to explain their great success and eminence in their professional lives.

Dr. Willard Parker was elected President of this Academy in 1854. At the time of his death he was the senior ex-president, and within a few months of eighty-four years of age. For many years he was the most prominent and conspicuous medical man in this city, not only as a surgeon, but as a general practitioner. With the exception of Dr. Benjamin Rush, a hundred years ago, I do not think any physician in this country ever commanded so powerful an influence over the community where he resided, both professional and public, as Dr. Parker did for many years in this city. His commanding and attractive person, his genial frank manner, his uniform cheerfulness, his practical uncommon good sense, his ease and fluency in conversation, all combined to produce a magnetic influence on those brought in contact with him. The most prominent characteristics of his professional mind were quick perception, a kind of insight which gave him an intuitive power of seeing the essential and radical features of diseases and distinguishing the incidental, or what was merely coincident or secondary. In the treatment of his cases I may say that while I do not know that he could be ranked as a great theoretical student, he was a practical man of extraordinary success, as I think he always relieved and made his patients feel that they were better. I have never known a physician who more thoroughly appreciated the influence of the morale on the physique even in improving function, or more constantly utilized this knowledge in his practice. All his patients had the benefit of the stimulating and tonic effects of cheerfulness, confidence, and hope. I may mention one illustration. Thirty-two years ago I received a note from Dr. Parker, which is still in my possession, saying that he had a call to see a patient some distance in the country. Dr. Sabine being out of town he gave a list of a few patients whom he wished me to visit. The first I found an extremely accomplished and clever lady. As I entered her room, her bed being in such a position that she could not see me, she said: "His very foot has music in 't As he comes up the stair."

I introduced myself, saying that I was saluted by a very apt quotation, but misapplied in the present case, as there was a great difference between B and P. I am certain that no one ever entered or left his consulting-room quoting from Dante’s Inferno, "Who enters here leaves hope behind."

His general and hygienic directions to patients must have been of unusual excellence. Some years ago he

1 Dr. Samuel T. Hubbard.
gave a course of lectures on health, both in this city and Brooklyn, which he called "The House we Live In," although they were meagrely and imperfectly reported in the daily papers. I well remember that I carefully read them all, and regarded them as the most sensible and useful of popular lectures on health which had appeared since the famous work of Andrew Combe.

Of his rank hereafter as a great surgeon, I am not competent to speak. Dr. Parker's life was too early and imperfectly occupied by active practice to permit him to add very largely to the literature of our profession, but many valuable papers by him were published in the medical journals. I think few can estimate the number of lives which he has been the means of saving by his paper on "Operations for Abscess of the Appendix Verminiformis." I speak of this from a sense of personal gratitude, as it led to the saving of the lives of two of my own patients.

Many notes which I have received from Dr. Parker, during the past six years, and his presence at every meeting of special interest, so long as health permitted, warrant me in saying that he kept up to the last the warmest friendship with me and with the Academy of Medicine.

Professor S. D. Gross, who, within the past month, died in the seventy-ninth year of his age, was elected a Corresponding Fellow of this Academy in 1851, and an Honorary Fellow in 1876. No man of the present age—I assert this without any qualification—has made such a reputation as a great surgical teacher and writer as he. No one of the profession in this country has ever received such honor from universities and learned societies in Europe, and in this country the profession have given him the highest honors within their gift. In regard to him the voice of envy is never heard, and I believe no one has ever whispered, so far as I ever heard, that all these honors have not been honestly earned. All this is in harmony with the rare and curious fact, that even those who had no personal acquaintance with him seemed always to speak of him with an unconscious coloring of personal regard and affection. This is probably due in a large measure to the honesty, sincerity, and integrity of purpose which stamped his personal bearing, and was conspicuous in the present day might feel proud to have never heard a disparaging remark in regard to him, either personal or professional. His industry and his ability were marvellous; the amount of work which he accomplished was monumental.

I do not believe that in medical history there can be found another instance of a man seventy-eight years of age, speaking as well as he did at the last meeting of the American Medical Association, on "Laceration of the Female Sexual Organs consequent upon Parturition." In its familiarity with all the recent literature of the subject, in its breadth of treatment, in its soundness of teaching, although in some few points many would hold different opinions, the most distinguished gynecologists of the present day might feel proud to have written it. Many may not know that one of his early works was a translation of Hatin's "Manual of Obstetrics," at this day rarely found, but I have now the honor of presenting a copy to the Academy.

The last time Dr. Gross met with us was the evening when this hall was first opened. On that morning I had received a telegram from him saying that he should be unable to be here, but he was subsequently induced by Dr. Flint to come. Dr. Acland, Regius Professor of Medicine, in his speech, alluded in warm terms to Dr. Gross as the senior graduate of Oxford. No one present at that time can forget his appearance when called up by the chair. It was evident that he had not anticipated such attention, and his face was the more touching in its effective simplicity of any made that evening. It came straight from the heart, dropping with it some valuable suggestions, as he always did when speaking.

To each of the two men—Willard Parker and Samuel D. Gross—may be applied with much greater truth than it usually is, the very trite quotation:

"He was a man, take him for all in all. I shall not look upon his like again."

Their name and fame are a part of the common inheritance of the Academy. There is no greater inducement to stimulate those who are coming after than the character and success of the great ones who preceeded, and therefore it is our privilege as well as duty to sacredly cherish their memory.

"Lives of great men all remind us.
We can make our lives sublime,
Anddeparting, leave behind us
Footsteps, to be followed by the multitudes."

Dr. E. A. Burlall, at the close of the President's remarks, offered a resolution of condolence with Dr. Samuel T. Hubbard, on the death of his son, Dr. William Hustace Hubbard, which was unanimously adopted.

Dr. R. W. Amidon then read a paper entitled

A PLEA FOR MORE HEROIC SURGICAL INTERFERENCE IN AFFECTIONS OF THE BRAIN,

in which he referred, first, to the case in which Broca trephined over the speech-centre, and greatly relieved an aphasic patient by evacuating a cerebral abscess. After referring to some of the probable reasons why cerebral surgery has not been practised more extensively and thoroughly since Broca's operation than it was before Dr. Amidon remarked that, judging from the statistics given in text-books on surgery, one was led to the conclusion that the operation was a dangerous one per se. He then reviewed the statistics published in the St. Bartholomew Hospital Reports, and offered the criticism that the rate of mortality—10.6—of the operation itself had been placed too high, because it had been based on considerations which for some time the cases treated without the beneficial influence of Listerian.

Dr. Amidon then gave an analysis of 100 published cases operated upon since 1879, and it appeared that of these the patients in 26 died; that in 23 of these there existed at the time of the operation symptoms of conditions which of themselves endangered life, thus leaving for the operation per se a mortality only three per cent., a result which should rob the operation of its terrors. The author of the paper then referred to a remarkable case in which trephining was performed at five different times for the relief of spinal symptoms, the patient remaining well after the last operation.

After alluding to the fact that the duramater is not particularly sensitive at the borders of the sinuses, and on the processes of inflammation, Dr. Amidon reviewed the cases in which it was interfered with, and although the mortality was apparently high, it was reduced to 7.6 per cent. by throwing out certain cases in which the conditions were such as to render death almost inevitable independent of operative interference with this covering of the brain.

Reference was then made to cases which illustrated how much injury the brain may receive without resulting in either death or marked permanent damage. The conclusion given was that the brain has a remarkable tolerance of injury, and a very great amount of reparative power.

Special attention was then directed to the topography of the skull, with reference to central localization, as given by Broca. After expressing his views concerning central localization, to the effect that neurologists were perfectly sure that there were certain definite regions of the brain, particularly parts of the cortex, which when irritated, compressed, or destroyed, gave rise to perfectly unmistakable symptoms—localised paralyses with localized epilepsies—Dr. Amidon gave the following conclusions concerning trephining for affections of the brain.

We have in trephining an operation proving fatal in
only three per cent. of published cases. The operation when combined with the operation of opening the dura mater has proved fatal in only 7.6 per cent. of published cases. The brain is an organ tolerant of injury and ready to take on reparative processes. We have knowledge which convinces us that certain parts of the brain are diseased, and we have anatomical data to tell us exactly where to operate to reach the location of the disease. We have, then, the element of safety and anatomical accuracy, and why should cerebral surgery be less daring than the surgery which has already successfully invaded the other important organs.

Dr. Amidon then spoke of the advantages which the dental engine possessed over the older instruments for the operation, for example, that the amount of bone removed could be limited, and the opening could be made of any desired shape, etc.

The operation should always be done under antisepctic precautions, without much compression from the flap. Use cold antisepctic dressings, with the strictest quiet subsequently, the freest possible drainage, simple diet, slightly loose condition of the bowels, jaborandi on the slightest rise of arterial tension or temperature, quinine and alcohol only in tonic doses, anodynes as indicated, never opium, but to ease pain and induce sleep. A single tablet of strychnine, one grain, every ten to fifteen minutes until the desired effect is pronounced.

Quinine and alcohol in large doses, and opium in any dose, aggravate intra-cranial inflammation, and, as he believed, might sometimes produce it. Where the dura mater and the brain are invaded, either accidentally or intentionally, these suggestions were equally important and must be strictly applicable.

Good indications for opening the skull: an injury of the vault, however slight the marks of external violence, provided there be coma, aphasia, hemiplegia, or hemi-spasms of the lower part of the face, of the arm, or leg, or all three, constituting hemileptics, whether accompanied or not by chills, fever, headache, and vomiting. General epileptic convulsions do not constitute so good indications for operation. Cases where, after the lapse of months, or years even, unmistakable cerebral symptoms follow an injury to the head—atrocious and incurable headaches, particularly if localized; aphasia, monophasias, or monospasm; hemiplegia or hemileptics. Seizures or general epileptic attacks, if they have an spasmodic character.

In compound fracture of the skull, whether the depression was visible or not, or whether or not there were cerebral symptoms, trephining was indicated. The dura mater should be opened when the hypodermic needle revealed the products of purulent inflammation or fluid blood beneath it.

Penetrating wounds of the substance of the brain, the presence of foreign bodies, hidden collections of pus, indicate trephining and search with fine dull instruments.

Finally, accessible neoplasm of the brain, which has resisted medical treatment and threatens life, should be excised, for the reason that it is usually single, seldom is followed by secondary deposits, is surrounded by a zone of inflammatory demarkation, and always kills by pressure.

Dr. J. P. Garrish related a case of traumatic epilepsy in which, five years after the original injury, he trephined, removed a depressed portion of bone, and cured the patient. He had trephined five epileptics and effected a cure in each case. He also referred to the case of a soldier who, fifty years after the battle of Antietam, in a state of unconsciousness with a depressed portion of the skull. He trephined the man at once, who opened his eyes immediately after the pressure from the bone was removed, and the soldier recovered completely.

Dr. M. John Robertson spoke of the advantages which the electrical trephine possessed over the dental engine, especially with reference to the size of the opening which each was capable of making; also of the advantage it had over the old instruments, in the use of which tactile sensibility was substantially abolished.

Dr. H. D. Noyes referred to two cases which had been under his care, one of which had been mentioned previously, and then there ensued a rise of temperature, with acceleration of pulse, but the patient ultimately recovered. He thought it had been in the minds of surgeons for a long time to undertake cerebral surgery, but the lack of ability to make an unquestionable diagnosis and the absence of definite indications had deterred them from resorting to these serious operative procedures.

It had been suggested by Dr. Amidon that in his (Dr. Noyes') last case the administration of large doses of quinine had probably developed a meningitis that caused the patient's death, and he would ask if there was a general concurrence in the view that the use of quinine and alcoholic stimulants mitigated against the patient's chances of recovery.

Dr. L. Putzel had made many autopsies after injuries of the skull with hemorrhage under the dura mater, and it had occurred to him that in some of them, at least, chances of life might have been afforded by trephining.

The statistics, however, which Dr. Amidon had given were open to the criticism to which all new statistics were liable, and that was that only the favorable cases, or the great pain, were reported.

Concerning localization, he must differ with the author of the paper, and believed that not very much was positively known concerning cerebral localization. To be sure, it was well known that certain cerebral areas presided over certain functions, but we cannot tell positively that a lesion is situated in that region. Besides, there are many cases in which the symptoms are not what they should be, according to our present knowledge, to enable us to decide positively concerning the exact situation of the lesion. We know positively only with regard to motor centres.

Dr. Putzel believed with Dr. Noyes, that the question of certainty is recognized less and the key-note of the whole subject, and that before serious cutting operations involving the contents of the cranial cavity were undertaken, our means of diagnosis must be further advanced than they now are. With regard to quinine and alcohol, he thought it had not been positively decided that it was improper to administer them in such cases as had been mentioned. With reference to the administration of ten to fifteen grains of hydrate of chloral every ten to fifteen minutes, as recommended by Dr. Amidon, he should object, as he believed there was a very great liability that the combined effect of two or three doses might kill the patient.

Dr. Amidon, in closing the discussion, said concerning quinine that he agreed with Dr. Putzel and Dr. Noyes, that it was not definitely proven that the remedy could develop meningitis; but in the case which was under his observation, and which he had cited, there were symptoms which were usually regarded as those pointing strongly toward meningitis, but which disappeared with the discontinuance of the quinine, and at the autopsy, made no appearance.

Finally, he said that after that case, there were no evidences that the patient had had tubercular meningitis from which he had recovered.

With reference to cerebral localization, all he had claimed was included in what he had read, and which he would read again; that is, neurologists are perfectly sure that there are certain definite regions of the brain, principally portions of the cortex, which, when irritated, compressed, or destroyed, give rise to perfectly unmistakable. 
ble symptoms, localized paralyses with localized, epilepties.

PUBLIC PARKS OF THE CITY OF NEW YORK.

Dr. F. A. Castle made a few introductory remarks, and then offered the following resolution, which was unanimously adopted:

Whereas, A bill is now before his Excellency Governor Cleveland, for an improvement, which provides for the laying out of a number of parks in the upper part of the city and adjacent territory; and

Whereas, The health of a city's population is vastly improved by the number and size of its open areas; therefore,

Resolved, That it is the sense of this meeting that the plan sanctioned by the Legislature should meet with the approval of Governor Cleveland.

On motion the by-laws were suspended, and the Academy adjourned to meet on the first Thursday in October.

Correspondence.

OUR PARIS LETTER.
(From our Special Correspondent.)

PASTEUR'S INVESTIGATIONS IN HYDROPHOBIA—THE DEATH OF PROFESSOR WURTZ.

Paris, May 23, 1884.

M. Pasteur, persevering in his researches which he commenced four years ago to discover a remedy against rabies, believes that his efforts have been crowned with success, and submitted the results of his experiments to the Academy of Sciences at its meeting on Monday last. Fully impressed with the belief that every virus is so attenuated or modified by a single inoculation as to render an animal so inoculated insusceptible for an indefinite period to the effects of subsequent inoculations, as in the case of vaccination and small-pox, directed his efforts toward other virulent affections.

In his culture of the rabid virus, M. Pasteur observed that it lost its strength in certain animals, and became more violent in others. In the rabbit, for instance, the intensity of the virus is increased, in the monkey it is considerably attenuated. He then proceeded to demonstrate his mode of preparing the virus, and to illustrate the results, which may be summed up as follows: He inoculated a monkey with the virus extracted from the brain of a dog that died from rabies; the monkey died. He inoculated a second monkey with the virus taken from the first, and then a third with the virus from the second. After the third inoculation he obtained a virus almost completely attenuated. With this virus, which he inoculated into a rabbit; the intensity of the virus was slightly increased. He then inoculated a second rabbit from the first, and the virus was still more intensified. From this he inoculated a third and a fourth rabbit, until it reached its maximum intensity. By this means he obtained virus of degrees varying in intensity, just in the same way as he obtained, in chemical media, the microbe of charbon more or less noxious. With the rabid virus, however, the microbe of which is still unknown, but the existence of which is for M. Pasteur certain, was cultivated through the medium of animals, each presenting a different aptitude to contract and sustain the malady.

Having thus cultivated the virus, M. Pasteur asserts that by inoculating any animal, or even man, with the virus, the subject so inoculated may be preserved from rabies, or even cured of the affection. The following is the manner in which he proceeds: He inoculates a dog with the three degrees of virus taken from inoculated rabbits in starting from the weakest degree, passing on to the next, until he reaches, after a few days, the maximum degree of intensity. If after this he inoculates the dog so treated with the virus of any other rabid dog, it does not get affected; it is insusceptible to the malady. Any other animal not submitted to this treatment succumbs, on the contrary, after the usual time. In pushing his experiments still further, and by way of comparison, M. Pasteur inoculates two dogs with the rabid virus. He leaves one to itself; after a lapse of seven or eight days, sometimes more, sometimes less, the dog becomes rabid, which assumes either the furious or the paralytic form. M. Pasteur inoculates the other dog, twice successively, with the attenuated virus of different degrees, passing from the weakest to the strongest, and before the termination of the primary incubation, that is to say after eleven days, this dog was taped, or rather it did not get ill, from which M. Pasteur concludes that the second dog was influenced by the inoculation.

Encouraged by these results, M. Pasteur is induced to try these experiments on man; but before doing so he very judiciously proposed that a series of experiments be carried out in presence of men under the control of a commission. This proposition has been favorably received, and application has been made to the Minister of Public Instruction to give it effect. At the recommendation of the Academy the following is a list of the members who are to compose the commission: Dr. Beclard, Permanent Secretary of the Academy of Medicine, Professor of Physiology, and Dean of the Paris Faculty of Medicine; M. Paul Bert, Member of the Institute, Professor of General Physiology at the Faculty of Sciences of Paris; M. Bouley, Member of the Institute and of the Academy of Medicine, Professor of Comparative Pathology at the Museum of Natural History; Dr. Villiers, Member of the Academy of Medicine, Professor of Clinical Medicine at the Military School of Metz; Director of the Academy of Paris; Dr. Vulpian, Member of the Institute and of the Academy of Medicine, Professor of Comparative and Experimental Pathology at the Faculty of Medicine of Paris; M. Tissand, Director of the Ministry of Agriculture. Until the report of the commission is published any comment would be premature. I may, however, predict for the public success, a little more or less, not as regards immediate results, but as to the expediency of inoculating human subjects with such a potent virus. The idea is anything but pleasant or assuring, and its application would be beset with so many difficulties that it will have to be abandoned.

As a mark of esteem for his persevering efforts in the cause of science and for the performance of the immense service he has rendered to science and to industry, it is proposed to offer M. Pasteur a seat in the Senate of the French Republic in the room of the lamented M. Wurtz, the eminent chemist, who died on the 12th inst.

You will have seen obituary notices of Professor Wurtz, so that one in this letter would be superfluous. I may, however, in connexion with his death which may not be generally known. The immediate cause of death was uraemic poisoning, by which is meant the intoxication of the system with all the elements of the urine, which in this case was produced by the reflux of urine to the kidneys and then into the blood, resulting from voluntary retention of urine, which occurred under the following circumstances: A day or two before his death M. Wurtz had been travelling by rail, and not finding time to empty his bladder he retained his water for a considerable time. On his arrival at his residence in Paris he was seized with symptoms of blood-poisoning and was carried off in a few hours. I may mention that M. Wurtz had for a long time been suffering from diabetes.

The above melancholy event ought to be a warning to those who are in the habit of retaining their water for a length of time, and would point to the necessity of one emptying his bladder at short intervals. Many similar accidents have doubtless occurred in railway travelling, but have not been made known, and it is time that the railway companies should attend more to the comforts of travellers than they do, by stopping a sufficient time at the stations or having carriages fitted up for the convenience of travellers.
OUR LONDON LETTER.
(From our Special Correspondent.)

THE HEALTH EXHIBITION AND HEALTH CONGRESSES--THE INTERNATIONAL MEDICAL CONGRESS--TOUTING FOR PATIENTS AT CONTINENTAL SPAS--MEDICAL REFORM--THE COLLEGE OF SURGEONS AND ITS EXAMINERS--MR. TREVES' CASE OF ACTINOMYCOSIS.

London, May 24, 1884.

The Health Exhibition is nearing completion. Several congresses are to be held in connection with it. One is to open shortly to consider the question of dwellings for the poor. The most directly interesting to medical men is that on domestic sanitation, which will meet from June 9th to 14th. Of this I hope to send you further details shortly.

The International Medical Congress, to be held shortly in Copenhagen, will not, I fancy, attract many English visitors. Danish is not a favorite subject of study in this country, and I fancy very few English medical men have any acquaintance with it. Most of them are well content if they can manage French and German. Of course all the proceedings will not be in Danish, but the visitor who knows nothing of the language of the country will be at a decided disadvantage. I have not yet been able to see any programme, so cannot give any particulars about the subjects to be specially brought forward at the Congress.

This is the season in which physicians deport their troublesome patients to continental spas. The competition among the resident practitioners is pretty keen, and touting for patients is actively carried on both directly and indirectly. It is very common for the physicians of foreign watering-places to pay a visit to London and go the round of several hospitals and call on as many medical men as they can make any reasonable pretext for doing. Their avowed object is to cultivate their English (I) and see British practice. Their real object is to tout for patients. Their English is bad enough as a rule, but I was not aware their sense of professional honor was as low as I find it to be. I had before me, as I write, a letter in bad English from a French resident at a well-known watering-place, addressed to a London physician and asking for patients. The Gallic Aesculapius further promises to pay his British colleague ‘£ one for every patient coming under treatment through your medium. I fear the recipients of this sort of commission are insufficient to be affected by the promised bribe to make any considerable addition to the sender's list of patients.

Medical reform advances with slow steps. The block of business in the House of Commons is so hopeless that there is little prospect of the Medical Bill passing, and the twenty licensing bodies are all so selfishly intent on their own interests, and so utterly dead to the interests of the general body of the profession, that they will do their best to oppose it. The College of Surgeons, which has a larger constituency than any other medical licensing body in Great Britain, has once more exhibited the spectacle of a score of irresponsible councillors defying the declared will of its Fellows and members. The College sadly overstepped its bounds.

Amongst other needed reforms I would suggest that this piocene body should in future select gentlemen for examiners. Some of its past examiners have certainly not been such. One of them, whose name I will not mention as he is not now living, could, lay but scant claim to the designation. A London physician of my acquaintance fiercely literally dragged round the room by his collar by this man. This occurred during the last decade.

Going back a little farther, manners were still more uncouth. A London practitioner, whose name is well known both in this country and America, has told me that when he was being examined for his diploma his examiner wore at him. The candidate made a statement as to the treatment of a common surgical affection he had been adopted in one of the London hospitals by one of the surgeons. The examiner denied the accuracy of this, and throwing himself back in his chair and elevating his heels in the air, used language I should be sorry to reproduce in your columns. The candidate replied that the President who was present, was the surgeon he had seen employ the procedure. The President, addressing the President, the examiner said, "Here, — , do you hear what this — fool says? Did you ever — ?"

The President replied that he had, so the examiner said no more but went on to another subject. As the surgeon I have mentioned referring to afterward became a writer on religious subjects, I presume he mended his manners later in life.

Present examiners are not as bad as this, but their manners are not of the best, as I can testify from personal experience.

I lately referred to the University of London. That institution is by no means perfection, as I took occasion to observe, nor are its officials all of them models of politeness. Its examiners are, however, all of them gentlemen, compared with those of Lincoln's Inn Fields, though not, perhaps, if measured by a higher standard. But perfection cannot be expected at a mere "crum-shop." Professor Ray Lankester has been lately writing in the London "Mail" advocating the establishment in London of a real University—not a mere examining body with an irresponsible senate to govern it.

The Morbid Growth Committee of the Pathological Society have pronounced Mr. Treves' case of supposed actinomycosis to be one of large-celled sarcoma.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 1 to June 7, 1884.

MOORE, John, Lieutenant-Colonel and Assistant Medical Purveyor. Ordered to perform, in addition to his present duties, those of Medical Storekeeper, San Francisco, Calif.

JOHNSON, Henry, Captain and Medical Storekeeper. Relieved from duty at the Medical Purveying Depot at San Francisco, Calif., and ordered to report for duty at the Medical Purveying Depot, New York City, relieving Captain Andrew V. Cherbonnier, Medical Storekeeper.

Captain Cherbonnier, on being relieved by Captain Johnson, will proceed to St. Louis, Mo., and report in person to Captain George T. Beall, Medical Storekeeper and Acting Assistant Medical Purveyor, for duty at the Purveying Depot at St. Louis, relieving Captain Beall of his duties as Medical Storekeeper.

S. O. 128, par. 9, A. G. O., June 3, 1884.

FYREY, Blencowe E., Major and Surgeon. Granted leave of absence for one year, from July 1, 1884.

S. O. 128, par. 7, A. G. O., June 3, 1884.

HALL, John D., Captain and Assistant Surgeon. Granted leave of absence for three months, to take effect on his arrival at St. Paul, Minn.

S. O. 128, par. 8, A. G. O., June 3, 1884.

HEGER, Anthony, Major and Surgeon. Assigned to duty at Fort McHenry, Md., as Post Surgeon.

S. O. 108, par. 1, Headquarters Department of the East, June 2, 1884.

HUNTINGTON, David L., Major and Surgeon. During the absence of the Surgeon-General, directed to take charge of the office of the Surgeon-General, and perform his duties.

S. O. 129, par. 6, A. G. O., June 4, 1884.

BENTLEY, Edwin, Major and Surgeon. Assigned to duty at Fort Clark, Tex., as Post Surgeon.

S. O. 68, par. 1, Headquarters Department of Texas, May 31, 1884.
Koerper, Egon A., Captain and Assistant Surgeon. Assigned to duty at Fort Keogh, M. T. S. O. 58, par. 1, Headquarters Department of Dakota, May 27, 1884.

Barnett, Richards, Captain and Assistant Surgeon. Now on sick leave of absence; is relieved from duty at Columbus Barracks, O., and ordered to report to Commanding General, Department of the East, for assignment to duty. S. O. 129, par. 2, A. G. O., June 4, 1884.

Cunningham, T. A., Captain and Assistant Surgeon. Ordered to relieve Assistant Surgeon C. B. Byrne, U. S. A., from duty at Fort Lewis, Colo. Assistant Surgeon Byrne, when so relieved, to proceed to Fort Gibson, Ind. Terr., and report to the Fort Commander for duty. S. O. 112, par. 2, Headquarters Department of the Missouri, June 4, 1884.

Banister, J. M., First Lieutenant and Assistant Surgeon. Granted leave of absence for one month and seven days, to commence June 13th. S. O. 22, Headquarters Division of the Atlantic, June 5, 1884.

McCreeky, George, First Lieutenant and Assistant Surgeon. Granted leave of absence for two months, with permission to apply to the Adjutant-General of the Army for two months' extension. S. O. 56, par. 3, Headquarters Division of the Missouri, June 5, 1884.

Wilson, George F., First Lieutenant and Assistant Surgeon. Relieved from temporary duty at Fort Canby, Wash. Terr., and ordered to return to his proper station (Fort Walla Walla, Wash. Terr.). S. O. 70, par. 2, Headquarters Division of the Colorado, May 26, 1884.

Owen, William O., Jr., First Lieutenant and Assistant Surgeon. Having reported at these headquarters, in compliance with par. 5, Department Special Orders, No. 62, current series, will return to, and take station at, Fort Stevens, Oregon. In addition to his duties at Fort Stevens, Assistant Surgeon Owen will perform those of Medical Officer at Fort Canby, Wash. Terr. S. O. 70, par. 1, Headquarters Department of Colorado, May 26, 1884.

Official List of Changes in the Medical Corps of the U. S. Navy, during the week ending June 7, 1884.

Martin, W., Assistant Surgeon. Detached from U. S. S. Constellation, ordered to U. S. S. Passaic.

Craig, T. C., Passed Assistant Surgeon. Detached from U. S. S. Minnesota, ordered to U. S. S. Vandalia.

Hall, J. H., Passed Assistant Surgeon. Detached from U. S. S. Minnesota, ordered to Naval Hospital, Brooklyn.

Wales, P. S., Medical Director. To continue present duty, until August 1, 1884.

Wells, H. M., Surgeon. To temporary duty at Naval Laboratory.

Scott, H. B., Assistant Surgeon. Commission to date from July 11, 1883.

Means, V. C. B., Assistant Surgeon. Commission to date from June 3, 1884.

Hester, F. A., Assistant Surgeon. Commission to date from June 3, 1884.

Medical Items.

Contagious Diseases—Weekly Statement. Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 7, 1884:

Germany's Home Guard.—Germany has an army of eighteen thousand men, who devote their time to the grotesque task of hunting for trichine and other parasites in the flesh that is to enter the food. This, say their French neighbors, is because the Germans adhere to the barbaric practice of eating raw meat.

How to Treat Tapeworm.—A subscriber writes: "Will you kindly obtain an expression of the profession for the benefit of your subscribers upon the treatment of tapeworm. I have had under my care a most obstatne case in which the parasite is the tenuis solium. I first used Dundas Dick & Co.'s capsules of male fern and kamala, and got away about thirty feet. In two months later I again used them, with some benefit. I have tried since then turpentine, kousso, and pumpkin seeds, and so far have not succeeded in securing the head, although the stools were very carefully watched and examined, and altogether some eighty feet of the worm passed.

Virchow's Speech at the Tercentenary Banquet at Edinburgh.—Of the twenty-five speakers at the grand banquet held April 17th, after the ceremonies of receiving delegates and presenting degrees, Professor Virchow was the only medical man who was called upon. He said: "It is not merely an accident that the foundation of the Edinburgh Medical School, and the reformers. Scientific medicine, as we know it to-day, is very young. At the same time and upon the same field when the great war between despotism and religious liberty broke out, a legitimate rebellion arose against that dogmatic medicine which had been recognized by the Church and received into her system. It was in the sixteenth century that the first great victories over Galenism were won by Vesalius and Paracelsus. Observation, experiment, criticism triumphed over tradition, research over speculation. To be sure, we are proud to represent a branch of human knowledge of the highest antiquity. (Cheers.) Medicine, like theology, derives its descent from priestly traditions, and we rejoice to be able to trace our genealogy to the time of the first establishment of Hellenism upon the islands now the crest of Asia Minor. But it is not the materia of Hippocrates that we teach our students to-day. The old humoral pathology has lost its roots since Harvey showed that the blood is a circulating spirit, not a parenchymatous juice. (Cheers.) The University of Edinburgh was closing its first century before the new was generally accepted, and only about that time medicine began to be converted from an art into a science. But then its progress was a rapid one. (Cheers.) Five generations of men, after the common calculations, perhaps ten generations of professors, sufficed to produce that great reform in medicine whose fruits we now enjoy, but which is not yet completed. During this whole period the members
of the schools of Edinburgh stood in the first line of the active champions, and I am happy to say that through all these years a hearty alliance existed between the Edinburgh school and German medicine. (Cheers.)

Since the time when William Cullen continued in clinical medicine the world commended by George Ernst and Frederick Hoeck, the much-lamented Goodall, and I find after me a long series of younger friends, whose scientific education I helped to guide in the same direction as I think that distinguished professor would have conducted them. A professor is not only a teacher, but also a assistant. I know what I myself have received, and what science has received from scholars.

For this purpose large and well-appointed institutions are put under his charge. Each of them should be a school of workers. We of the older generation, we had not such rich institutions for our instruction as the present students enjoy; we had not the same facilities of working as our predecessors. We now possess, we expect that our assistants will excel us, and that our students will overtop our assistants. This University is now so rich in new and admirable institutes of the largest size, that we must perhaps express the wish that the size may not diminish the influence of the professors.

May the spirit of true science never disappear from these buildings as Mr. Graham has so often been not only the welfare of the city, but also the science of medicine throughout the world." (Loud cheers.)

CAUSES AND CURE FOR COPRULENCE.—A stout, active man began to superintend the working of new beer in a brewery, and occasionally to sit up at night to watch the sweet-wort; an employment requiring neither activity nor labours. He was not to drink new beer, in addition to leading a quiet and inactive life; he commenced to increase in bulk, and continued to enlarge until he became of such unwieldy size as to be unable to move about, and could not get up from the sitting or lying posture without help. His heels hung down to his shoulders and breasts, and finally he was distended, and was reduced to those peculiar figures, suffering but little over one hundred and forty pounds. His story was that, being unable to work, he was at first almost starved. When he became sufficiently reduced in size as to be able to walk about, he engaged as farm labourer, and was able finally to go through very hard work for a whole day on an extremely small pittance of bread and cheese. His health had never been so good as it then was, and his only drink was water.

REDUCING WEIGHT.—A gentleman weighing thirty-two stone and nine pounds, or four hundred and fifty-seven pounds, put himself upon a strict diet of four ounces of meat, six ounces of bread, and two pounds of liquid per day. In one week he lost thirty pounds, and in six months one hundred and thirty-four pounds. His health and spirits were much improved, and he was very active for a man of twenty-three stone, or three hundred and twenty-two pounds.

ANTEPARTUSES.—The celebrated Erasmus, though a native of Rotterdam, had such an aversion to fish, that the smell of it threw him into a fever. Ambrose Paré had a patient who could never see an eel without fainting; and another who would fall into convulsions at the sight of a carp. What would have been the effect of an electric eel on these gentlemen? Joseph Scaliger and others could never drink milk. Gardan was disgusted at the sight of eggs. A King of Poland and a Secretary of France bled at the nose when they looked at apples. Henry III. of France, and many others had a great aversion to cats, mice, spiders, etc. A great huntsman in Hanover, who would attack a wild boar valiantly, always fainted at the sight of a roasted pig, if he had not time to run away.

The anticipations of this prophecy, have been humorously accounted for by the belief of the time in the omnipotence of souls. Those who had been flies in a former state were horribly afraid of spiders; those who had been mice, did not like cats; and those who had been cats did not love dogs, etc. Amatus Lusitanus knew a person who fainted whenever he saw a rose, and always kept his house when there were blossoms. The new moon was considered a cause of the constipation of the bowels. Kaye himself turned pale at the sight of water-cresses; Tycho-Brahé fainted at the sight of a fox; Henry III. of France, at that of a cat; Marshal d’Albret at a pig. A lady, wonderful enough, could not endure the feel of silk or satin. A man, not so strangely, was known to faint whenever he heard a servant sweeping. Nicanor swooned whenever he heard a bagpipe; Bayle fainted when he heard the splashing of water.

SEPTENARY PERIODICITY.—The moon quarters every 7 days, and completes its revolution in 4 times 7, or 28 days. Natural, regular typical cases of menstruation occur every 28th day, or the 4th multiple of 7. The normal period of gestation in the human female and in the cow is a multiple of 7, i.e., 40 times 7, or 280 days. The ewe which remains unimpregnated comes in heat every twice 7, or 14 days; this includes calves, buffalo, every 4 times 7, or 28 days. The whale also carries her young 280 days. Gestation in the dog lasts 63 days, or 9 times 7; in the cat, 56 days, or 8 times 7; in the fox, 42 days, or 6 times 7. The common hen sits on her eggs 21 days, or 3 times 7; the duck and goose, 28 days; the swan, 42 days; the peacock, 28 days; the crow, 21 days; the larks, carrion, bird, pigeon, and goldfinch, 14 days. Bees’ eggs hatch out in 21 days; moth eggs in 14. Fever and ague has a tendency to terminate spontaneously after the 7th, 14th, and 21st paroxysms, and relapses are apt to occur at the same time. Relapsing fever is a disease of 7 days’ duration, common typhus is a 14 days’ fever, and typhoid a 21 day disorder. The incubation of measles is 14 days, and it occupies 7 days, viz., 3 days of catarrh and 4 of eruption, before it declines. Scarlet fever and erysipelas occupy 7 days. Small-pox requires a double septennial period of 14 days; the first 7 days are occupied with the primary fever and the full development of the eruption up to its very clear state; the secondary fever, which commenced on the 9th day, has gone, and the whole crop of pustules has been converted into desiccated scabs. In 1,034 cases in which measles were successfully inoculated the fever and catarrhal symptoms commenced on the 7th day and declined on the 14th. In 14 cases of erysipelas the period of incubation was 7 days.

THE NUMBER SEVEN.—Hippocrates says the septennial number, by its occult virtues, tends to the accomplishment of all things, and is the fountain of all the changes in life; and, like Shakespeare, he divided the life of man into seven ages. The teeth spring out in the 7th month or sooner, and are shed and renewed in the 7th year, when infancy is fully changed into childhood; at twice 7 years puberty begins; at 3 times 7 the adolescent faculties are developed, manhood commences, and man becomes a fully complete and independent civil act. At the 7th man is in full possession of all his strength; at 7 times 7 he is fit for all the business of the world; at 7 times 7 he becomes wise, if ever; at 7 times 7 he is in his apogee, and from that time decays; at 8 times 7 he is in his first climacteric; at 9 times 7, or 63, he is in his last or grand climacteric; and at 10 times 7, or three score and ten, he has approached the normal period of life.
ORIGIN OF THE USE OF TOBACCO AS A MEDICINE.—Sir John Nicot, ambassador of the King of England to Portugal from 1559 to 1561, received a present of this then unknown drug from Florida in his garden, where it grew abundantly, and finally heard that a man had been cured of a noli me tangere on his cheek, near unto his nose, and which already had begun to take root at the gristle of his nose, by applying tobacco-juice and the bruised herb. From that time forward this plant began to be famous throughout all Portugal for ulcers of the leg, ringworm, and scrofula. It was finally sent to France to help Lady Montigny, who suffered with an ulcer bred in her breast, and the Countess of Ruffe to heal her face. The Lord of Jarnac caused the nicotine to be distilled and drank, mingled with the water of euphraisia, otherwise called eyebright, by one that was short-breathed or asthmatic, and it cured him. When the juice was absorbed it sometimes made the patient exceedingly uncomfortable and faint.

MOTHER MAPP, THE BONE-SETTER, was the daughter of a man named Wallis, who claimed to be a natural bone-setter who could set the bones of natural foals better than any skilled surgeon. Sally Wallis set up for herself, and succeeded in humbugging the citizens of Epsom to such an extent that they preferred her to Epsom salts and took up a subscription to keep her among them forever; but her fame extending to London, the dupes of that place got her to drive down once a week to the city. She always came in a coach and six with outriders. She was once mobbed by mistake for one of the king's mistresses, but when she swore roundly at them and said she was only Mrs. Mapp, the bone-setter, she was greeted with loud huzzas.

AN AGED SPIRIT-DRINKER.—Daniel McCarthy, of County Kerry, Ireland, died in 1752, aged one hundred and eleven. At the age of eighty-four he married his fifth wife, by whom he had two children. For the last seventy years of his life he drank plentifully of raw rum and brandy, and for the last ten years he even drank so much as spirits after it to qualify it. The fools and liars were not all dead in those times.

The church not only regarded, but made him defunct by performing the solemn ceremonial of the burial service over him, on the day that he was consigned to the lazaretto. He was placed in a pall, placed before the altar on trestles, and the mass for the dead celebrated over him, and then a shovelful of earth thrown upon him in imitation of the closure of his grave. After which time he was always obliged to wear the peculiar leper's gait, to carry a leper's stick, with which only could he touch any person, or thing, never being allowed to shake hands, or touch his hands any person, animal, or chattel, or to wash his hands, or apparel, or anything pertaining to him in any running stream, or public watering-place, or to speak to any non-leprous person, lest his pestilential breath, or the infectious odor exhaled from him should annoy or infect any well person. In the year A.D. 1313 the King of France burned all his lepers and pokey people, as well women as men, for he supposed they had poisoned the waters, which caused his leprosy.

Dr. George E. Post has been for many years a medical missionary in Syria, connected with the Presbyterian Church of this country. He has achieved a high professional reputation in that country, and the character of his work is quite graphically portrayed in a recent letter published in the New York Evangelist. The writer, who is Rev. Dr. Field, the editor, says: "He is the first surgeon in Syria. If he were to give himself up to private practice he could amass a fortune rapidly. As it is, he has a great many cases forced upon him, especially difficult cases of surgery. If a Turkish Pole breaks his leg, he will have no trouble in getting it set right, but the American Missionary. But he prefers to give his services to the poor, and of these services there is no end. Every man who gets into a street fight and is battered and bruised feels that he has a right to call on him for help. One morning we were riding out of the yard when we met several men coming in, one of whom was bleeding fearfully. The doctor sprang out in an instant, and calling for a pail of water washed the poor fellow's head till he discovered that the injuries were not fatal, prescribed for him on the spot, told his friends how to bind up his wound, wrote an order on the dispensary for the medicines which he needed, and springing into his buggy again, was off to some other duty. This sort of thing is of frequent occurrence. He is going from morning until night, giving his services in the hospital without any compensation, as well as his lectures in the college, writing books and editing a medical journal. He has prepared a series of text-books on surgery, materia medica, botany, zoology, and physiology, besides a concordance of the Arabic Bible, a large octavo volume. Then, for want of sufficient occupation to fill up his time, he edits a monthly medical journal which he has carried on his shoulders for years. It may also be said in regard to Dr. Post's literary work that he has been engaged recently on the preparation of a work on the flora of Syria and Palestine. This is not only the first work in Arabic on the subject, but the first comprehensive work in any language. It is expected that it will be of great value to students and all engaged in the work of Palestine exploration.

The leper was introduced into England in the reign of Henry I., apparently from Egypt or the East by the Crusaders. At one time there were 150,000 in Europe, and nearly half the hospitals in England were built for them. They were so numerous in 1170 that they were empowered to erect churches for themselves and have their own leprous ministers.

The acetate of silver is a new form of silver recommended by Rosenthal for hypodermic use in tabes. He begins with a dose of 0.01 dissolved in 10 grammes of water, of which from five to sixty drops are injected.
PRACTICAL HINTS REGARDING THE METHODS OF EXAMINATION EMPLOYED AS AIDS IN THE DIAGNOSIS OF NERVOUS DISEASES.1

BY A. L. RANNEY, M.D.,
PROFESSOR OF APPLIED ANATOMY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

A TABLE OF THE MORE IMPORTANT TESTS OF THE NERVES OR NERVE-CENTRES.

Tests employed to determine the REFLLEX EXCITABILITY OF THE SPINAL CORD:

The "SUPERFICIAL" OR SKIN REFLLEXES.

The "DEEP" OR TENDON REFLLEXES.

The "ORGANIC" REFLLEXES.

Tests of MOTOR PARALYSIS are employed for the following purposes:

To determine its EXACT LIMITS.
To determine its DISTRIBUTION.
To determine the TROPHIC CONDITION of the affected muscles.
To determine the POWER OF COORDINATION of muscular movement.
To determine the so-called "MUSCULAR SENSE."
To determine the IRITABILITY of the muscles.

Tests to determine the "IRITABILITY" of the muscles:

Motor Tests—
For "diminished muscular tension."
For "increased muscular tension."
For fibrillary twitchings.
For tremors.
For contracture of muscles.

ELECTRIC TESTS—
By the faradic current.
By the galvanic current.

Tests for the SENSORY NERVES enable us to decide respecting the following conditions:

Abnormalities of TACTILE SENSIBILITY—
Anesthesia.
Hyperesthesia.
Delayed sensation.
Abnormalities of SENSIBILITY TO TEMPERATURE.
Abnormalities of SENSIBILITY TO PAIN.
Abnormal condition of the ORGANS OF THE SPECIAL SENSES.

THE SPINAL REFLLEXES.

"SUPERFICIAL" OR "SKIN REFLLEXES."—These are performed by different segments of the cord. Stimulation of the skin of the sole of the foot by a scratch, prick, or touch with the nail,2 for example, induces a contraction of the foot-muscles (plantar reflex) through the lower part of the lumbar enlargement of the cord. The skin of the buttock calls into action the gluteal muscles (gluteal reflex), through a segment which corresponds to the escape of the fourth or fifth lumbar nerve. The skin upon the inner aspect of the thigh causes the cremaster muscle to draw the corresponding testicle toward the external abdominal ring (cremaster reflex), by influencing the cord at the level of the first or second lumbar nerves. The skin upon the side of the abdomen causes reflex movements of the abdominal muscles (abdominal reflex), by affecting a segment of the cord situated between the levels of the eighth and twelfth dorsal nerves. The skin upon the side of the chest creates a reflex response in the region of the epigastrium (epigastric reflex), which depends upon a spinal segment extending from the fourth to the seventh dorsal nerves. Finally, the skin between the shoulder-blades causes the posterior axillary fold or the teres major muscle to contract (scapular reflex), by influencing the spinal segment between the levels of the fifth cervical and third dorsal nerves.

By means of these reflexes we are thus enabled to test the various spinal segments, from the neck to the terminal extremity of the cord. Should any be found to be absent it should be remembered: (1) that the reflex excitability of the cord varies with individuals and is always greater in youth than old age; (2) that the planter, cremasteric, abdominal, and epigastric reflexes are variable in health but are more constant than the scapular; (3) that cerebral lesions may impair them on the side of the hemiplegia, for reasons not as yet well understood;1 and (4) that systematic lesions of Burdach's or Goll's columns (see Fig. 21) tend to diminish or abolish them.

DEEP OR "TENDON REFLLEXES."—These are also of great value as a means of determining the condition of excitability of different segments of the cord. The ones now commonly employed are called the knee-jerk or patella reflex; the peroneal reflex; the foot-clonus; and the tendo-Achilles reflex. The method of obtaining these reflexes in the most satisfactory manner will be described separately. It is important, however, to remember in connexion with these reflexes that their clinical significance, viz., that the reflexes should be tested upon both sides and compared with each other, because any perceptible differences between the two sides is a positive indication of some pathological lesion of the cord.

The knee-jerk has for years been recognized and employed by Charcot in diagnosis, although it was first systematically investigated as a clinical symptom by Westphal and Erb. Gowers remarks in a late work: "It is not a little curious that this knee-jerk, which for generations has amused school-boys, should have become an important clinical symptom."

To properly test this reflex movement of the limb, the muscles of the quadriceps extensor tendon must be put upon the stretch to a moderate degree, and the leg be unrestricted in its ability to respond. The common method employed is to have the patient cross the leg over the knee and allow it to hang passively at an angle of nearly ninety degrees. Perhaps a still better way is that employed by Gowers, viz., to allow it to hang over the forearm of the physician when his hand is placed upon the opposite knee of the patient; because, in this way the jerk is often elicited in stout people when it otherwise fails. The space between the patella and the tibia is then struck with a percussion hammer or the side of the physician's hand upon the bare skin with sufficient

---

1 Gowers advances a theory to explain this fact which is certainly ingenious and possibly its true interpretation. He starts with the assumption that the corpora quadrigemina or the optic thalami are the terminations of the fibres which mediate or convey the manifestation of the skin-reflexes in man, as the optic lobes have been proven to do in the dog. He assumes, in the second place, that the higher or motor centres of the cerebral cortex are capable in health of overpowering or controlling in some way these reflexes.

2 Now, if the motor centres are prevented from exercising this function (by becoming themselves diseased or mechanically separated from the fibres that are functionally associated with them, as in the case of apoplexy, or from the injury or destruction of the brain substance, tumors, etc.) the centre which inhibits the skin-reflexes is enabled to become overthrown, so that, in health unlessthe spinal lesion is sever enough to prevent the spinal lesion are severed; hence the skin reflexes are no longer controlled by the higher centres and are therefore enabled to respond to even more delicate stimuli than in health.
force to slightly increase the state of muscular tension which has resulted from flexion of the leg. This will cause a reflex contraction of the quadriceps extensor muscles and the foot will be jerked upward without the volition of the patient as a factor in the movement.

The ankle-jerk. If the muscles of the tendo-Achilles be put upon the stretch by flexion of the foot, a blow upon that tendon will cause a similar extension of the foot.

The foot-convuls. When the extensibility of the cord is excessive, if the foot be firmly flexed and held so by the pressure of the hand against the sole, a series of rhythmical reflex movements of extension follows, which vary between six and ten per second. They can be traced upon a revolving drum by attaching a pencil to the foot, as easily as a sphygmographic tracing is made. This clonus is more apparent when the knee is firmly extended than when flexed.

The peroneal reflex. The tendons of the peroneal muscles pass to the bones of the foot at the outer side of the ankle. A blow made upon them when the foot is bent inward to produce a moderate degree of tension of these muscles, will elicit a reflex movement, as in the case of the patella tendon.

The "walking contraction." Gowers has described a reflex test for increased spinal irritability that he considers particularly delicate. It consists in flexing the foot with the hand upon the sole, the knee being extended, and applying the blow to the muscles on the anterior aspect of the leg. It is followed by a reflex contraction of the muscles of the tendo-Achilles which are not directly affected by the blow.

Although the deep reflexes are commonly tested only in the lower extremities, the same phenomena may be elicited in the triceps or biceps muscle of the arm as in those of the thigh and calf, if subjected to the necessary position to insure tension of the muscles before the tap is given over the tendon.

Let us attempt to summarize the more important clinical deductions pertaining to these deep spinal reflexes.

1. A persistent foot-clonus never occurs in health. It indicates that the lateral columns of the cord are probably involved by some spinal lesion. In supposed hysterical affections this symptom will often decide the question of the existence of organic disease. It must not be mistaken for the involuntary foot-clonus which sometimes occurs when an unnatural posture is long maintained, even in health. It is usually associated with exaggeration of all the other deep reflexes.

2. All reflex tests become abolished when the muscles are separated from their connection with the spinal cord; hence severing of a nerve, posterior spinal sclerosis, compression of the spinal nerve-roots, destruction of the gray matter of the cord, poisons, etc., are often associated with their complete abolition.

3. Disease of the lateral columns usually decreases the skin reflexes, especially those of the trunk. This is particularly true of the so-called descending degeneration of these columns, which follows the development of cerebr al lesions.

4. Sclerosis of the lateral columns always increases the "deep" or tendon reflexes.

5. When marked incoordination of movements is present and the deep reflexes are not abolished, it indicates that sclerosis of the lateral columns probably coexists with similar changes in Burdach's columns.

6. Spasm is a marked symptom in many diseases of the spinal cord. It commonly indicates an excessive action of the reflex motor centres. It is particularly common as an acute symptom in spinal meningitis. In chronic organic diseases of the cord, it assumes the form of contracture of muscles, especially if the lateral columns of the cord are attacked; this condition becomes transformed into that of genuine spasm when the slightest forms of peripheral impressions are experienced, as in delicately manipulating the muscles, for example.

THE ORGANIC REFLEXES.—The bladder and rectum.—The bladder and rectum are more or less affected, in respect to the performance of their functions, by those diseases of the spinal cord that tend to impair or destroy the special nervous mechanism connected with them. The nocturnal incontinence of children, who "set the bed" in spite of all precautions against the accident, is an evidence either of spasm of the bladder, excessive stimulation of the centripetal nerves connected with the so-called "vesical centres" of the spinal cord, or atony of the sphincter muscle. If due to spasm, it may be excited by worms of the intestine. When the spinal cord is subjected to sudden injury low down, or is attacked by some disease-process that involves the lumbar region of the spinal cord, the bladder and the rectum are liable to be paralyzed. In such cases, if the paralysis be complete, the urine has to be drawn with a catheter. Sometimes, if not drawn at regular intervals, it overflows when the bladder becomes excessively distended. This compels the patient to wear some form of apparatus to prevent wetting of the clothing. Urinal overflow should never mislead the physician into the belief that the bladder is empty.

True incontinence is a rare condition in the adult. The term "incontinence" is not, however, restricted by many authors to that condition characterized by a continued escape of urine and emptiness of the bladder.

Bramwell gives the following table, as an aid in the diagnosis of two forms of incontinence that are commonly recognized:

<table>

SOMATIC INCOORDINATION

Constant Forces away urine. Any age but generally old age. May be amnionical and paresis. If central, generally a symmetric affection of legs and paraplegia.

PARALYTIC INCOORDINATION

In all cases, where either incontinence or retention of urine is developed in connection with abnormal nerve-symptoms, the urethra and rectum should always be carefully explored for the purpose of detecting disease, or of eliminating, if absent, all local causes of these conditions. The table given by—In the lumbar region of the spinal cord a centre is situated that governs the acts of erection and seminal ejaculation. It may be called into action either by impressions made upon the sensory nerves of the skin of certain regions or by cerebral influences that are exerted upon the sexual centre as the result of some emotional impulse.

Destructive processes in this centre of the spinal cord cause a loss of the power of erection and ejaculation, i.e., impotence. General spinal weakness from any cause may also lessen the duration and degree of erection or render ejaculation premature.

Linked with some forms of nervous disease comes priapism, or the state of erection without sexual desire. It may be a result of irritation or excessive stimulation of the following structures: (1) the sensory nerves (as in gonorrhoea); (2) the sexual centre itself; (3) the nerves that convey the emotional impulses from the brain to the sexual centre through the spinal cord; (4) the parts of the cerebral cortex functionally associated with sexual emotions. The latter are, as yet, under investigation. Priapism may be complicated by painful and incomplete and painless. It may last for days. It occurs not infrequently in connection with disease in the lower cervical or upper dorsal regions of the spinal cord.
The pupillary reflex.—The last two cervical and the three upper dorsal segments of the spinal cord probably embrace the so-called "ciliospinal centre." From it sympathetic nerves pass to the muscular fibres of the iris. Irritation of this centre causes the pupil to dilate; destruction of it causes the pupil to contract. The tests for the "Robertson pupil" have been described in previous pages. This peculiar condition of the pupil is one of the most valuable signs of the disease called "locomotor ataxia" or posterior spinal sclerosis. It is the only condition of the eye that allows of the movements of the pupil in attempts to focus near objects and destroys at the same time the response of the pupil to varying degrees of light.

TESTS FOR MOTOR PARALYSIS.

As mentioned in preceding pages, the physician may be called upon to recognize five forms of paralysis of motion, viz.: monoplegia, hemiplegia, paraplegia, hemiparaplegia, and complete paralysis. If the paralysis be of an incomplete or partial form in any type, it is called "crossed paralysis.

Cerebral diseases commonly produce either monoplegia or hemiplegia of the opposite side of the body, in case the paralysis occurs either as a result of localized pressure upon the brain or of destruction of some of its component fibres. In those cases where the lesion involves both hemispheres, the paralysis may be bilateral. Such lesions are generally present at the base of the brain. When "crossed paralysis" is developed, definite information is afforded respecting the seat and extent of the lesion.

Spinal paralysis is bilateral in the great majority of cases and is limited to the muscles of the legs (paraplegia). This is to be explained (1) by the fact that the motor tracts of the spinal cord are in such close relation to each other that acute diseases are seldom confined to one lateral half of the cord, and (2) to the fact that the muscles below the seat of the lesion are necessarily paralyzed in proportion to the amount of injury sustained by the motor fibres. In those rare cases, where the spinal lesion is situated above the point at which the nerves to the upper extremities are given off, bilateral paralysis is apparent in both extremities (arms and legs), constituting the condition termed "cervical paraplegia" by some authors.

The points to be tested, in any case of motor paralysis, have been enumerated in a preceding table. Without further explanation, we will now proceed to consider each separately.

THE EXACT SEAT AND LIMITS OF THE PARALYSIS.—To ascertain the exact limits of the paralysis is important as an aid in the determination of the seat of the exciting lesion, be it cerebral or spinal. The peculiarities of attitude and gait will often aid, in a rough and imperfect way, in deciding as to the muscles that are chiefly affected; but a more detailed examination of the separate muscles, by instructing the patient to perform designated movements that shall call different sets successively into action, will be more accurate and scientific. To employ these tests in a skilful manner, however, the physician must first be thoroughly familiar with the action of the various muscles, both individually and in conjunction with others.

In some forms of spinal diseases, where great accuracy in the diagnosis and localization of the lesion is required, it may become necessary to test the motor condition of the various spinal segments by means of the muscles that are governed by them. The investigations of Yeo and Ferrer upon the monkey tribe, as well as those of Maccacci and Port upon dogs and cats, seem to have demonstrated that each pair of spinal nerves exerts an influence upon definite muscular movements. The limits of this article will preclude a summary of the results obtained by these observers; the reader being referred to the author's work, "The Applied Anatomy of the Nervous System" (D. Appleton & Co.), for details.

THE DEGREE OF MOTOR PARALYSIS.—Complete paralysis, of course, abolishes all power in the muscles affected, but paresis does not, and therefore varies in degree. It is often important to decide as to the force that can be exerted by the partially paralyzed muscles before completing a diagnosis. This can be best accomplished, in the muscles of the upper extremity, by the employment of an instrument devised by Matthieu, an instrument-maker of Paris, called the dynamometer. It is shown in the cut.

When grasped in the hand, the index shows the amount of power that is exerted upon the spring. The index remains fixed until mechanically replaced after it has been used; this enables the physician to direct his attention to other points in the case while the patient is trying his muscles. It is really a test for the "grasping power" of the flexor muscles of the forearm only. An apparatus for tracing the effects of muscular contraction is sometimes attached to the dynamometer. It is called the dynamograph. It shows irregularities of muscular contraction.

The strength of the muscles of the c alf can be tested, as Gowars suggests, by requesting the patient to jump on tip-toe.
Bilateral paralysis requires that the power of the muscles should be compared with that of a healthy individual of about the same muscular development as the patient, if great accuracy is desired. In unilateral paralysis, the healthy side can be used as a standard of comparison.

The Trophic Condition of the Muscles.—The amount of atrophy or wasting that ensues simply from disuse of most of the spinal grey substance are the “trophic centres” for the motor fibres found in the anterior roots of each spinal nerve. When these cells become the seat of disease, the muscles undergo extreme and rapid atrophy. Similar changes also occur when the nerves are cut off from connection with them, as in wounds of a nerve, pressure upon a nerve, etc.

The Power of Coordination and Muscular Movements.—Disease of the cerebellum and of the columns of Burdach and Goll in the spinal cord (see Fig. 21) are commonly associated with a peculiar inability on the part of the patient to perform certain muscular movements in a proper way, because the muscles do not act in unison or in the order necessary to accomplish them. This is termed “incoordination of movement.”

Various tests are employed in determining the degree of this abnormal state, because one that will answer for the lower limbs will not for the upper extremities, or vice versa. Besides, it is necessary in these cases to decide both as to their ability to perform complex movements with accuracy and also as to the state of the so-called “muscular sense.” Let us consider first the tests of the former.

When so-called “ataxic patients” are requested to follow a designated line in the floor or carpet as they walk across a room, they invariably keep their eyes fixed upon the floor and have extreme difficulty in following the line. Now ask such a patient to do the same with the eyes looking straight ahead of him, and the attempt will prove a still more lamentable failure than before. In advanced stages of the disease, the patient may fall.

A second manifestation of lack of coordination in the muscles of the legs lies in an inability on the part of the patient to stand erect with the feet in close contact, without toppling over. This is particularly evident when the patient is instructed to close the eyes. It must be remembered, however, that an inability to stand erect and motionless with the eyes closed is not always due to ataxia. I have seen the same result produced artificially in a healthy subject by freezing the soles of the feet to a degree sufficient to destroy the appreciation of its contact with the floor or carpet. The test is a reliable one only for the presence of marked anæsthesia of the soles of the feet; hence it is common in ataxic subjects, in whom sensation is always more or less impaired.

Considerable stress may be laid upon this point, because it is stated by some neurologists that this symptom or test is to be regarded as a positive sign of locomotor ataxia. That it is a valuable diagnostic point in that disease, when associated with other evidences of its existence, cannot be disputed; but it is by means a pathognomonic symptom, as it might exist in any disease (cerebral, spinal, or functional) that could cause marked anæsthesia of both lower extremities.

In the maintenance of the equilibrium during an erect posture when the feet are in contact, it is necessary that the nerves of sensation allow the keenest appreciation by the nerve-centres of variations in the amount of pressure exerted by the weight of the subject upon the different regions of the sole of the feet. When such information is withheld from any cause (chiefly by sensory paralysis or anæsthesia) the nerve-centres can no longer properly govern the muscles to counteract a tendency toward a fall, provided that the sense of sight is prevented from giving them the necessary information. This explains why it is that ataxic patients often notice a difficulty in washing the face at a washstand when the eyes are closed; why they keep the vision fixed upon the ground as an aid in governing the movements of walking; and why they rely on and accurately walk upon some small object, as in mounting a horse by means of the stirrup; and many others of a similar kind.

The tests for incoordination of the muscles of the upper extremity have not as yet been described.

The handwriting is sometimes seriously affected in ataxic patients, by an inability to make continuous curves with accuracy, as in the case of the capital letters C, D, G, etc. This is because the acts required of the muscles in making these curves are complicated and must follow each other in a certain sequence in order to properly execute them. Again, the clothes are buttoned and unbbuttoned with extreme difficulty, because these simple acts are dependent on the incoordination of movements of a complex character. Food and drink are caught by the mouth with difficulty in some cases, especially when the eyes are closed or in the dark. These patients cannot touch designated parts of the face with the finger with accuracy and rapidity when the incoordination of the upper extremities is well developed, or the so-called “muscular sense” is destroyed. These tests will be mentioned later.

The Muscular Sense.—By this term we mean the power which each individual possesses, in health, of discriminating in regard to the amount of muscular force required to accomplish certain ends. Thus, for example, if two objects are held in the hands, the difference in weight between them should be estimated with an approach to accuracy. Again, if the eyes are closed, the fingers can be made to touch rapidly any designated portion of the body with perfect certainty. Movements of progress should be also performed with the eyes closed nearly as well as when open, if the distance be short and the location a familiar one. Finally, the handwriting should not make mistakes due to the incoordination of letters when made with the eyes shut or open.

Now in some forms of nervous derangements, the muscular sense is impaired; hence it becomes necessary to sometimes test it before making a final diagnosis. Several tests are commonly employed. They may be designated as the “weight” test, the “movement” test, and the “handwriting” test.

In testing the power of discrimination of weights held in the hands, it is best to have them all of uniform size, in order to avoid the patient using the sense of sight as a factor in his decision. Hanging different weights from the foot in a handkerchief will test the muscular sense in the lower extremity. Metallc balls of different thickness but of uniform size, either covered or uncovered, answer the purposes of the “weight” test.

To test the accuracy of movement, direct the patient to close the eyes tightly or blindfold him, and then instruct him to rapidly place the forefinger of either hand alternately on some spot upon his body which shall be chosen by the examiner, each instance utterly new, the upper lip, lower lip, ear of either side, etc. When the lower limbs are to be tested, he may be instructed to place his great toe upon the opposite instep, heel, knee-cap, etc., or to raise the foot to a given height when lying on the back, and then to slowly lower it till it rests upon some designated spot on the other foot.

The handwriting of a patient is often of value in diag-
nosis; especially when a sentence written with the eyes open is compared with the same written with the eyes closed. In health the muscular sense should enable almost any one to perform both with a fair degree of precision. In motor paralysis or ataxia the changes are marked; especially in the latter, because incoordination of muscular movements prevents the formation of continuous and well-formed curves, even when the eyes are open, and utterly destroys the legibility of the letters if closed. The existence of tremor or the presence of profound motor paralysis will, of course, interfere most seriously with the ability of the patient to write legibly, if at all, irrespective of the aid of vision.

**THE IRRITABILITY OF THE MUSCLES.**

In some forms of cerebral and spinal disease it becomes necessary to test the so-called "irritability" of the muscles. Two forms of tests are employed for this purpose, viz., mechanical and electric.

By means of mechanical tests we are enabled to decide (1) as to the existence of diminished or increased tension of the muscles; (2) the presence of twitches of individual muscular fibres in certain regions (as if a live animal were imprisoned beneath the skin); (3) the presence of tremor; and (4) the state of muscular rigidity and permanent shortening known as "contracture."

Electric currents are furthermore employed chiefly in determining the question of degenerative changes in the muscles. The increase or decrease of such changes, when they have been found to exist, can also be scientifically determined by the employment of electric tests from time to time.

**MECHANICAL IRRITABILITY OF MUSCLES.**—When the muscles are subjected either to manipulation, a light tapping with the tip of the finger, or a stroke with a percussion hammer, either an abnormal exaggeration or a diminution of the mechanical excitability of the part struck is sometimes detected in connection with disease or injury of the brain, the spinal cord, or of the nerves themselves.

The following clinical deductions are offered as a summary of these tests:

1. Motor paralysis usually decreases the mechanical excitability of the muscles affected.

2. When the "galvanic excitability" is markedly increased (reaction of degeneration), the mechanical excitability of the muscles is also increased.

3. An increase in the "deep" or "tendon reflexes" is likewise associated with an increase in the mechanical excitability of muscles. This is particularly characteristic of sclerosis or hardening of the lateral columns of the spinal cord.

4. Atrophy, or wasting of the muscles, as the result of disease-processes, such as functional paralysis, poliomyelitis, etc., usually tends to diminish the excitatory power of the affected muscles (state of flaccidity). An exception to this rule exists for a time in amyotrophic lateral sclerosis and other conditions where marked muscular rigidity precedes the atrophy.

5. Any disease that tends to cause irritation of the motor nerves or to arrest the control of the brain over the spinal segments, is liable to be associated with a rigidity of the muscles. Twitchings, muscular cramps, tremors, spasms, and contractures may be associated with this increase of muscular tension.

The distribution of the muscular rigidity differs if the exciting cause be confined to the spinal coverings or the substance of the cord itself. In the former case the fibres are chiefly involved; while hardening or sclerosis of the lateral columns of the cord usually causes the lower limbs to be firmly extended and closely approximated to each other.

6. The disease known as "progressive muscular atrophy" is the one most commonly associated with contractions of separate fibres or bundles of fibres in the muscles—the so-called "fibrillary twitchings." These twitchings are not confined, however, to this condition. Hypochondriacs and certain functional diseases of the spinal cord may also be associated with them. A slow destructive process affecting the motor nerve-cells or the motor nerves themselves may also cause them.

7. A permanent shortening of muscles (state of contraction) is a frequent sequel to extensive atrophy or wasting of the muscular fibres. It may result also from the prolonged and unrestrained action of certain muscles whose antagonists are lacking in muscular power, as in the case of infantile paralysis.

**THE ELECTRIC IRRITABILITY OF THE MUSCLES.**—The various electric tests that are employed as aids in the diagnosis of nervous affections are too complex to be clearly described and explained to the general practitioner without entering somewhat into the domain of physics and physiology. Erb has lately written an excellent work upon the subject, and most of the later treatises upon physiology will afford the reader general information respecting the reactions of healthy muscle to the faradic and galvanic currents. The few practical hints which are given in this article are offered with an apology for their incompleteness; although it is hoped that they will assist the reader in his studies in this field.

A. Having first moistened the electrodes and connected them with the battery in action, hold them both in one hand (close together, but not in contact) and apply them to the ball of the thumb of the opposite hand to see if the current is passing properly. If the current to be employed is a very weak one, touch the electrodes to the tip of the tongue, before it is used upon the patient.

B. Next sponge the part of the patient's body to be tested with a weak solution of table-salt in warm water; in order to render the skin a good conductor of the electric currents.

![Diagram](image-url)
placed over the muscle to be tested; usually at the point where the motor-nerve enters its substance—the so-called “motor-point” of the muscle. In this way the action of the two poles can be readily distinguished. In my work, “The Applied Anatomy of the Nervous System,” I have reproduced the cuts of Ziemssen, illustrating the situation of the motor-points of the various muscles. In case the interrupted or faradic current is to be employed, the “polar method” described above need not be strictly adhered to; as it is decidedly more painful than when the electrodes are less widely separated.

D. Use both the continuous or galvanic current, and the interrupted or faradic current in testing muscular reactions. The former is of the greatest value in diagnosis.

E. In studying the muscular reactions to the different currents employed, remember (1) that the negative pole is called the cathode (C.); (2) that muscular contractions occur both when the current is altered in strength and when the circuit is closed or opened; (3) that the faradic current produces an apparently continuous muscular contraction because its interruptions are so very rapid; (4) that very weak currents do not produce contractions; (5) that alterations in the strength of the current cause proportionate variations in the contractions; (6) that the contractions are short, sharp, and sudden in health; (7) that the effects of applying the electrode over the substance of the muscle and over its motor-point are identical in health, but not in some diseased conditions; (8) that the galvanic current will not usually produce muscular contractions while it is constant, but only when its strength is modified or when the circuit is closed or broken; (9) that the direction of the current can be changed without altering the position of the electrodes, by a simple apparatus that changes the cathode into the anode and vice versa.

F. The current passes always from the anode to the cathode. Hence, when one pole is placed on the breast or neck, and the other on the muscle to be tested, we can have a descending current if the cathode be on the muscle; or an ascending current, if the anode be on the same distant or neutral point.

G. An “interrupter” is necessary in employing the galvanic current.

The descending current, when closed and again broken, can thus give us:

1. The cathodal closure contraction... C. C. C.
2. The cathodal opening contraction... C. O. C.

The ascending current, when closed and again broken, can give us:

1. The anodal closure contraction... A. C. C.
2. The anodal opening contraction... A. O. C.

H. These four forms of contraction require currents of different strengths to produce them. They are therefore induced by gradually increasing the number of cells employed. The following order is the one commonly observed in healthy muscle:

1. .................................. C. C. C.
2. .................................. A. C. C.
3. .................................. A. O. C.
4. .................................. C. O. C.

It will be observed that the cathodal contractions appear first and last, while the anodal contractions follow each other; also, that the closure contractions precede the opening contractions of both the cathode and anode.

I. As the strength of the current is gradually increased, the contractions which have successively appeared become intensified proportionately (as is shown below), and new reactions are added.

1. First stage (moderate current), C. C. C.
2. Second stage (stronger current), C. C. C. and A. C. C.
3. Third stage (still stronger current), C. C. C. and A. C. C. and A. O. C.
4. Fourth stage (very strong current), C. C. C. and A. C. C. and A. O. C.
5. Fifth stage (very strong current), C. C. C. and A. O. C.

Ch. C. C. C. is called “cathodal tetanus,” because the contraction is very violent. Sometimes the anodal contractions both occur with the same intensity of cur-
(3) The muscular contractions produced by the galvonic current are diminished for about ten days. Subsequently the excitability of the muscles to slowly interrupted galvonic currents becomes increased, so that very weak currents may excite contractions. This may disappear in five or six months.

(4) The polar reactions become altered in their sequence. The muscle contractions appear before those of the cathode, as shown below:

<table>
<thead>
<tr>
<th>1</th>
<th>A. C. C. instead of C. C. C. as in health.</th>
</tr>
</thead>
<tbody>
<tr>
<td>2</td>
<td>C. C. C.</td>
</tr>
<tr>
<td>3</td>
<td>A. C. C.</td>
</tr>
<tr>
<td>4</td>
<td>C. O. C.</td>
</tr>
<tr>
<td>5</td>
<td>A. O. C.</td>
</tr>
</tbody>
</table>

(5) The character of the muscular contractions becomes altered. In health, they are sharp, short, and sudden. When degeneration occurs, they are slow to appear; they are prolonged and continue even during the passage of the current; and, finally, they assume the character of "tetanic" contractions, irrespective of the strength of the current employed.

(To be continued.)

THE PRACTICAL TREATMENT OF ABDOMINAL HERNIA.

By W. B. De Garmo, M.D.

New York.

Inguinal Hernia.—In a previous paper under the above title I endeavored to point out the importance of more careful attention being given to this subject, and in the remarks to follow I trust may be found some practical suggestions.

While differential diagnosis does not come within the scope of the present writing, I cannot pass it over without emphasizing the necessity of ascertaining by thorough examination the exact form, condition, and variety of the hernia before attempting its treatment.

The amount of pressure required for its retention may be estimated approximately by having the patient, who should be in the upright position, cough or strain, while the hernia is retained by the ends of one or two of the surgeon's fingers pressed over the canal.

Heather Begg, of London, claims to have devised an apparatus which, applied over the canal, will indicate in number of ounces the exact pressure necessary for the retention of the hernia. I have little faith, however, in the practical utility of such a method, and deem it quite unnecessary, as a small amount of experience will enable the surgeon to judge with considerable accuracy as to the requisite retentive power in a given case.

The ordinary methods of truss-fitting are open to the most serious objection, for the reason that even those with large and constant experience seldom become so expert in shaping the springs that they are able to adjust them accurately to every individual peculiarity of form, and failing in this, the entire reliance is quite likely to prove irksome to the wearer or a complete failure in its retentive action.

In the majority of cases trusses are put on without being fitted to the person in any particular, but by those who attempt to fit them the usual method is to judge of the patient's shape by inspection, and bend the spring to the supposed form.

The difficulties of this undertaking will be readily understood when we take into account the fact that one could scarcely find two individuals of exactly the same form, even though their circumference be alike, and that all parts of the person cannot be seen at the same instant. Having many times experienced these difficulties myself, after repeated trials by different methods to overcome them, I have found in the simple process described below all that I had sought for, and have used it for the past two years with great satisfaction to myself and benefit to my patients. By its aid any good truss-spring can be fitted to a body of the most irregular shape with perfect accuracy, thereby ensuring safety in action and comfort to the wearer. By it truss-fitting is changed from mere guesswork to a more scientific basis.

The method referred to consists in securing a diagram upon paper of the exact shape of the pelvis on a line with the hernia. The only preparation necessary to carry out this proceeding is to have a piece of sheet lead one-sixteenth of an inch thick, half an inch wide, and for use on adults about twenty inches long; this should be covered with chamois-skin or kid, to save the patient the otherwise unpleasant sensation of having the lead placed upon the surface of the body.

Have the patient stand with the left side toward you, place the lead horizontally across the front of the abdomen with the end over the right internal ring, and thence pass it around the left hip to the spine or beyond; pass the fingers gently over the lead that it may be perfectly moulded to the form, and then remove carefully and place edgewise in the case-book or upon paper. A tracing of its inner surface may now be made with a pencil, and after smoothing the lead out upon an even surface repeat the operation in the same manner for the other side, which, when transferred to the paper, completes the circumference of the hips. The measure should also be made in number of inches as a guide in selecting a truss. Having selected one of suitable size and pattern, its spring or springs should be shaped to correspond exactly with the diagram.

I have found in using this method that it secures far greater accuracy, and it does away with the necessity of trying a truss upon the patient many times to ascertain the changes required. In fitting ladies in this manner they are saved the mortification of exposure and the repeated trials of the truss before a fit is secured. The form can be taken beneath the clothing, and by the diagram thus obtained the truss fully prepared before its first application.

Before speaking of the selection of the truss I should perhaps state—as I have found that many physicians are ignorant of the fact—that every truss-spring should be so tempered that it may be shaped to the exact form of the wearer. A spring that will not stand this kind of manipulation is worthless, and should be returned to the maker.

Manufacturers know quite well how to produce such a spring, but owing to excessive competition some firms have been prompted to put upon the market inferior goods, fit for show only. Druggists would soon find that trusses of the latter class would remain dead stock on their hands if due attention was given to the mechanical treatment of hernia by physicians.

In selecting a truss we have a great variety from which to choose, many of them good but a great number absolutely worthless. So great is the number now being manufactured in this country that it is only possible to speak of them on general principles. It is the writer's opinion that no thoroughly efficient truss can be produced without the use of metallic springs. Certainly none such have been produced up to the present time. Those made of elastic webbing and other flexible material, while they may be worn for a time with satisfaction, are almost certain to allow the hernia to increase in size from their imperfect action; besides which they expose the wearer constantly to the danger of strangulation by leading him to believe that his hernia is perfectly retained when in reality it is lying in the canal or even pulling at the inguinal ring.

This state of affairs may exist for months without producing much inconvenience, but sooner or later the canal and rings are dilated to such an extent that the hernia becomes uncontrollable by all ordinary means. Many instances of strangulation have occurred in such cases in persons who believed their hernias securely held.

1 The Medical Record, August 11, 1883.
In single trusses, that form of spring which crosses the front of the abdomen is far more efficient and comfortable than those which are applied from the affected side, and commonly known as the French or German truss. By encircling fully two-thirds of the body they retain their position better, and the direction in which pressure is made by the front pad is more in accordance with the indications as to the proper retention of the protruding viscera.

Personally I am opposed to the use of the single truss in any case, having seen many instances wherein hernia of the opposite side has been the undoubted result of their use. Nor is it in the least unreasonable to expect just such a result, when we consider the forces put in action and the altered relations produced between the abdominal parietes and their contained viscera. Strong pressure over the right inguinal region, for example, will diminish the antero-posterior diameter of the abdominal cavity at this point, with a consequent displacement of the viscera to the left side, producing thereby an unnatural pressure upon the inner part of the left inguinal region. Furthermore, the same predisposition which may have been the primary cause of the first hernia is quite as likely to act equally upon the opposite side.

In supporting both inguinal regions the pressure over the apparently sound side should be very light, while that over the hernia should be adequate to the requirements of that particular part. I have of late used quite extensively an appliance similar to that originally designed by the late Dr. Hood, of Kentucky. Several patents have been obtained upon unimportant modifications in this truss, which have enabled the patentee to issue them under a new name; in other respects they are worthless.

The advantages of the "Hood" truss are:
First, that both inguinal regions are supported in every case.
Second, being solid in front there is no relative change in the position of the supporting pads. Third, the arched springs, passing just beneath the crest of the ilium on either side, rest upon a surface almost entirely uninfluenced by muscular action, and hence are not liable to displacement. Fourth, the counter-pressure in the back is not over the spine, as in most other trusses, but comes upon the gluteal muscles, where it can be borne with less discomfort. Pads of any design which appear to be indicated can be attached to these springs; the springs may be of steel, tempered brass, or German silver, covered with leather, chamois, or, what is superior to both, rubber, or even a composition of leather and rubber.

In extreme cases of scrotal hernia the truss just mentioned may not be sufficiently powerful, and in such cases I am in the habit of using a truss well known to the trade as the "Radical Cure" truss. That this truss has the special curative action once claimed for it, is an absurdity scarcely worth a denial in this place. On the other hand, I believe it to be, when judiciously used, one of the most valuable appliances at our command for the mechanical treatment of certain cases of inguinal hernia.

My custom has been to employ it in difficult cases, and to use it only until the case has been brought under control, after which I have removed it and applied in its place either the "Hood" or some equally light truss. For this special use I know of nothing its equal, but I do not endorse it as a suitable appliance for permanent wear. I have seen much harm result from its indiscriminate use by incompetent truss-vendors. Like many other valuable remedies, it should be used only under the supervision of the intelligent physician.

In the case of cases of most inguinal hernia, the cases of the most inguinal hernia, will be found to be representing "trusses for scrotal hernia," with pads of enormous size attached to the spring, and straps around the thigh to hold them in place. The construction of such an ungainly, cumbersome appliance is based upon total ignorance of the subject, and the belief that the larger the hernia, the larger should be the retaining pad, while in reality the contrary rule holds true. Within certain reasonable limits it is best to select a small, prominent pad for the first retention of a large hernia, changed to a larger and more flat pad as the case improves, and it is equally advisable to use on a recent hernia the one last mentioned.

Scrotal hernia merely indicates a degree in the development of inguinal hernia, and requires no special treatment if reducible.

Several pads have been designed with the view of preventing pressure upon the spermatic cord, most prominent among which are the "horse-shoe" pad of Dr. Wood, of London, and the grooved or "multipalped" pad of the late Dr. Riggs, of this city. After repeated trials I am convinced that neither of them protects the cord in the slightest degree, although I have used that devised by Dr. Riggs very frequently, because it retains its position upon the body somewhat better than the smooth convex pad, and is equally efficient in the retention of the hernia. Furthermore, I believe that if a truss is properly applied the spermatic cord does not require any special protection; only when the pad rests upon the pubic bone is the cord compressed, and in this position it should never be worn.

The centre of a truss pad should not be over the external ring, as most frequently applied, but as nearly over the internal ring as it can be worn and retain the hernia. In scrotal hernia of long standing the internal ring is often constricted down and cannot be allowed to extend an extent that it becomes necessary to place the pressure low; if, however, the case be properly cared for, after a few months the truss will prove equally efficient if placed higher, and it is quite essential, in order to secure the greatest amount of improvement, that its position should be so changed.

Any case in which an attempt is made to produce a cure, it is always advisable to have the patient wear a truss at night as well as during the day. A light elastic truss is well suited for night use, and the change from that worn in the daytime should always be made in the recumbent position. I believe it to be an impossibility to combine in a single appliance one which shall be equally good for night and day use.

In the management of hernias that are reducible, it is not only necessary that the patient be given an appliance that is exactly suited to the requirements of the case, but it is equally essential that he be carefully instructed in its proper use, and that it be modified from time to time as his condition improves. The hernia once under the control of the truss, or the appliance of some one entirely different, will be held even for a moment; the patient should never stand upon his feet or assume the upright position without having the appliance in place. These suggestions must be strictly followed in order to secure the best results; besides which, it is a fact confirmed by many observers, that if a previously neglected hernia is retained for a time, there is, upon its descent, far greater danger of strangulation than ever before. This should be carefully impressed upon the mind of the patient, in order that he may guard himself in this respect.

Persons suffering from large hernias are frequently under the impression that a suitable truss will be at once efficient in action, and perfectly comfortable to wear. This is an error which should be removed from the patient's mind before treatment is commenced, otherwise he may become discouraged and not persevere in the use of an appliance, which may be in every way suited to his case. In slight cases a truss should not cause any amount of discomfort from the first; but in cases requiring strong pressure, it is absolutely certain that the patient will experience considerable suffering; in many instances, more annoyance than has his hernia. This difficulty is, however, limited to the first three or four days, after which the skin becomes accustomed to the pressure, and little, if any more trouble will be experienced. If the patient is prepared for it beforehand, he will usually go through the tempering period without
much complaint; if not, he is quite as likely to abandon the appliance under the impression that it is not right.

It is best to instruct the patient respecting the absolute cleanliness of the parts and of the truss. If the truss is of hard rubber, it should be washed at least every week; if of soft material, it should be covered by a homemade slip of linen or muslin, which should be changed frequently. These precautions and the use of the powder recommended in my previous paper will, even in the most sensitive, prevent the formation of troublesome sores.

THREE CASES OF COMPOUND DEPRESSED FRACTURE OF SKULL,
WITH REMOVAL OF DEPRESSED BONE IN FIRST AND SECOND CASES, NO OPERATION IN THIRD—RECOVERY IN ALL.

By ALFRED NORTH, M.D.,
WATERBURY, CONN.

CASE I.—James H., aged twenty-four; Irish; laborer. On the night of June 2, 1875, went fishing about one half past midnight, when absorbed in his work, a man approached from behind and dealt him a blow upon the head with a club. He was felled to the ground, where he lay unconscious until 5 A.M., June 3d, when he regained consciousness, got up, and walked home without assistance. He then cleansed the wound thoroughly, staunched the blood by a compress and bandage, and came to my office, arriving about 6 A.M. I removed the dressings, examined the wound, and found that the force of the blow had fallen upon the anterior part of the right parietal eminence. There was a scalp wound about two and a half inches in length extending antero-posteriorly. Beneath this there was a stellate fracture of the bone with considerable depression, the bone being broken in many fragments. The area of depression was about the size of a silver dollar, and about half an inch in depth.

I advised him to go home and prepare for an operation, which he willingly did. Was not unconscious at any time during the day, but suffered from severe headache and feeling of pressure at seat of injury.

At 12 M. I proceeded to operate, with the assistance of Dr. Castle. Enlarged the scalp wound and drew the edges aside. As the fragments could be seized with forceps the trephine was not used. Removed one piece of bone after another until thirteen fragments had been removed. Dura mater was, as far as could be ascertained, not injured. Then smoothed off the edges of the bone well with forceps, removed all remnants, and closed the wound. The region of fracture was limited to the right parietal bone.

I then placed a drainage-tube in the wound and closed it with silk sutures. The dressing was completed by the application of a compress and bandage.

A detailed history of the progress of the case after the operation was not kept, but the facts of treatment were substantially as follows: After the first or second day the wound was regularly cleansed by passing carbolized water through the drainage-tube by means of a syringe. There was intense swelling and infiltration of the scalp on this side of the head, especially about the wound. The ice-cap was used from the start. Patient was delirious and raving the greater part of the time for three weeks after the operation, with occasional rational periods. At one time during the third week he would have jumped from a third-story window had he not been restrained. Opium, bromide, and chloral were used as the case required. The diet consisted chiefly of milk. After the third week there was no delirium, and convalescence henceforth was uninterrupted.

Was able to be out of bed on July 26th. Two weeks after this walked to my office. Was strong and well enough to go to work about the middle of August.

Three pieces of bone have been discharged from the wound at different times since the injury, the last two years after the operation. For the last year he has been troubled with vertigo, and was so much affected by the sun’s heat that his wife had to carry his dinner to him daily during the first summer. Has not been able to bear noise or excitement to any extent at any time since the injury. Alcohol has a very prompt and peculiar effect, producing very silly and idiotic appearance and actions. Is obliged to live a quiet and retired life.

Aside from the above-named particulars his general health has been good, and he has worked constantly to date.

CASE II.—William E. H., twenty-seven years of age; employee of the Blake & Johnson Machine Co. The accident occurred on September 3, 1873. He was driving a small planer enlarging a groove in a twenty-five-pound casting. At one end of this casting was an elbow with a projection of six or eight inches at right angles to the main portion. The planer worked automatically, moving slowly forward and returning quickly. In the upright portion of the machine is what is called the screw-head, which is a screw, the head of which is held in place by a screw, the square head of which projects an inch or more directly toward the casting. When the planer bed moved forward there was left only about four inches space between the projection on the casting and the end of this screw-head, which is about three-quarters of an inch square. Wishing to obtain a better position for the planer, the planer moved forward so that his head came directly between the casting elbow and the projecting screw-head. Unconscious of his danger, he kept his head in this position until the casting elbow drove his head against the projecting screw-head, which slowly crushed its way through the skull in the right temporal region, depressing the hair against the skin.

The maximum point of contact being reached, the planer bed shot backward and H——fell to the floor. He was put into a hack and brought to my office, not having been unconscious in the meantime. He walked up one flight of stairs to reach the office.

Upon examination there was found to be externally a scalp wound, semicircular in shape, convexity upward, anterior extremity near outer angle of orbit, and posterior backward, toward and above the ear. The scalp flap was loosened and turned downward. On introducing the finger the bone was found to be fractured into several fragments, and at the anterior edge to be depressed about one-half an inch.

The nature of the injury and the operation required being explained to him, he expressed his entire willing- ness to submit to my judgment. He was put into a hack and driven to his home, which was about half a mile distant.

Patient being etherized, I proceeded to operate, being assisted by Drs. Abbott and Axtell. I first enlarged the opening in the soft parts, both forward and backward, and drew the flap well down. On examination the bone was found to be so much crushed as to put elevation out of the question, so I proceeded to remove the fragments. First removed a small fragment from anterior inferior region of depression. This seemed to be a portion of the tip of the great wing of the sphenoid. Next removed from posterior superior region a fragment about size of a silver twenty-five-cent piece, and on examination of inner surface of this found the groove which lodges the termination of the trunk and the beginning of the two branches of the middle meningeal artery, thus demonstrating it to be the anterior inferior angle of the parasphenoid bone.

Next was removed from the lower region a fragment about one and one-fourth inch in length antero-posteriorly and about one-half an inch in width, thought to be parts of squamous portion of temporal and great wing of sphenoid, as a suture was found about midway.
Lastly there was removed from the anterior superior region a piece about the size of a dime. This was depressed so much that it rested almost vertically with regard to the brain, and on raising it the deeper edge was found to rest in the fissure of Sylvius, where it had lacerated the dura mater just posterior to the floor of the fissure. This was the only point at which the dura mater was torn, and as far as could be ascertained the brain substance was not injured.

All small spinal fragments were carefully removed, and all sharp corners gnawed off with bone forceps. A considerable portion of frontal and parietal bones at upper border were fractured and at the lower border depressed and upper border still attached. This lower border was raised with elevator and remained in position.

The wound was then thoroughly cleansed with carbonized water, all hemorrhage stopped, a drainage-tube inserted with the deeper end resting in the fissure of Sylvius and the other end projecting posteriorly, the tube resting on the dura mater for two inches, after which the edges were brought into apposition with silk sutures, and wound dressed with compress and bandage. Patient was kept in a horizontal position as much as was given.

Patient was put to bed and ice-cap applied from the start. Nausea and projectile vomiting on recovering from ether. Soon became conscious of everything.

September 6th.—A.M.: Pulse, 45, of same nature; respiration, 16, deep and regular; temperature, 98.5°. Slept well during night. Mind clear. Pupils respond. Retains food; took 3 ss. of milk at times during night, appetite good. Carbonized water passed through drainage-tube with syringe and 3 ss. pus washed out. Sutures removed from lower part of wound. P.M.: Pulse, 50; respiration, 12; temperature, 101.4°. Slept six hours during day. Took 3 j. of milk and 3 j. of beef tea by mouth. No nausea. Little pain in head. Pupils respond to light. Mind clear. Small amount of pus discharged from tube. Still considerable swelling extending around eye.

September 8th.—A.M.: Wound united by first intention, except a small portion about one inch above outer angle of eye and a portion posteriorly where drainage-tube enters. Complains of dull pain in head. Slept thirteen hours out of past twenty-four. Pulse, 50; respiration, 10; temperature, 98.5°. Took 3 j. of milk, 3 j. of chicken-broth and 3 j. of beef tea. Dull and unrestful. Wound washed through tube and bathed frequently during day with carbolic solution. Ice cap on head from start. P.M.: Pulse, 50; respiration, 14; temperature, 100.5°. Other symptoms same. Urine voided voluntarily. Pupils normal. Doing well in every respect.

September 12th.—A.M.: Passed the first comfortable night without morphia, and this morning feels much better than a day or two since accident. Headache almost gone, and seems cheerful.

From this time forward convalescence was almost uninterrupted. Was taken down-stairs at end of four weeks, but remained in bed until end of seven weeks. Got up and walked about at end of seventh week, and went out of house at end of eighth week. For first ten days after getting out felt very light-headed, and could not walk alone.

December 1st.—Commenced to work, making about three-fourths time, and continued to work for ten days.

December 13th.—I examined wound and found a small point at upper part which had not healed, and through which a small spicula of bone protruded. I attempted to remove this, but failed to ascertain the point at the opposite end. This was followed on the same day by swelling of this whole side of the head, with more or less bulging at seat of injury. At 4 A.M. next day a spontaneous opening took place at wound, with discharge of about 3 j. of pus. Discharge continued about one week, confining him to house. Since then has at different times discharged small spicule of bone, six or seven in all.

Patient feels well, except slight dizziness occasionally, and works every day. Wound healed except a small point where last piece of bone escaped. Head has always been clear.

Careful examination of the fragments of bone removed demonstrates the fracture to have taken place at the point of union of the frontal, parietal, temporal, and sphenoid bones, a portion of each of these several bones having been removed.

When he first resumed work was much annoyed by the noise in the factory, which caused pain, dizziness, and throbbing in the head, but finds himself from day to day suffering less inconvenience from this source.

A peculiarity of this case was the persistently slow pulse, ranging from 40 to 56 per minute for first two weeks. During the third week the pulse gradually increased to 70 per minute, and has been normal since.
The drainage-tube was gradually withdrawn from day to day, and entirely removed on the fourteenth day.

Case II.—Patrick S——, aged nine years. October 5, 1883, while taking walnuts from a tree patient fell from a limb about twenty feet above the ground, striking his head upon a large rock embedded in the earth beneath. He was unconscious for a few moments, but soon recovered and walked to a house about one hundred yards from the tree. He then rode home, a distance of two miles, where he was seen by me about two hours after the fall.

On examination it was found that a semicircular nodule on the face of the rock had penetrated the left parietal bone near the posterior superior angle, making, as it were, a bony flap or valve hinged on the sagittal suture where the bone was even with the opposite parietal, but depressed externally so that the outer table of the depressed portion was on a level with, or below, the inner table of the surrounding bone.

Patient being perfectly conscious and there being no unfavorable symptoms, I merely spared the wound carelessly with carbolized water till thoroughly cleansed, laid a drainage-tube in the cut, and stitched the scalp over it. Ordered the wound syringed with carbolized water every four hours, changing the bandage and control fever and restlessness, and enjoined absolute quiet.

Patient did not sleep well the first night, and had some vomiting the next morning after taking too much milk. With these exceptions made an uninterrupted and speedy recovery. Was in bed two weeks, clear-headed and comfortable all the time. The syringing was continued thirty days, during the time of discharge, and after the fourth or fifth day the dressing was completed by the application of balsam of Peru to the wound. At the third week he was playing in the kitchen. Seven weeks after the accident patient walked to the office—one mile—saying that the discharge had commenced again. On examination I found a serousum, which on removal forced him to being about one inch long, one-fourth inch wide, and one-eighth inch thick, which I removed.

December 22d.—Has been going to school for past two weeks. Has no head symptoms and is perfectly well.

I was led to adopt this conservative course of treatment on account of the youth of the patient, and his greater liability to spontaneous recovery than the adult.

Fever Attitude.—Under this title (courbature fiébrile) Dr. C. Eloy describes the condition characterized by a moderate degree of pyrexia, some gastric disturbance, and extreme lassitude, with a bruised feeling in the muscles. There is often a constant headache with pains in the legs and lumbar region. The fever is moderate, seldom more than two or three degrees above the normal, and usually presents an evening exacerbation. The digestive disturbances are slight. The abdomen is soft and painless, and without any eruption. Constipation is the rule. The fever subsides in three or four days, but the headache and anorexia remain for a few days longer. The cause of this condition is found in excessive fatigue following prolonged muscular exertion. It also results from exposure to extreme cold or heat. Violent emotion or a severe mental shock may cause similar phenomena. It is due to disturbances in trophic innervation, and occurs with great frequency at the two extremes of life, when the nutritive processes are either very active or very sluggish. It may at the outset be mistaken for a commencing typhoid fever, but a short time suffices to clear up the diagnosis. It may be distinguished from a bilious attack by the condition of the tongue, which in the latter is heavily coated, while in courbature it is usually clean. The treatment consists in taking a moderate dose of sulphate of iron with a small dose of new wine. The feeling of extreme weakness is best relieved by cocoa or alcohol in some form.—L'Union Médicale, May 24, 1884.

Reports of Hospitals.

ST. MICHAEL'S HOSPITAL, NEWARK, N. J.

A Case of Cancer of the Pancreas and Omentum.

(Reported by Charles D. Bennett, M.D., House Physician.)

MINA K——, aged forty years, married, born in Germany, was admitted to St. Michael's Hospital on January 14, 1884. Patient dated the commencement of her illness eight weeks ago. At that time, while engaged in housework and lifting a heavy tub of water, she was seized with a sudden and severe lancinating pain in the abdomen, having its origin a little above and to the right of the umbilicus, radiating downward toward the bladder. This pain continued and was so severe that she became faint, vomited, and was compelled to lie down. A physician being summoned, a hasty diagnosis of renal colic was made, morphine administered hypodermically, and the pain relieved but not entirely removed. The pain continuing for several days, another physician was called, who finding now no lancinating pain, and only a dull, steady aching across the lumbar region, diagnosed lumbago, ascribed the foregoing symptoms to hysteria, and applied a blister to the left of the spinal column. Her pain now became less severe, and for two or three weeks, although never without pain, she felt much better and able to work, but soon her sufferings increased and finally she entered the hospital in the service of Dr. J. T. Wrightson. Until her present illness began she had been very healthy save for a slight attack of acute Bright's disease seven years ago and for occasional mild attacks of dyspepsia.

On admission patient was well nourished, rather corpulent, and of good color. She complained of severe pain all over her abdomen, most intense about three inches above the umbilicus and a little to the right of the median line and extending around the abdomen nearly to the spine. This pain was steady, not at all colicky, of a dull character and accompanied with considerable tenderness, also more marked in the left hypochondrial region. This tenderness was so great that no examination by palpation could be endured. Patient's bowels were and had been rather constipated, there was no nausea or vomiting. She had no tympanites, nor had there been any serious disturbance of the digestive tract, although close questioning revealed that she had suffered slightly from dyspepsia with occasional vomiting for about a year, a statement which, in the light of subsequent developments, became of considerable importance. Pulse was 146, temperature 101 1/2° F., P.M. She was given sufficient morphine to quiet the pain and hot fomentations applied over the abdomen.

The next day, although her pulse continued at 120 and temperature 102 1/2 A.M., and 102 1/2° P.M., she felt much easier. Her abdomen was much less tender, and on closer examination at the point of greatest tenderness could be felt a hard mass, smooth, of irregular outline, deep attached in the abdominal cavity, immovable, and yielding on percussion a dull note, into which a tympanitic element entered, as if a coil of intestines lay over the mass.

The area of dulness was ill-defined, but extended farthest in a transverse direction toward the liver, but it was doubtful as to whether it joined the dull area over that gland. It appeared to correspond pretty closely with the transverse colon, and one or two of the consultants believed the mass could be indented and ventured a diagnosis of impacted feces.

Acting on this opinion a cathartic was given, causing several very profuse stools and yielding some relief. Still the mass persisted much the same. Patient was allowed to remain quiet for several days, during which active purgation was continued, bringing away copious stools. But the fever and the rapid pulse continued and the patient showed signs of emaciation.
The fingers, pressed firmly on the mass, detected a tremendous pulsation, evidently transmitted from the aorta. This seemed to be simply an upward impulse, and no lateral expansion could be perceived. Stronger pressure with the palm of the hand stopped the beat in both femoral arteries. Nothing could be heard by auscultation. The urine has been normal in quality, but in quantity, since the initial attack of pain, rather deficient. Two days later the tumor was aspirated, and about four ounces of a light, reddish-brown, opaline, serous fluid, of specific gravity 1.020, and which turned nearly solid with nitric acid, were withdrawn.

Under the microscope this fluid presented no distinguishing characteristics. It contained great quantities of epithelium in an advanced stage of fatty degeneration (the "compound granular cells" of Besse), many leucocytes, a little blood, and a few pavement epithelial cells not yet fatty—indeed, such a fluid as might be drawn from any benign cystic growth.

Vaginal examination revealed a profuse leucorrhoeic discharge, the uterus slightly enlarged and firmly fixed, and surrounded on all sides by hard masses, evidently the exudation of peritonitis.

Patient continued in much the same condition for several days, but was evidently failing under her disease. Her daily temperature varied from 101° A.M. to 102° P.M., and her pulse beat steadily at about 120. Emaciation had made rapid strides. She was much weaker, her fever continued, and she was losing her memory and began to become delirious. The day or two after lying for two days in that condition she died, twenty-four days after admission.

At the autopsy, held twenty-four hours after death, no pathological phenomena were found in the chest, save numerous pleuritic adhesions on the right side, moderately firm. On opening the abdomen no evidences of general peritonitis or pelvic peritonitis were apparent; there was considerable ascitic fluid, and low down in the pelvis, surrounding and fixing the uterus, were large masses of the exudation characteristic of pelvic peritonitis. In the great omentum were found masses of scirrhous cancer, increasing in amount toward its gastric extremity and involving and binding together in one mass the stomach, pancreas, omentum, the glands of the mesentry and those at the portal fissure of the liver, and surrounding but not seriously constricting the transverse colon. The mucous coat of the stomach was not yet diseased, and the pylorus was only slightly constricted.

The intestines were apparently not affected, and at no place was the mucous lining marked. There was little or no ascitic fluid and no extravasation of blood or other fluids. The entire peritoneal cavity was occupied by the cancerous growths which were concretionary in character, and cut the passages of the contents. The pancreas presented scirrhous disease throughout its whole extent, and was apparently the organ in which the process originated. The gall-bladder was very small and filled with dark, thick bile. Its duct ran through the cancerous mass and must have been constricted, but the bladder was not at all enlarged. The right kidney was slightly enlarged and showed considerable fatty degeneration. Where the right ureter dipped into the pelvis a broad band of inflammation tissue ran across and compressed it, so that the pelvis of that kidney was considerably dilated, containing about two ounces of urine. In one of the calices of this kidney was found a calcareous (phosphatic) mass, perhaps one-third of an inch in diameter. The other organs were normal.

Remarks.—Was this a case of primary cancer of the pancreas, or was it omental, involving the pancreas secondarily?

Jenner, quoted in Reynolds' "System of Medicine," vol. iii., p. 423, writes: "No symptoms are pathognomonic of cancer; an assemblage of symptoms indicates the probability of its lesion." But all authorities agree that pancreatic disease causes obscure digestive symptoms. Now for a year this woman had had slight trouble with, as she supposed, her stomach, yet the symptoms of local trouble in the stomach were very few, and the presence or absence of food seemed to make little difference as to the pain. Moreover, the autopsy showed the gastric mucous membrane to be healthy and the peritoneal coat only slightly involved, and that near the pyloric extremity, as if the disease were attacking it by extension. Then the eleven months of slight vomiting and dyspeptic pain, followed by the ten weeks of severe pain with fever, might well be explained by the theory of primary cancer of the pancreas suddenly taking an active growth and attacking the peritoneum and adjacent organs.

Again, Waldeyer's theorem, that true carcinoma invariably originates from epithelium, as distinguished from endothelium, has never been disproved, but is rather gaining ground. If it is true, the probability of the disease in this case originating in the pancreas is great, for in no other portion of the infected tissue can true epithelial cells be found save in the pancreas.

In no portion of the cancerous mass could any signs of degeneration be distinguished by which the comparative age of different parts could be estimated. So with the negative evidence of the autopsy and the meagre history of the case prior to the severe stage it seems impossible to locate the origin of the disease positively, but there is at least a strong probability that it was pancreatic.

The case well illustrates the difficulties which occasionally arise in the examination of abdominal tumors. The diagnosis here was not made before death. Her history pointed rather to an acute trouble, as if it only involved the right kidney. Death came on rather suddenly, so little noticed by her that even though she was of rather more than ordinary intelligence and anxious to tell all she knew about herself, she said nothing about any stomach trouble until closely questioned, and even then was disposed to consider it of no significance.

Again, her health appeared quite good and the utter absence of cachexia seemed to exclude any chronic disease, especially one known to induce emaciation and loss of strength. Our patient was beginning to show the ravages of her disease before she died, but so little progress had emaciation made that at the autopsy the fat on the abdomen was nearly two inches thick and the mesentry correspondingly heavily loaded.

The mode of onset of her serious symptoms apparently indicated some grave obstructive troubles, such as the passage of a renal or gall-stone or the internal strangulation of intestine. The latter opinion, at first seriously considered, was gradually abandoned as the case wore on, but the former rather gained than lost in favor. The case suggested to us the idea that the most striking feature of the disease was the great enlargement and persistence of the mass without the slightest indication of local trouble in the stomach or intestines, and further that the diagnosis showed the falsity of the first attack of pain was due to the impaction of a renal calculus in the ureter; that thus was caused obstruction to the flow of urine and subsequent dilatation of the renal pelvis, running on to hydropnephrosis. The aspiration only strengthened this view, and although the autopsy showed that no hydropnephrosis existed, it is still a matter of doubt whether or not the first attack was due to the passage of a renal calculus.

No search for the stone had been made in the voided urine, and the concretion found in the right kidney showed that some deposit of urinary salts had certainly occurred.

The compression of the right ureter by the inflammatory band was not sufficient to account for the painful symptoms, nor could the dilatation of the renal pelvis produce them.

The cause of the pelvic peritonitis was not manifest. The inflammation was strictly confined to the pelvis, and the peritoneum elsewhere, except where distinctly cancerous, was apparently perfectly healthy.

Looking back over the case, it is hard to see how a positive diagnosis could have been made. None of her symptoms warranted the anti-mortem diagnosis of pancreatic disease, and in fact the symptoms subsequent to her first attack, ten weeks before death, were such as might be explained by almost any abdominal tumor complicated with peritonitis.
THE MEDICAL RECORD.

Progress of Medical Science.

PROPHYLAXIS OF RABIES.—Professor Sperino finds an analogy in the pathogenicity of syphilis and rabies in the following facts: 1, there is in each of the diseases a long period of incubation after the introduction of the virus; and 2, in many cases in rabies, as in syphilis, there is induration around the point of introduction of the poison, and in a few days an adenopathy arises in the lymphatic glands situated above the infecting part. Afflicted by these resemblances, and by others of minor importance, the author tried the effects of mercury in eleven individuals bitten by mad dogs. The cases were seen from three to twelve days after having been bitten. Mercurial fumi were made to the affected limbs until the adenopathy had completely disappeared. None of the persons so treated was attacked with hydrophobia. Though no positive deduction can be made from so small a number of experiments, yet the favorable results obtained in these eleven cases would suggest the utility of further trials of Sperino's method.—Giacente delle Malattie Veneree e della Pelle, April, 1884.

CHLORFORMIC PURPURA.—Dr. Morel-Lavallée has observed an erosion of purpuric spots occurring within a minute or two after the administration of chloroform was begun. The macules were small, about one-seventh of an inch in diameter, and a few were raised up in the form of purpuric blebs. The erosion occupied chiefly the anterior portion of the thorax, and was absent from the under part of the body. The author did not regard the erosion as due to the action of the chloroform, but thought it resembled rather the purpura, described by Vidal and Fournier, caused by violent emotion.—Giornale Italiano delle Malattie Veneree e della Pelle, March, April, 1884.

HYSTERIA IN THE MALE.—At a recent meeting of the Hospital Society of Paris, Dr. Debove related the case of a man who had an attack of what resembled apoplexy followed by hemiplegia, while at the same time there were contractures of the affected muscles. These attacks were cured and recurred three times in as many years. In other similar cases the author had obtained excellent results with the magnet, and he proposed to attempt the same treatment in this case. He expressed the opinion that hysteria is a much more common condition in man than is generally supposed.—Journal de Medecine et de Chirurgie Pratiques, May, 1884.

AMBLYOPIA FROM TOBACCO.—The distinguishing characters of this form of amblyopia, according to Dr. Maselon, are as follows: 1. Reduced vision in varying degree, appearing gradually or suddenly, affecting both eyes; but of unequal intensity on the two sides. There is the appearance of a veil before the eyes, or of a cloud in which the patient sees at times to see snow-flakes falling. The sight improves somewhat after sunset. 2. Central scotoma for colors. This is a sign always present, and one of special diagnostic importance in those cases in which the ophthalmoscope reveals no lesion. The following is the author's mode of testing the color sense. A card is pierced with a hole four or five lines in diameter, and at the distance of three lines from the hole a dot is marked on the card. One eye being closed, the patient looks attentively with the other at the hole in the card behind which other colored cards are passed. It is found that blue is the only color recognized without hesitation; green is taken for a light gray, and red for a dark gray or black. If the patient now looks at the point beside the hole, and not at the hole itself, he distinguishes the three colors without difficulty. Thus in amblyopia from tobacco the three colors are indistinguishable, and this is in contrast to the conditions existing in amblyopia. In some cases of long standing the green cannot be determined in the second test. This is because the scotoma for this color has increased to such an extent as to cover the entire visual field. Patients thus affected complain of their inability to distinguish gold from silver coin. 3. Finally there is a modification of the field of vision in the perception of white. This is not ordinarily noticed, but a careful examination will reveal the fact that the greater part of the upper half of the visual field is the seat of a scotoma of varying intensity, but of equal extent in the two eyes. According to the author this symptom is pathognomonic.—Gazzetta Medica de l'Algerie, May 15, 1884.

DEATH FROM HEMORRHAGE AFTER TRACHEOTOMY.—The Paris correspondent of the British Medical Journal of May 24, 1884, writes that M. d'Heilly, at a recent meeting of the Societe Medicale des Hopitaux, showed some pathological specimens removed from a child which had died after tracheotomy for diptheria. The canula had been kept permanently in position only a short time, and for some days before death occurred it was removed during several hours in the day. Toward the twelfth day violent hemorrhage occurred, both tracheal and buccal, and death quickly followed. At the necropsy it was found that the anterior wall of the trachea was ulcerated, and that the ulceration extended to the innominate artery. The seat of the ulceration corresponded to the position of the canula. M. d'Heilly therefore concluded that the rubbing of the sharp edge of the canula against the wall of the trachea caused the ulceration. Two similar cases have been previously recorded.

TRAUMATISM.—This is the name given by Dr. Schivardi (Gazzette degli Ospedali) to a solution of one part of gutta-percha in ten of chloroform. When applied by means of a brush to the skin it forms a firm and durable pellicle. It may be used pure in place of collodion, or as a vehicle for the application of various medicaments to the skin. It is an excellent excipient for chrysarobin or for pyrogallic or salicylic acids. The application is unirritating.

KAIRIN IN PHYSIS.—Dr. Sorgius states that he has used kairin with good effect in reducing the pyrexia in pulmonary phthisis, and has never observed any unpleasant action of the drug. It exerts no influence, however, upon the local condition of cases, and demands considerable watchfulness on the part of the physician, it is suitable only for use in hospital practice.—Wiener Medicinische Wochenschrift, April 26, 1884.

HEMORRHAGE FOLLOWING SCARIFICATION OF THE CERVIX.—Dr. A. Muratoff relates a case in which he scarified the cervix uteri, making three incisions on either side of the external os. As the operation was well borne and seemed to answer the indications in the case, he repeated it a second and a third time. A short time after the last scarification the woman was seized with such severe a hemorrhage that it was found necessary to pass a suture through each of the incisions in order to control it. The author concludes from this experience that scarification of the cervix uteri is not so trivial an operation as is usually supposed, and he warns his readers not to lose sight of the patient until some hours have elapsed and it is certain that no more bleeding will occur.—Deutsche Medicinale Zeitung, May 12, 1884.

TREATMENT OF INDOLENT SINUSES.—Dr. W. W. Hall recommends sponge-grafting to promote the healing of indolent sinuses (Edinburgh Medical Journal). He relates an instance in which he had used all the ordinary means without success. He then determined to try the effects of sponge-grafting. A long, narrow strip of sponge was prepared by soaking in nitro-muriatic acid, and then, after being sterilized, was packed into the sinus completely filling the tract. An antiseptic dressing was then applied, and the sinus healed rapidly, leaving only an insignificant cicatrix.
THE MEDICAL RECORD:

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY
WM. WOOD & CO., Nos. 56 and 58 Lafayette Place.

New York, June 21, 1884.

AN OCCASIONAL CAUSE OF FAILURE AFTER OPERATIONS.

No one but a blind skeptic can for a moment doubt that operative surgery has taken immense strides ahead in the past few years. The discovery of anesthesia, the prevention of hemorrhage during an operation, and the general adoption of antiseptic precautions in one form or another, not to speak of increased skill in operating, in which respect we are perhaps not so greatly superior to our fathers, have all contributed to better the chances of the patient as well as to encourage the boldness of the surgeon. It is but a truism to say that operations are now undertaken and successfully terminated which a few years ago it would have been deemed madness to attempt. Nevertheless, the success even of the best operators is not uniform. It sometimes happens that a case in which everything seems to conspire to render a favorable result certain, and where every precaution has been taken to avert disaster, terminates unsuccessfully. Now, it is eminently unscientific to attribute these failures to chance or poor luck, and such cases ought to be most carefully studied, in order, if possible, to determine the reason of the evil termination, so that the same error may be avoided in the future. In an article on this subject (Schmidt's Jahrbücher, No. 10, 1883), Dr. D. Domec calls attention to one frequent cause of failure in surgical operations, or of evil results following apparently insignificant injuries. This resides in some constitutional fault or diathesis hitherto latent, and only called into action by the traumaism. He does not, of course, refer to evident cachexia which every surgeon recognizes and dreads, but to latent dyscrasia, often inherited, which may have previously given no sign of their existence, and which might never have declared themselves were it not for the traumaism inflicted either by accident or by the knife of the surgeon. The recent French literature contains numerous illustrations of untoward results following operation, or injury, directly chargeable to one or other of these unrecognized constitutional taints, where, had the conditions been previously understood, preventive measures might have been adopted in time and the evil averted. We have learned how to fight and to overcome the enemies from without, but are only too apt to forget that a more insidious foe may lurk within, whose evil work may be accomplished even before we are aware that he is present.

THE DANGERS OF THE LOOKING-GLASS.

It would seem as if the catalogue of perils to which we are exposed while peacefully resting in our boudoirs, or sleeping the sleep of the just in our bedchambers, is never to be complete. Every few days we are startled by the discovery of some unsuspected source of evil, and learn with alarm that our feeling of security was baseless, and that the enemy was working destruction under the guise of a friend. The wall-paper, the carpets, the upholstery, the furnace, the fresh-air flue, and the area drain have all had their evil actions brought to light, and now the aged mirror, which seemed to be an angel of light, is shown to have worked deeds of darkness. Dr. Neunheir (Centralblatt für Klinische Medicin, March 15, 1884) reports having met with several cases of chronic mercurial poisoning, manifested by severe stomatitis with pains in the lower jaw, swelling of the submaxillary glands, ptyalism, and a fetid breath. The presence of mercury in considerable quantity was also detected in the urine. In two cases, of a man and his wife, the cause of the trouble was in a looking-glass hanging in the bed-room, the wooden back of which was dotted with thousands of minute globules of mercury. The apartment was heated during the night. In another instance the source of the poisoning was a mirror, forty years old, whose back had become weak and from whose face the quicksilver freshness was fading. The aged culprit having been summarily removed, their victims speedily recovered. Thus has yet another of our trusted friends been proved false! And now we must either destroy our mirrors while they are yet young and innocent, or else keep a watchful eye on them and brace up their backs the moment the signs of decrepitude become apparent. If worse comes to worst, we can at least take refuge in the burnished steel of our forefathers.

IMPORTANT TO VACCINATORS.

The Local Government Board of England has at last published the official records of Dr. Cory's experiments in vaccinating himself with lymph from the arms of syphilitic children. After three experiments which were failures, Dr. Cory finally succeeded in inoculating himself with syphilis, using the pure lymph without any blood. His experiments conclusively prove, in the opinion of a committee appointed to examine them, and composed of Dr. Bristowe, Dr. Humphrey, Dr. Ballard, and Mr. Hutchinson, "that it is possible for syphilis to be communicated in vaccination from a vaccine-vesicle on a syphilitic person notwithstanding that the operation be performed with the utmost care to avoid the admixture of blood." The results of Dr. Cory's experiment are important, and should be widely known. No doubt the anti-vaccinators will take pains to diffuse information concerning them.

The British Medical Journal attempts, wrongly, to belittle the facts elucidated by Dr. Cory. It states that the lymph was taken from a child in the active stage of syphilis with cutaneous lesions; that no careful physician would ever use lymph from such a child, and that in practice, by the observance of recognized rules, there can be no danger of transferring syphilis. All this is probably true, but no one can deny that if the lymph of a
syphilitic is a bearer of contagion at one time, it may be at another, and that the absence of cutaneous lesions does not with absolute certainty show that the lymph is harmless.

The lesson from Dr. Cory's experiments is that vaccination should be done with increased care, and that bovine lymph should be used when any of good quality can be obtained.

THE COPENHAGEN CONGRESS.

We have received a copy of the official programme of the Eighth International Congress, to be held at Copenhagen, August 10 to 16, 1884.

A glance at its contents shows that the profession may expect the meeting to be one of real scientific importance and interest. The papers promised are not nearly so numerous as at the last session, but we observe with pleasure that many of the leading and representative physicians of Europe are to be present and contribute to the work. In the general meetings, addresses are to be delivered by Virchow, Pasteur, Sir William Gull, Cruedi, Verneuil, and Panum, every country being represented except Austria and America.

The Sections on Anatomy and Physiology are particularly promising, thirty-seven papers being announced. Among the readers we observe the familiar names of Bizzozero, Ranvier, Merkel, Meyer, His, Kölliker, Hammarsten, Malassez, Heidenhain, Munk, Marey, and Burdon-Sanderson.

In the Section on Pathology, Koch, Cornil, Gull, Friedländer, and others, will read papers.

In the Section on Medicine, papers will be read by Jürgenssen, Liebermeister, Bouchard, Ewald, Leube, Austin Flint, and others.

Surgery is to be represented by such men as Esmarch, Lister, Schede, Bert, Gussenbauer, Ferrier, and Lucas-Championnière; Obstetrics by Lawson Tait, Schröder, Simpson, Mikulicz, Hegar, and others. In the ten other Sections equally prominent names might be cited.

The official languages of the Congress are German, French, and English. It is worthy of note, as showing the broadness and cosmopolitan character of medical science, that the language of the city and country in which the Congress is held is not to be used.

THE ANALYSIS OF CUCUMBERS.

Dr. Waller's report to the Health Department on the analysis of cucumbers, which he found contained the equivalent of 2,515 grm. of copper sulphate per pound, added for the purpose of imparting a bright green color, reminds us of the conflicting testimony given by high authorities in the English courts in 1877, on the occasion of the trial of some dealers who had been arrested for selling peas colored in like manner.

The amount of metal found in the peas corresponded to from 2 to 2½ grm. of copper sulphate per pound.

Dr. Pavy testified that in his opinion this amount was harmless. Pereira was quoted as saying that 6 grm. of copper (sulphate?) could be repeatedly administered without injury to health. On the other hand, Drs. Tidy, Dupré, and Pless all expressed a belief that the proportions of copper found were injurious.

Dr. C. Evans said that the amounts might be injurious to some and not to others. He also asserted that 20.4 per cent. of cases of accidental poisoning in France were due to the use of copper culinary utensils.

Dr. Guy testified that poisoning had occurred from small amounts of copper; that repeated small amounts were more dangerous than large, as the larger quantities would have an emetic effect.

The decisions in these cases were against the vendors. The discussion, however, was taken up by the Society of Public Analysts. In a paper read before this Society, Messrs. Paul and Kingsett ( Analyst, vol. ii., p. 98) reported that they had each taken daily doses of 0.3 grm. of copper sulphate without ill effects. The urine contained no copper after this, but considerable amounts were found in the feces. Dr. Rowe cited cases where water containing copper, in one instance to the extent of 16 grm. per imperial gallon, was taken without producing ill effects on those drinking it. Dr. Thompson stated that he had exhibited 1 grm. daily to a dog for some time without apparent effect. Dr. Redwood asserted that he knew of cases of poisoning from canned peas, where each pound of the vegetable contained 2 grm. of copper.

Dr. Galippe ( Comptes Rend., vol. lxxxiv., p. 718) refers to results obtained by him in 1875, where he proved (to his own satisfaction at least) that large doses of copper sulphate produced vomiting, while small ones had no apparent effect.

Dr. Blythe's comments as follows on these cases: "1. The whole question of the injurious action of coppered peas rests entirely on theory; 2, the theory of the poisonous action is based by single case upon any observed instance of chronic or acute poisoning; 3, in no case has the Analyst been able to state the form in which the copper exists." He characterizes it as an adulterative, but is unwilling to assert that it is an injurious adulterant.

We believe that the addition of copper compounds to articles of food is dangerous, and should be prohibited, and we are glad to see that the Health Board takes the same view of the question.

News of the Week.

THE LONG AND SHORT OF THE MILK TREATMENT.—The last issue of the Journal of the American Medical Association devotes eight columns to an article on "Milk Treatment of Disease." The London Medical Press and Circular, May 11, 1870, gives the same information in eight lines.

Dr. George B. Fowler has been elected Professor of Physiological Chemistry in the New York Polyclinic.

The Governor has vetoed an appropriation of $25,000, for enlarging the homeopathic lunatic asylum at Middletown.

Another Discoverer of the Yellow Fever Germ.—Dr. L. Girerd, of the Panama Canal Company, has successfully cultivated the yellow fever germ, and has inoculated many animals. He is about to publish his observations.

[June 21, 1884.] THE MEDICAL RECORD.
THE MEDICAL RECORD.

[June 21, 1884.

THE INDEX MEDICUS.—The last issue of this valuable periodical states that, despite the death of the publisher, Mr. Leyboldt, it will be continued in its present form until the end of the year.

SUING A MEDICAL COLLEGE.—A suit has been begun in Atlanta, Ga., against the Eclectic Medical College of that city. It is charged that this institution has granted diplomas to persons who have not studied medicine two full years as required by the law of the State. The suit is for $15,000, one-half to go to the informer.

A PROVINCIAL MEDICAL JOURNAL.—The Midland Medical Miscellany has just published two editorials from The Record in its own editorial columns without any acknowledgment. Our contemporary is undoubtedly doing the best thing possible to make its columns brilliant and attractive. But such methods are not considered honest over here. We beg our provincial contemporary to desist.

NEW PARKS FOR NEW YORK CITY.—The Governor has signed the bill providing for new parks for this city.

CHOLERA IN CATS.—Mr. John C. Lucas refers in the Lancet of May 24th to an epidemic of cholera in cats occurring at Ahmednugghur and Sirroor, and reported upon by the Government of Bombay. He refers also to another epidemic which occurred at Delhi in 1875. It thus seems to be established that cholera can at times affect pigs and cats. Yet Koch failed to produce the disease in them with his bacilli or by other means.

DR. WILLIAM A. HAMMOND'S NOVEL, entitled "Lal," is announced by the Appleton to appear this month.

ERGOT AND GRASS.—Dr. S. C. Franks, of Bentonport, Ia., writes that "in Iowa and also in Kansas and all Western States we have a wild rye growing with the grass, from which the cattle obtain the ergot."

DR. CHARLES J. KIPP, of Newark, N. J., writes: "In the report of the meeting of the Medical Society of New Jersey, I am made to say that in 24.3 per cent. of the cases of purulent ophthalmia of the new-born treated the cornea was damaged. What I said was that in 24.3 per cent. of the cases corneal disease was present when the cases came under my care. Furthermore, I did not say that corneal complications are most easily subdued by local depletion, etc., but that they require in addition to the other treatment instillations of atropine and eserine. With regard to the indications for the use of the nitrate of silver I said that they were a copious purulent discharge and swelling and succulence of the conjunctiva; but I did not say anything about shreds of nerve or less firmly adherent fibrin.

FREE HOME FOR DESTITUTE YOUNG GIRLS AT 23 EAST ELEVENTH STREET.—As probably few medical practitioners in this city know of the existence of such an institution, and as they often encounter just such cases of distress as this Home is intended to relieve, we are very glad to insert the following brief notice: "Destitute young girls under twenty-five years of age, of all religious denominations and of good character, received free of all charge for a month or more, and places found for them in the country. Matron, Mrs. V. M. Bokee; Officers, Mrs. J. W. Baker, Mrs. H. K. Thurber, Mrs. Henry W. Johnson, Mrs. John H. Mortimer."

ANALYSIS OF PICKLED CUCUMBERS.—Dr. Elwyn Walters, chemist of the Health Department, in his report to the sanitary authorities on the analyses of pickled cucumbers colored artificially with copper, lays stress on two facts noted by him. 1. The cucumbers contained a much larger proportion of copper than the vinegar in which they were immersed. 2. Cucumbers in the same lot contained widely different amounts of copper.

The first fact refutes the assertion on the part of the manufacturer, that soaking the pickles in water or vinegar removes the copper, and also shows that the vegetables have a certain amount of affinity for the metal.

The second fact demonstrates that the method of coloring—immersing a plate of copper in a vat containing cucumbers and vinegar—causes the cucumbers nearest the copper to absorb more of the poison than those situated a little distance off.

The doctor has found copper in all cereals and vegetables grown in soil containing it. Consequently he states that "the question of fraudulent addition of cupric salts to articles of food turns not on the mere presence of copper, but on the proportion present." More than ten parts per million, according to Dr. Dupré, indicates artificial or accidental contamination.

Reports of Societies.

AMERICAN NEUROLOGICAL ASSOCIATION.

Tenth Annual Meeting, held in New York, June 18, 19, and 20, 1884.

WEDNESDAY, JUNE 18TH—FIRST DAY—AFTERNOON SESSION.

The Association met in the hall of the New York Academy of Medicine, and in the absence of the President, Dr. ROBERT T. EDES, of Boston, was called to order by Dr. W. J. MORTON, of New York, Vice-President, who made a few appropriate remarks on the progress which had been made in neurology, and then introduced the President-elect, Dr. ISAAC OTT, of Easton, Pa.

THE PRESIDENT'S ADDRESS.

Dr. Ott, after thanking the Association for the honor it had conferred upon him, delivered an address on "The Paths of the Various Fibres in the Spinal Cord." It is now about seventy years ago that Charles Bell announced that the anterior roots of the spinal cord were motor and the posterior sensory. During this period many thousands of experiments have been made upon the paths of conduction of motion and sensation in the spinal cord, with a gradual increase of knowledge. The physiology of the spinal cord as taught to-day is mainly due to perfection in technique; that is, the use of immovable protecting knives and the subsequent microscopic examination of the hardened cord, two points neglected by Professors Schiff and Brown-Séquard. Up to 1840 various opinions were held by different observers, when Longen arrived at the conclusion that the anterior columns were motor and the posterior sensory.

Brown-Séquard also made an extended series of experiments, and believed that the transmission of sensory impressions in the cord takes place chiefly through the gray matter and partly through the anterior columns; that the voluntary impressions in the posterior part of the cervical portion were in the lateral columns and in the gray matter between them and the anterior columns; that no tactile sensations ascend the posterior columns to the brain. These views, it is fair to state, have been somewhat modified.
Professor Schiff's idea of the spinal cord is that the posterior columns conduct tactile impressions; that the gray matter conducts in all directions affereent impulses, which give rise to affections of general sensibility, and such afferent impulses as are paths of reflex action.

Dr. Ott then gave Schiff's theory of the spinal cord. He mentioned these views to show that the statements made were greatly in need of correction. According to Ludwig's experiments made on the lumbar cord of the rabbit, sensory and motor fibres run in the lateral columns. Dr. Ott had, in conjunction with Dr. R. R. Smith, proved that the same statement was true for the cervical segment of the spinal cord of the rabbit. By subsequent experiments on kittens he had proved that, in addition to the lateral columns, the anterior contained voluntary motor fibres.

Dr. Ott then gave a résumé of the experiments which had been made by Wordscifff, Kussnin, and others, all of which went to show that the lateral columns were the principal conductors of sensation and motion; that the gray matter does not directly participate; that the anterior columns conduct voluntary motion.

As regards the posterior columns, Dr. Ott could substantiate Professor Schiff's assertion that after bleeding a rabbit and dividing the whole cord, except the posterior columns, impressions of touch were still conveyed. That tactile impressions also pass up the lateral columns is also true. He had not referred to the recent works of comparative anatomists, but in the main they were in accordance with these views.

Dr. Ott also stated that decussation of fibres in the central nervous system was quite extensive; thus the motor, sensory, vaso-motor, sudorific, and inhibitory, the two latter running in the lateral columns, all cross over each other.

NOMINATIONS FOR MEMBERSHIP.

Drs. Sarah J. McNutt, J. Leonard Cornning, and Geo. W. Jacoby, of New York, and Dr. G. Belton Massey, of Philadelphia, were nominated for membership.

Dr. S. F. Danils, privy-docent at the Imperial Academy of Medicine, St. Petersburg, Russia, was nominated by Dr. Morton for Associate Member.

ELECTION OF OFFICERS.

President—Dr. Burt G. Wilder, of Ithaca, N. Y.; Vice-President—Dr. Leonard Weber, of New York; Secretary and Treasurer—Dr. Grant M. Hammond, of New York; Councilors—Drs. W. R. Birdsaull and W. J. Morton, of New York. The tellers were Drs. Bannister, of Chicago, Ill., and W. J. Morton, of New York.

The first scientific communication was by Dr. Burt G. Wilder, of Ithaca, N. Y., and consisted of an exhibition of preparations illustrating (a) the existence and circumcision of the porcine (foramina monroi) in the adult human brain; (b) the presence of the crista fockatis in fetal and newborn human brains; (c) two additional cases of absence of the callosum in the domestic cat; (d) the covering of the cerebral hemispheres in a young chimpanzee whose brain had been hardened within the skull.

Dr. Amidon, of New York, exhibited a specimen, loaned to him by Dr. Frank Ferguson, of New York, which showed absence of the corpus callosum in the adult human brain.

Remarks were made by Dr. E. C. Spitzka, of New York, and Dr. Wilder, after which the Association adjourned to meet at 8.30 o'clock.

FIRST DAY—EVENING SESSION.

The Association was called to order by the President.

NEW MEMBERS.

After the reading of the minutes the Council reported favorably on the nomination of Drs. Sarah J. McNutt and George M. Jacoby, of New York, and Dr. G. Belton Massey, of Philadelphia, for active members.

The report was accepted and adopted, and the above candidates were elected by ballot.

THE "WILLIAM A. HAMMOND PRIZE."

The Secretary read the report of the Committee, Drs. F. T. Miles, of Baltimore; J. S. Jebb, of Chicago, and E. C. Seguin, of New York, on the Hammond Prize to be awarded to the author of the best essay on the "Functions of the Thalamus in Man." One essay had been submitted which was reviewed in the report, and received exceedingly high commendation, but to its author the committee declined to award the prize because the essay hardly filled the scope of the prize problem, because it treated the functions of the thalamus in a too restricted way, and because the material relating to human physiology of the part was too limited.

The report was accepted, and after considerable discussion, participated in by Drs. Wilder, of Ithaca; Spitzka, of New York; Webber, of Boston; Yana, Birdsaull, and Rockwell, of New York, it was referred back to the Committee with the inquiry whether or not they took into consideration, in reaching their conclusion, the fact that no clause giving them power to reject all essays appeared in their circular, and that it would seem that their elaborate and laudatory comments would have justified a somewhat more favorable report.

Dr. E. C. Spitzka, of New York, gave notice of a proposed amendment to the by-laws, adding a clause which will provide for an executive session in which the election of members, officers, etc., shall be held.

Dr. B. G. Wilder, of Ithaca, then read a paper on macroscopic encephalic nomenclature, which he divided into descriptive and designatory. The object aimed at by the author of the paper was to get rid of the present heterogeneous encephalic names, and to employ, as far as possible, technical names which are brief and composed each of a single word. In other words he offered a monomial system, the advantages of which were (1) brevity, (2) flexibility, (3) adaptability, and (4) capacity for future classification.

The discussion on the paper was postponed until the afternoon session on Thursday.

Dr. A. D. Rockwell, of New York, then read a paper entitled tonic spasm of the diaphragm (?), in which he reported a case, still under observation, and unique in character. Mrs. X—, thirty-five years of age, the mother of four children, began to suffer from peculiar attacks twelve years ago. The patient is awakened from sleep by a vague feeling of pressure and distress about the lower end of the sternum, over the epigastrum, extending to the back—a feeling as if she was being crushed by a great weight. Respiration becomes short and gasping, chiefly with the upper part of the thorax; the pulse remains regular, although it becomes weak; the attacks last from twenty minutes to three-quarters of an hour, require anaesthetics to control them, and leave a sore feeling which remains for several days. There is no evidence of disease of the heart, or genitourinary organs, has been no disturbance of deglutition, no change in the external appearance of the abdominal walls during the attacks, no evidence of the passage of gall-stones. He had excluded angina pectoris, and, although the case lacked some of the symptoms said to be usually present, Dr. Rockwell felt convinced that it was a case of spasm.

There had been a remarkable improvement in the general condition of the patient, and no attack had occurred since he began the use of the actual cautery along the spine, early in this year.
He commended the activity of the few and deplored the indifference of the many for Society work and warmly urged the necessity of the willing participation of each member in elevating the work of the Society by earnest individual effort.

The time and money expended in attendance upon medical associations are well spent and profitably invested, and no medical man is so poor as not to afford to become a member of a society, or should be such a slave to his patrons that he cannot take time to attend its meetings.

It was enjoined upon the members that care should be taken that they do not receive into their offices or admit to their patronage young aspirants for the medical profession who cannot exhibit evidences of preparatory education. The doors should be wide open to the educated, but carefully guarded against the entrance of the ignorant, even at the risk of occasionally excluding a brilliant mind.

The address was concluded by some criticisms upon the present registration law. The writer did not believe registration laws were for the sole purpose of ascertaining the number of births and deaths and cause of death, but that they should be a most valuable genealogical record.

Among the radical changes advised, the writer advocated that physicians should not be the medium through which registration returns should be made.

That in the case of deaths it should be done by the public authorities, and in the case of births by the parents.

Dr. C. P. Bancroft, Superintendent of the New Hampshire Asylum, read a paper entitled "An inquiry into the causes of insanity, with especial reference to prevention and treatment."

Allusion was made to the marked progress in the scientific knowledge of insanity acquired during the last fifty years. The intimate relationship between insanity and general constitutional dyscrasia was shown. The alternation of mind disease and other diseases—such as chorea, epilepsy, phthisis, asthma, and rheumatism—in the same individual illustrate how intimately related are mental alienation and these constitutional diseases, a faulty diathesis leading at one time to insanity and at another time to some other disease. But a certain proportion of the prevailing insanity of the day was considered to be of acute character, and to arise in the majority of cases from an overtaxed nervous system and faulty habits of living.

About seventy-five per cent. of the insanity seen in the State Hospital is chronic in character and arises from general constitutional causes—in other words, from a general constitutional heredity. This class of mental disease is, as a rule, irrecoverable. The remaining twenty-five per cent. is acute in character and proceeds from causes developed by the individual, and not from a dyscrasia transmitted to him. This class of insanity is, as a rule, preventable and as recoverable as any form of acute disease under a proper treatment.

In the chronic types of insanity hereditary predisposition was considered to be the most prominent etiological factor. But especial emphasis was placed upon this point, viz., that insanity itself was not necessarily transmitted from parents to children, but some one of the allied constitutional diseases might appear in its stead. Disorders of malnutrition, such as phthisis, scrofula, syphilis, and the like, may not appear in the descendants in that particular form; they may lead to such an impairment of the great nerve-centres that chorea, or epilepsy, or insanity may appear in conjunction with, or in place of, lung disease or other constitutional affections.

The causes of the largest proportion of the chronic insanity seen in our hospitals are to be searched for in the innermost life of the individual, by means of
which a deteriorated cell-structure becomes established. This in its turn may, by the law of heredity, be transmitted to another generation. And so what appeared as insanity, or phthisis, or epilepsy in the antecedents, may have so weakened and deteriorated the cerebral centres that in the descendants actual mental aberration obtains as a result of a deterioration of the organ of mind; and this retrograde change may have had its origin one, or even two or three generations back.

Undoubtedly the most satisfactory method for the prevention of the large proportion of chronic insanity would be the non-union of men and women in whom exist such dangerous factors as intemperance, phthisis, epilepsy, chorea, syphilis, and other depressory constitutional diseases. But in the present social status of the world this is impossible. The prevention of insanity was unfortunately narrowed down to the judicious treatment of predisposing conditions by one thoroughly versed in the constitutional tendencies of families.

Dr. J. G. ANTOINE, of Antrim, next offered a paper on AIDS IN OBSTETRICS.

Chloroform stood at the head of the list. Its advantages over ether are as follows: its effect was almost immediate; it was not necessary to render the patient wholly unconscious; it did not produce the excitability that ether did, and when given in the following manner was just as safe: Fold a handkerchief, place it in the palm of the left hand, apply it to the bottle of chloroform and quickly invert it twice; grasp it to prevent evaporation and apply to the face of the patient as soon as the pain commences, and remove it when the pain ceases. Never give it to complete anesthesia. When that is necessary use ether. It will stop irregular, spasmodic pains, till the true ones come. The efforts of the patient go on the same, and the uterus contracts as firmly as if no chloroform has been given, and the object being to take off the sharp edges of the pain, which it will do with perfect safety. He had given it about one hundred times and seen no bad result to either mother or child.

The rigid ice yields under the influence of anaesthetics and much time is saved in the first stage of labor. In excessive resistance of the muscular fibre of the perineum, it may be of great advantage. In supporting the perineum, lubricate it with lard or oil, and with the right hand, the ulnar side below the anus, endeavor to raise it toward the symphysis pubis. When laceration seems imminent the application of the short forceps is the greatest aid, for with it the operator can lift the head from the perineum. He had never met with this accident but once when the forceps were used.

When uterine pains become extinct it is much safer to apply the forceps than to give ether. Apply the forceps rather than let the head press against the perineum for hours. The lever is a useful instrument, especially at the superior strait, when it is difficult to apply the forceps, and to convert face to vertex presentation.

THE REPOPT ON SURGERY was read by Dr. EDWARD O. OTIS, of Exeter. First the present status and methods of the antiseptic treatment were discussed, a list of the antiseptics and antiseptic materials at present in vogue being given. Especial emphasis was laid upon the application of the first bandage, particularly with reference to drainage, and the method of drainage by skin and muscle canalization was referred to and explained. The "dauerverband" (lastling bandage) was next referred to, and statistics given from Neuber's "Antiseptischen Wundbehandlung und des Dauerverbandes." In a series of fifty-five cases of resection of the knee-joint, the primary bandage remained untouched in thirty-four until they were quite or nearly healed. Other statistics of like remarkable results were quoted from Neuber.

The method of dressing the wound by Neure and antiseptic dressing was given. In connection with this subject, the matter of rest and immobilization in the treatment of wounds was spoken of. The "absorbent cotton-wool tissue" of Mr. Gamgee was exhibited, and his methods of producing immobilization in particular were explained, the one the plaster-of-Paris posterior splint for fractures of the leg, and the other a handy method for making plaster-of-Paris straight splints for various uses. Next the matter of antiseptic obstetrics was considered, and the conclusion arrived at that with pure air and strict attention to cleanliness, the ordinary lying-in case in country practice will do well and puerperal fever be exceedingly rare. Immediate operation for ruptured perineum, with antiseptic precautions, was strongly advocated.

The surgical treatment of pleurisy with effusion and of empyema was next considered, and early paracentesis was advocated in the former and a permanent opening with antiseptic precautions and dressings in the latter. A description of the method of Dr. Cabot, of Boston, was given, and exhibited. The method of saline injections as a substitute for the transfusion of blood was described, and the apparatus required exhibited; the reader thought it not unlikely that the obstetrician of the future would carry in his bag the simple apparatus for the performance of this operation as constantly as he now carries his bottle of ergot.

Sir Henry Thompson's method of digital exploration of the bladder through an opening from the perineum into the membranous portion of the urethra was next considered, and a case apparently calling for the operation cited in illustration.

Brief mention was made of Otis' method of treating strictures of large calibre by dilating urethrotomy, the reader giving it as his conception that this method of saline injections as a substitute for the transfusion of blood would receive greater and greater attention from the profession. No one could deny, he said, that this method had done very much toward a more exact and intelligent treatment of strictures, and that the most hopeful prospects in gleet were from its use, depending upon Otis' proposition, which he believed true, that gleet was the result of a mechanical condition, namely, stricture.

Mr. Lister's treatment of fractures of the patella by wiring the fragments was referred to in brief, and lastly administrations of ether by the rectum, the writer considering that the dangers of anesthesia were much increased by this method, the degree of etherisation not being under perfect control, and serious intestinal irritation being at times caused. The manner of using this method at the Boston City Hospital was given, with some results, anesthesia having been produced in a time varying from four and three-quarters to thirteen minutes, and with two ounces of ether anesthesia had lasted about thirty minutes.

DR. CHARLES R. WALKER, of Concord, next discussed on SURGICAL CLEANLINESS.

The popularizing of antisepticism by Lister was briefly spoken of. The present status of the spray was then alluded to, and in the light of our present knowledge its use was considered not only impracticable in country practice. The various antiseptics and dressings, the writer thought that, sided by the pure air of the country, one should not despair of keeping a wound aseptic by means of cotton or any thickly applied clean absorbent material.
The second part of the paper was devoted to showing how clean workmanship, as exemplified by accurate coating of surfaces, firm compression, and rest, was the real secret of much of the success of all dressings, antiseptic or otherwise. Finally, he claimed, we impel our results by too frequent dressings, declaring that the law of the greatest antiseptic and antiphlogistic material should govern also the change in all simpler dressings.

Dr. S. M. Dinsmoor, of Keene, read an interesting paper on "Diseases of the Eye," and Dr. S. C. Murrill, of Concord, an essay on the "Treatment of Phthisis."

Dr. E. S. Berry, of Dover, read a paper on RESPIRATORY IRRIGATION IN THE TREATMENT OF EMPYEMA.

The principal object of the paper was to advocate the great value of traction in bringing about a more rapid expansion of the lung, and to illustrate the positive advantages of the treatment of empyema in private and country practice by so-called respiratory irrigation over Listerism. After referring briefly to the opinion held by the profession in regard to tapping the chest, prior to 1850, when Dr. Bowditch contributed such valuable service by his earnest advocacy of paracentesis, the reader proceeded to discuss the comparative advantages of Listerism over free drainage and frequent washing out the cavity, claiming that the application or recognition of the principle of traction in the use of the Lister dressing by Dr. Cabot, of Boston, marked an important advance in the treatment of empyema by Listerism. He then reported a case of empyema, treated by respiratory irrigation, in which one end of a rubber tube was made to penetrate the pleural cavity, and held in place by a rubber disk, the other end opening under a solution of thymol in a bottle, which was carried in the pocket. The solution was changed as often as it became turbid, the cavity thus being kept aseptic and constantly irrigated, as with every respiration the solution could be seen to rush up the tube. This traction was also constantly exerted upon the compressed lung by the weight of the column of water in the tube. The patient made a rapid and perfect recovery, and required but little after-treatment.

He stated that the above case was reported to a local society in March, 1883, and the value of the principle of traction about a rapidly expanding lung was at that time strongly advocated. Since then Dr. Cabot, of Boston, after a much more extended application of this principle, has given strong testimony as to its great value.

In conclusion the reader urged the following in support of the foregoing method of treatment: First, local septic changes are prevented as completely by this method as by the Lister dressing. Second, the important principle of traction is applied continuously by this method and must be as effective in bringing about a rapid expansion of the lung as the Lister dressing as applied by Dr. Cabot. Third, constant irrigation of the suppurating cavity, by which fibrous and purulent clots are washed out, must at least be as effective in keeping the cavity free from these irritating substances as the occasional washing by the other method. Fourth, the greatest advantage of respiratory irrigation over Listerism, aside from the great expense of the latter, is to be seen in the amount of care and attention required in its management. By the method described the expense is reduced to a minimum and the after-treatment and attention to comparatively nothing.

For these reasons the reader believes that the treatment of empyema by respiratory irrigation commends itself to the attention of the busy general practitioner.

Dr. M. C. Lathrop, of Dover, read a paper on MOTHER'S MARKS.

After remarking upon the place and value of philosophic authority, and noting prominent names that endorse the popular belief that impressions made upon the pregnant woman's imagination or sensibilities may appear again physically reflected, as it were, in the body of her child, the reader claimed that the only raison d'être for this belief, viz., its asserted necessity—arising from the apparent difficulty in otherwise accounting for the coincidence in resemblance that sometimes exists between parent and offspring and congenital disfigurement—was only apparent, while the physiological objections presented by the wholly parasitic nature of the relation of offspring to mother from the moment of conception to birth, and from the entire distinctness throughout that period of their separate individualities, making the processes of general nutrition the only avenue of operation for such influences, are insuperable. The elaborate attempts of Carpenter and Dalton to prove the a priori possibility of their belief are shown to be fallacious. The former, to avoid the "vulgar error," limits his explanation to a small part of the wonderful facts, and most strangely claims to get at the same time, and from identical conditions, most unequal and opposite effects, two asymmetrical developments and growths. Dalton, at the last moment, escapes this absurdity (and in the act throws up his case) by assuming under the euphemism "more sensitive" an hereditary defect, which alone the reader offered as a rational and sufficient explanation of the whole matter.

Dr. Ezra Mitchell, of Lancaster, read a paper entitled a REPORT ON GYNECOLOGY, embracing a report of twenty-three cases of operations for lacerated cervix and perineum by Dawson's method and the results of the same. The radical difference and particular improvement of his operation over others is in the manner of denuding, and in using only two deep and one superficial sutures, thus avoiding the formation of abscesses. The patient also makes a more rapid recovery. The reader then narrated twenty-three cases in detail. These cases were all followed by excellent results, and demonstrated the fact that the earlier the operation the better the results. In eight cases the operation was performed upon both the cervix and perineum at the same time, and this the writer regarded as the best method of treatment. The paper was a strong one in advocacy of this method, and was so well illustrated by diagrams that the Society could not fail to comprehend the method of operation.

Dr. Mary S. Danforth read a report on "Obstetrics," in which several medicolegal questions were considered, and lastly, a paper was presented by Dr. Parry on "Laceration of the Perineum."

The report on Necrology, by Dr. E. E. Graves, of Boscawen, consisted of obituary notices of the late Dr. N. Wight, of Gilmanton, by Dr. John Wheeler, of Pittsfield; of Dr. S. M. Whipple, of New London; of Dr. D. P. Goodhue, of Springfield; of Dr. E. O. Fowler, of Danvers, by Dr. John Whist, of Bristol; of Dr. J. W. Merrill, of Concord, by Dr. C. P. Gage, of Concord.

Wednesday, June 18th—Second Day.

The meeting was called to order by the President, after which REPORTS OF DELEGATES OF DISTRICT SOCIETIES were presented, giving rise in turn to general practical discussions. The

OFFICERS ELECTED FOR THE ENSUING YEAR were: President—Dr. John Wheeler; Vice-President—Dr. George A. Crosby; Secretary—Dr. G. P. Coon; Treasurer—Dr. D. S. Adams; Executive Committee—Drs. Charles R. Walker, Geo. D. Towne, and John R. Kimball.

The meeting then adjourned until the third Thursday in June, 1885.
NEW YORK PATHOLOGICAL SOCIETY.

Sated Meeting, May 28, 1884.

GEORGE F. SHRADY, M.D., PRESIDENT, IN THE CHAIR.

DR. F. FERGUSON presented the following

REPORT OF THE COMMITTEE ON MICROSCOPY.

1. The uterus and tumor presented to the Pathological Society on the 14th inst., by Dr. C. C. Lee, is composed of fibrillated fibrous tissue almost entirely. It involves to a considerable extent the entire thickness of the wall of the fundus of the organ. The uterus in the neighborhood of the tumor presents the normal appearance of uterine tissue.

2. The spinal cord from a case of Pott's disease presented to the Pathological Society on April 30, 1884, by Dr. L. A. Sayre, having been placed in alcohol without the removal of the dura mater, the interior of the cord softened. No statement can be made as to whether pressure had been exerted at any point. In several places it was flattened from contact with the bottom of the vessel in which it was hardened.

CYSTIC OVARIOS—BATTIEY'S OPERATION.

DR. M. PUTNAM-JACOBI presented the ovaries and Fallopian tubes removed from an unmarried woman, thirty-five years of age, who had suffered greatly from dysmenorrhea since the age of twenty years, but to which no special importance had been attached until about four years ago. When Dr. Jacobi first examined the patient three years ago, she found the uterus sharply retroflexed, the cavity somewhat enlarged, the endometrium hyperemic and tender. The right ovary was prolapsed considerably. On the left side of the uterus no ovary could be felt; but there was a soft mass, not like the exudation of cellulitis, but exquisitely sensitive; and dragging the cervix toward the right side always caused pain which was referred to this particular point in the left side of the pelvis. At times the left ovary was found behind the cervix.

The patient suffered, not only from dysmenorrhea, but from constipation. She began a week before menstruation and went on increasing in intensity until the flow was established. She was also in the habit of having attacks of sharp pain four or five days after menstruation, partly colicky in character, and partly like abdominal neuralgia; also constant pain in left hypogastric region, and extending down the extremities; also considerable pain in the back.

The cervix was drawn up quite closely under the pubis and the tissues of the utero-vesical ligament were so sensitive that it was exceedingly difficult to replace the uterus, although the fundus was not adherent. The endometritis was only temporarily relieved by the replacement of the uterus.

The tension of the ligament was finally overcome by stretching, the sensiveness subsided, and the patient was somewhat relieved, but although the uterus was kept in position, and there was no trace of peritoneal inflammation, the pain continued.

The patient was then kept in bed, and cotton was packed into the pelvis, with the view of pushing up the ovaries and diminishing the oedema. Under this treatment she improved to a remarkable extent, very much more than under the treatment directed especially to the retroflexion. But after four or five months the pain began to return, she was a little worse each succeeding month, until in April last the dysmenorrhea became so severe that the operation for removal of the ovaries was decided upon.

About once in six months, while the patient was under observation, she was seized with colic, of most extraordinary intensity, like biliary or nephritic colic, much more violent than could be explained by simple uterine colic. Some hours after these attacks there escaped from the uterus a small mass of cheesy material. At that time Dr. Jacobi made the diagnosis of accumulation of inspissated mucus at the uterine extremity of the Fallopian tube, as the result of long-standing inflammation of the tube itself, and which excited violent contraction for its expulsion.

The operation was performed five days ago, by Dr. E. M. Cushier, and under antiseptic precautions. It lasted thirty-five minutes, and at no time did the intestines come to view. At no time subsequently had the patient's temperature been above 101° F., and there was every reason to suppose that she would make a complete recovery.

The operation was performed nine days after menstruation, and in view of the fact, special care was taken to count the number of Graafian follicles and also to note the different stages of development.

Leopold has given the result of his examination of twenty-two specimens of ovaries removed by operation, all associated with ovarian disease, and says, that in nearly all of them an unusually large number of follicles were in an advanced stage of development and ready to burst. From these observations he draws what seemed to Dr. Jacobi to be the most extraordinary conclusion, that the view that there is a special relation of time between the ripening of Graafian follicles and menstruation must be given up. Leopold, however, admits that, inasmuch as the specimens were in a pathological condition, the inference may be incorrect. In nearly all of his cases there was dysmenorrhea.

In the specimen presented, the right ovary had one large follicle lined with a membrane having a yellow color, and presenting an appearance somewhat like that seen in a corpus-luteum, but the lining membrane, instead of being thrown into folds formed a simple smooth layer. This follicle was so adherent that, when fresh, it would have held a large filbert. Besides, there were three other follicles on the anterior surface of the ovary; one filled with fluid but not ready to burst, another containing fluid, and of about the size of a pea, and a third which contained blood. The ovary did not appear especially hyperemic, although it was evidently enlarged. The Fallopian tube was not enlarged, but intensely hyperemic, and the blood-vessels in the peritoneal fold were very large. On opening the tube, the mucous surface was not nearly so red as was the peritoneal surface, but it was thrown into folds, and, at the uterine extremity, where the tube was twisted upon itself, there was a cheesy-like appearance as of inspissated mucus, corresponding to the view advanced concerning the character of the colic already described.

The left ovary contained a large cyst, in which there was no trace of tissue, resembling a corpus-luteum. The cyst was large, extended fully half-way down the ovary, was redden and filled with fluid, and doubtless was the part touched with the finger when making an examination. It was probable that into this cyst hemorrhage had occurred frequently. There was one follicle which presented the appearance of organization of a corpus-luteum. At the base of the ovary was a small fibroid of the size of a filbert. The Fallopian tube presented very much the same appearance as seen upon the right side; at the uterine extremity it was thickened mass as in the other.

There was a subperitoneal fibroid on the surface of the uterus. This, together with the small fibroid at the base of one ovary, possessed considerable interest in connection with the family history of the patient, who had lost one brother with osteo-sarcoma in the axilla, and a younger sister with sarcoma under the maxilla. It seemed to Dr. Jacobi that, in estimating cases suitable for Battey's operation, the family history should be taken into account, and also the length of time the case has been under treatment.
Dr. F. Ferguson presented specimens removed from the bodies of persons who died of general tuberculosis and head injury. The first illustrated case was that of an old peritonitis, although there was no history of peritonitis, and the peritonitis was not due to tuberculosis, although the specimen was obtained from the case of general tuberculosis. The coils of intestine were everywhere firmly sealed together by old adhesions. From the same case Dr. Ferguson presented a specimen of tubercular ulcer of the colon.

The second specimen illustrated was an injury of the vermiform appendix, shown by destruction of the appendix, just above the middle, and being converted into a fibrous cord. There were old adhesions binding the upper surface of the liver to the diaphragm.

Dr. W. M. Carpenter said, concerning the second specimen presented by Dr. Ferguson, that it reminded him of a recent monograph written by Vierordt, and entitled "Chronic Exudative Peritonitis," in which the author gives a history of several cases, in some of which the patients recovered and lived for several years, while others died of affections directly or indirectly dependent upon the chronic exudative peritonitis. The appearances described were very much like those presented by the intestines shown by Dr. Ferguson. General agglutination of all the coils of intestine with each other, more or less of thickening, but not necessarily any adhesions to the abdominal wall. Ascites was a prominent symptom at some time in the history of the case. While reading the paper he was reminded of two or three cases seen in private practice, in one of which typhoid fever was soon followed by symptoms of subacute peritonitis. In this case the patient, a woman, lived nearly two years after the sickness, and died without any symptoms referable to the peritoneum. At the autopsy there was found universal exudative peritonitis, with enormous dilatation of the large intestine, but no evidence of tubercle. There was also old pleurisy with fibrous induration at the apex of one lung. There was marked ascites in all the cases, and after a time the symptoms subsided under treatment, and two of the patients ultimately recovered. He had lived a number of years in this country. The condition was not traceable to the ordinary causes of peritonitis, nor was there any history of tuberculosis. One of the patients, a woman, lived for ten or twelve years after being under his care for this condition. Another, a man of somewhat advanced age, lived for four or five years, and ultimately died of cancer, which manifested itself upon the skin. At the autopsy a group of cases well described before reading the monograph by Vierordt, and he believed the case related by Dr. Ferguson belonged to that class. Vierordt also spoke of ulcer of the stomach as one of the causes of chronic exudative peritonitis. In Dr. Ferguson's specimen there existed ulcer of the large intestine, between which and the stomach a close relation existed.

Dr. J. C. Peters referred to a case occurring in a female, and caused by exposure to cold, which produced not only peritonitis, but pleurisy, pericarditis, congestion of the lungs, and metrorrhagia. She was sick between three and four months before she recovered passably. Eight or nine years had elapsed since, during which time the patient had suffered daily from pain in the abdomen, and excessive pain on defecation. The peritonitis was very distinct at the time of the attack, and diagnosis of adhesions of the intestines had been made repeatedly since by several physicians.

The Society then went into executive session.

Vacation of the Medical Societies.—After the end of June there will be no more meetings of medical societies until September.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

A NEW FLOATING SMALL-POX HOSPITAL.—THE PREVALENCE OF SMALL-POX—VACCINATION AND RE-VACCINATION.—THE ADDRESS IN MEDICINE AT BRETHERTON.—A.F.R.C.R.

London, June 21st, 1874.

Another hospital ship has been added to those already on the Thames by the acquisition of the twin-screw Catalina. As a Channel steamer she was unfortunate. Having been purchased for the moderate sum of £5,500 by the Metropolitan Asylums Board, the Catalina has been converted into a floating hospital for small-pox cases. It is to be hoped it may prove of greater service in its new capacity than it did in its old. Considerable trouble and expense have been incurred in converting the vessel for this new purpose. The wards between decks have been furnished with openings in the roof leading to a huge funnel, at the top of which is an exhaust apparatus. When the wind is blowing the exhaust a strong up-current in the funnel, and thus carries away the foul air from the wards. In a calm steam power is used to drive jets of air up the funnel, and thus create an artificial draught. Through apertures at the side of the ship, and is passed through chambers warmed by hot-water coils before gaining access to the patients' quarters.

The wards on the upper deck are ventilated on a different principle. The perforative force of the wind has here been brought into service. The arrangement adopted is simple and curious. We have already described the "pavilion" system. On each side of the ship are a series of wards with gabled roofs, which are placed so that their long axis is at an oblique angle with a line drawn fore and aft. These "huts" are detached, but connected with one another by passages running down the vessel. The advantage of the plan adopted is that the end windows catch the wind, which then passes out through the side windows, instead of the foul air being blown from bed to bed as would be the case were the position of the wards exactly transverse to the long axis of the ship, and the ventilation effected by windows on either side of the vessel. Accommodation for about two hundred patients is provided, and the ventilating arrangements provide for a supply of air to each patient. The Catalina will be stationed off Fleet.

Small-pox is still prevalent among us. The number of cases during the last two months has been much above the average. During the week ending May 24th the number of small-pox cases under treatment in the hospitals of the Metropolitan Asylums Board rose to 974, being an increase of 189 on the previous week. During the same period the deaths from small-pox in London were only 24, being little more than half of those of the preceding week. The majority of the cases are at the East end. There is little hope of stamping out the disease until vaccination is more universally carried out. We have to deal with, on the one hand, the fanaticism of anti-vaccinators. On the other hand, we must remember that a sufficient number of years has not yet elapsed since vaccination has been made compulsory to insure vaccination of the entire population. A large number of persons are still living who were born before compulsory vaccination came into existence, and many of these have never been vaccinated. Re-vaccination is not compulsory, and is commonly neglected. Some interesting letters have recently appeared in our medical weeklies, containing facts which show that the failure of re-vaccination does not prove the person to be protected, since repeated attempts...
at revaccination on the same person have finally succeeded. One or two instances are mentioned in which five revaccinations were performed on the same individual. The first four failed, but the last gave a good result.

Sir Andrew Clark will not, after all, give the address on "Medicine" at Belfast. His place will be taken by Dr. William Miller Ord, Physicist to and Joint-Lecturer on Medicine at St. Thomas' Hospital, London.

Dr. Acland has been made a K.C.B. I expressed surprise some time since that only the paltry C.B. should have been given him, and the Government now appear to see their error and to be willing to repair it. The K.C.B. is highly valued. It is much more thought of than an ordinary knighthood, and a baronetcy is only more esteemed as being hereditary; but Sir William Jenner accepted a K.C.B. after having been a baronet for many years.

The University of Durham is just now attracting a good deal of medical interest. A pretty little quarrel seems on the carpet. This Northern university, which until a few years since was virtually merely a place for parsons to graduate at, has lately pushed its medical department. It grants its medical degrees in two ways: 1, to those who attend for at least one year out of their first medical year, situated not at Durham, but at Newcastle-on-Tyne, some twenty miles distant; 2, to any practitioner who has been in practice fifteen years, and who is prepared to pay fifty guineas and pass a somewhat modified examination.

It has been suggested that practitioners should be allowed to go up for M.D. after only ten years' practice. Practitioners say that if a degree is to be of any use to them they need it earlier in life, and that if a man has been in practice fifteen years he should have made his mark and be independent of any mere titular distinction. Those who have graduated after residence say that the other mode of granting degrees should be abolished. Those who reside only obtain M.B., and have to wait two years before they can go up for the M.D. They say it is unfair because a man has been in practice a good many years to let him up without residence, and for an easy examination to give him the M.D. at once.

Both parties look at the matter from a purely selfish point of view, and with little regard for the real interests of the profession. The University of Durham does not advertise itself and discriminate against performers. The method of giving the M.D., no doubt a very important motive was the prospect of getting a good many fifty-guinea fees from the medicals, and thus get assistance in carrying on the work of qualifying a few imprecious clergy for ordination in the Church of England. It was certainly an unfortunate thing that when the university was founded—thirty or forty years ago—as an ecclesiastical college for the North of England, under the management of the Bishop of Durham and the Dean and Chapter, it should have been empowered to grant degrees in all the faculties, and thus have added one more to the already too numerous licensing bodies. With the enfrontery characteristic of a clerical high-school it imitates the other kind of medical schools which have had to struggle for insertion under one of the professors' assistants. These courses are very instructive, and although somewhat expensive are the means to obtain the confidence of the assistants, who have almost unlimited control of the wards, performing nearly all the obstetrical operations and a large proportion of the gynecological. They often remain as assistants for eight years, and they are greatly admired by the excellent teachers, enthusiastic in their work and making their courses among the most popular in Vienna.

Unfortunately, in 1883 the "Board of Regents" (?) established the plan of appointing for each ward a native of Austria, whose privilege it is to perform all operations the assistant may think indicated. This plan, it is hoped, will secure to the Austrian practitioner the opportunity of becoming skilled in obstetrical operations,
which privilege, it is claimed, has heretofore been monop

nolized by foreigners.

All patients applying for admission to the lying-in de

partment are sent to the several divisions, alternating in their order every twenty hours; or in the first stage of dis-

tributing the patients equally in the three divisions, and
gives the nurses and attendants every third day for rest, and
affords a better opportunity for the thorough disinfection
of the confinement rooms. There are between twenty-
five and thirty confinements daily, and a much larger
number of applicants for admission are examined by the
assistant, and if found fit to be in or near the first stage of
labor they are accepted, and four of the numerous stu-
dents and matriculants generally at hand on these occa-
sions are allowed to examine each patient so admitted.
Free access is given matriculants to the confinement
rooms at all hours of the day and night, two skilled mid-
wives are in attendance, the temperature of each patient
is taken, and those exhibiting a marked rise, or with
offensive lochia, are isolated and exempt from examina-
tion until full instructions have been received from the
assistant in the management of natural labor as carried
out there. I wish more particularly to note the fol-

lowing: First, absence of measures to hasten the com-

pletion of the second stage; second, absence of anesthetics;
third, measures to prevent laceration of the perineum;
forth, speedy completion of the third stage.

Braun says: "In the stage of dilatation nothing should
be done to hasten the physiological labor or to bring on
pains." He objects to steam baths, oxytocics, and dilating
vagina or os uteri; recommends systematic attention to
the employment of catheterization of the bladder, and
empties the rectum by warm-water injections.

Anesthetics are avoided in natural labor, and immunity
from post-partum hemorrhage is claimed in consequence.
In vertex presentations the patient is allowed to remain
in the dorsal position until the head appears at the vulva,
or until the perineum begins to show the pressure; she is
then turned on to her left side until the head is in the
breech, the right leg is extended, the right thigh flexed, and a pillow placed
under the right knee; the midwife sits at the back of the
patient, places her left hand under the patient's right
thigh, and presses upon the fetal head as it ap-

pears at the pubic arch; the right hand is free to "check the perineum," which is not advised, the ob-

ject being to keep the head until the perineum is
sufficiently distended, and to deliver if possible between
the pains.

Nearly all primipara are treated in this manner, and
those multipara in whom laceration of the perineum is
threatened. That this method preserves the continuity of
muscular tone, and there can be no doubt in the minds of those who have given it a trial, that certain midwives
in the Vienna wards a ruptured perineum scarcely ever
occurs, while with those less skilful and with matriculants
success is not so marked.

At the completion of the second stage the midwives
are instructed to wait for fifteen or twenty minutes before
making efforts to hasten the expulsion of the placenta.
They are not, however, careful to obey this rule to the
minute, for unless the placenta follows the expulsion of
the child in a few minutes, they employ Crede's method,
and if after several minutes of such kneeling the pla-
centa is not expelled, they forcibly express it.

After the completion of the third stage, and as soon as
the child has been duly prepared and so abundantly
swaddled that it looks like an Egyptian mummy, the pa-
tient is carried to another room, where she is kept for
eight days, and if all progresses favorably, is then sent to
the Foundling Asylum, where she remains for sixty days,
and from which she almost invariably departs without the
child, which, if a male, is carefully watched over by the
Government nurse.

Professor Carl Braun has had charge of the "First Ob-

stetric and Gynecological Clinic" in Vienna since
1856, and was for many years prior to that date assistant

in the same, and in his reports bearing on the causes
and prevention of puerperal fever, it appears that, during
the fifteen years from 1834 to 1849, there were in these
wards 44,105 confinements, with 3,487 deaths, or an
average rate of mortality of eight per cent.; the worst
year was 1842, when, out of 3,067 confinements, 531
deaths occurred, or 17.4 per cent.

The wards reserved for the instruction of midwives
showed more-favorable statistics at that time, the mor-
tality averaging about three per cent.; it must be re-

membered, however, that the matriculants in the first
and second stages of labor, at times frequenting the Pathological Insti-

tute, and many of them engaged in operative courses.
In the fourteen years from 1849 to 1863 there were 57-
569 confinements, with 2,044 deaths, or an average rate of
3.3 per cent. This series would have shown a better
average had it not been for the years 1854-55-56, in
which the average rate rose terribly, being 9.9 per cent.
in 1854, and due, it is claimed, to the abandonment of
antiseptic measures, although Lusk \(^1\) seems to have
arrived at an opposite conclusion.

In the sixteen years from 1863 to 1879, there were
61,949 confinements, with 998 deaths, an average rate of
1.6 per cent., as against eight per cent. in the first series,
1849-1863. In the worst year being 1872, with 528
matriculants working in the wards, and a death-rate of
9 per cent.; the best year 1877, with but 192 matriculants
and a mortality rate of one per cent. Of the 998 deaths, 825
were from puerperal fever, or eighty-three per cent.,
and of the remaining 173, the post-mat-

ten returns show 165, as follows: Bright's disease, 59;
placental separation, 28; inflammatory diseases of the
uterus, 14; acute amnionitis, 10; vitium cordis, 4; acute
atrophies of liver, 6; embolism of the pulmonary arteries,
3; meningitis; 3; cerebral apoplexy, 3; amyloid degen-
eration of liver, 3; variol, 3; pulmonary oedema, 2;
pericarditis, 2; endocarditis, 2; erysipelas, 2; hemato-
toma, 2; abscess of symphysis pubis, 2; rupture of sorts,
1; dysentery, 1; typhoid fever, 1; hemophyesia ulei,
1; poisoning, 1.

In 1847 Semmelweis held that puerperal fever was an
infectious disease, causes generally heterogenic, and in
accordance with these views prophylactic measures were
introduced in the Vienna wards, such as antiseptic wash-
ing of hands, dressings, instruments, etc. In 1846-47,
1848 and 1849, the death-rate was reduced to 0.17 per cent.
; it dropped after the introduction of these mea-

Lusk's Midwifery, p. 435.
AN INSTRUMENT FOR MAKING APPLICATIONS OF MEDICATED POWDERS TO THE MIDDLE EAR.

BY J. A. ANDREWS, M.D.,
OPTHALMIC SURGEON TO CHAITY HOSPITAL, ETC., NEW YORK.

The instrument figured below is a modified form of one described by the writer in the Archives of Medicine, vol. iii., April, 1850. The receiver for the powder is cone-shaped and has been made much larger, being 3.75 ctm. (1½ in.) in length and 1.5 ctm. (½ in.) in diameter at the base. The rubber tubing is adjusted at the side of the receiver. A mouthpiece may be substituted for the air-bag, but there is this objection to the use of the former—the moisture of the breath condenses on the interior of the tube, and the powder adheres to it and soon obstructs the tube; therefore, unless a large-sized tube be employed, it would be better to attach the small air-bag (1½ in. in diameter, 2 in. long). The metal tube is 12.5 ctm. (5 in.) long, and No. 5 of the French scale. The advantage of having the tube constructed so delicately is that it enables the operator at once to conduct its point to the perforation in the drum membrane, supposing the former to be very small, and offers as little obstacle to the irritation of the external auditory canal as would be occasioned by the introduction of a dentist's cotton-holder.

The mode of employing the instrument is as follows (it is understood that there must be a perforation in the drum membrane): Suppose a case of purulent inflammation of the middle ear, with a small perforation in the drum membrane—and it is in just such cases that this little instrument will be appreciated—the first thing to be done, of course, is to thoroughly cleanse the ear with absorbent cotton wrapped about the end of a dentist's cotton-holder, and with due respect for the delicacy of the parts at the bottom of the external auditory canal—and it is impossible to lay too much stress upon the importance of attention to this point. In some cases in which the membrane is considerably destroyed and the discharge is abundant and offensive, the syringe had better be used, and the ear afterward dried with the cotton-wool. This having been done, the chamber is filled with whatever powder may be chosen. The point of the tube is then conducted with care through an aural speculum, under good illumination from a mirror on the forehead, to the perforation in the drum-membrane and the powder blown into the middle ear by means of the mouthpiece, or air-bag.

Care should be taken not to pass the point of the instrument too far in the perforation in the drum-membrane; injury to parts in the middle ear will thus be avoided. If it be desired to use medicated fluids, then the instrument for applying them, described in the same number of the journal above referred to, may be employed.

New Instruments.

The Army Medical Examining Board, New York City, is dissolved, to take effect June 14, 1884.

GARDNER, EDWIN F., Captain and Assistant Surgeon. Relieved from duty at Fort Walla Walla, Wash. Ter., and assigned to duty as Post Surgeon, Fort Canby, Wash. Ter. S. O. 75, par. 1, Headquarters Department of Columbia, June 3, 1884.

BARNETT, RICHARDS, Captain and Assistant Surgeon. Assigned to duty as Post Surgeon, Mount Vernon Barracks, Ala. S. O. 113, par. 2, Headquarters Department of the East, June 9, 1884.

MIDDLETON, PASSMORE, Captain and Assistant Surgeon. Leave of absence extended three months on surgeon's certificate of disability. S. O. 134, par. 3, A. G. O., June 10, 1884.

BROWN, Jos. B., Lieutenant-Colonel and Surgeon, Upon completion of the business of the A. M. B., directed to comply with S. O. 44, current series, A. G. O., and return to New York City.

CLEMANTS, BENNETT A., Major and Surgeon. Directed to await orders in New York City.

KIMBALL, JAMES P., Captain and Assistant Surgeon. Granted leave of absence for two months and fourteen days, to take effect June 14, 1884, and ordered to report to duty as Post Surgeon, Fort Stockton, Tex., and assigned to duty as Post Surgeon, Fort Concho, Tex. S. O. 69, par. 4, Headquarters Department of Texas, June 2, 1884.
THE MEDICAL RECORD. [June 21, 1884.

Official List of Changes in the Medical Corps of the U. S. Navy, during the week ending June 14, 1884.

AUSTIN, A. A., Passed Assistant Surgeon. Detached from U. S. S. St. Louis, ordered to Naval Rendezvous, Philadelphia.

WHITAKER, H. W., Assistant Surgeon. Detached from Naval Rendezvous, Philadelphia, ordered for examination preliminary to promotion.

BROWNE, J. M., Medical Director. To attend the International Health Exhibition at Liverpool, England, and delegate to International Medical Congress, at Copenhagen, per steamer of July 2.

TRYON, I. R., Surgeon. To same duty, with Medical Director Browne, and on completion of this duty, to report for duty on U. S. S. Quinnebaug.

HUGG, J., Surgeon. Detached from U. S. S. Quinnebaug on reporting of relief, to return home and report arrival.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 14, 1884:

Neither Dead nor Speechless.—In 1730 the Duchess Dowager Hamilton was reported either dead or speechless. She published a contradiction, thus: "I have been ill in my health for several months, but never speechless, and my most intimate friends think that is the very last thing that will happen to me. E. Hamilton."

The Legality of Cremation.—An English case in the High Court of Justice recently turned upon the point whether cremating a corpse was an offence in the eye of the law, and the opinion rendered was very interesting. There was nothing in the common law on the subject which was controlling, and Parliament had never legislated for or against the practice. In the special case at bar, a person had been indicted by a grand jury for the act of burning the dead body of his child, upon the theory that it must be considered a misdemeanor, although not expressly stated to be so by statute, and the opinion from which we quote was delivered to the grand jury upon the question of the right to find such an indictment. The increasing frequency with which this mode of disposing of the dead is being adopted both in this country and in England makes the matter one of great interest. We quote as follows: "After full consideration, I am of opinion that a person who burns instead of burying a dead body, does not commit a criminal act, unless he does it in such a manner as to amount to a public nuisance at common law. My reason for this opinion is that, upon the fullest examination of the authorities, I have, as the preceding review of them shows, been unable to discover any authority for the proposition that it is a misdemeanor to burn a dead body, and in the absence of such authority I feel that I have no right to declare it to be one. There are some instances, no doubt, in which courts of justice have declared acts to be misdemeanors, which had previously been decided to be so, but I think it will be found that in every such case the act involved great public mischief or moral scandal. It is not my place to offer any opinion on the comparative merits of burning and burying corpses, but before I could hold that it must be a misdemeanor to burn a dead body, I must be satisfied not only that some people, even that many people, object to the practice, but that it is, on plain, undeniable grounds, highly mischievous or grossly scandalous. Even then I should pause long before I held it to be a misdemeanor, for many acts involving the grossest indecency and grave public mischief —incest, for instance, and where there is no conspiracy, seduction, or adultery—are not misdemeanors. But I cannot take even the first step. Sir Thomas Brown finishes his famous essay on urethral burials with a quotation from Lucan, which in eight words seems to sum up the matter: 'Thermes cadavera subito annis haud curtis'—Whether decay or fire consumes corpses matters not. The difference between the two processes is only that one is quick, the other slow. Each is so horrible that every healthy imagination would turn away from its details; but one or the other is inevitable, and each may be concealed from observation by proper precautions. There are no doubt religious conditions and feelings connected with the subject which every one would wish to treat with respect and tenderness, and I suppose there is no doubt that as a matter of historical fact the disuse of burning bodies was due to the force of those sentiments. I do not think, however, that it can be said that every practice which stalks and jars upon the religious sentiments of the majority of the population is for that reason a misdemeanor at common law. The statement of such a proposition, in plain words, is a sufficient refutation of it, but nothing short of this will support the conclusion that to burn a dead body must be a misdemeanor. As for the public interest in the matter, burning the one hand effects a saving of the dead from poisoning the living. On the other hand, it might no doubt destroy the evidence of crime. These, however, are matters for the legislature, not for me. It may be that it would be well for Parliament to regulate or to forbid the burning of bodies, but the great leading rule of criminal law is that nothing is a crime unless it is plainly forbidden by law. This rule is not subject to exceptions, but they are rare, narrow, and to be admitted with the greatest reluctance, and only upon the strongest reasons. This brings me to the last observation I have to make. Though I think that to burn a dead body decently and inoffensively is not criminal, it is obvious that if it is done in such a manner as to be offensive to others it is a nuisance of an aggravated kind. A common nuisance is an act which obstructs or causes inconvenience or damage to the public in the exercise of rights common to all her majesty's subjects. To burn a dead body in such a place and such a manner as to annoy persons passing along public roads or other places where they have a right to go is beyond all doubt a nuisance, as nothing more offensive can be thought of. Under these circumstances the nuisance is aggravated and increased. The depositions in this case do not state very distinctly the nature and situation of the place where this act was done, but if you think, upon inquiry, that there is evidence of its having been done in such a situation and manner as to be offensive to any considerable number of persons you should find a true bill."
UNUSUAL PARTURITIONS.—Dr. W. R. Chittick, of Detroit, Mich., writes: "Unusual parturitions being in order, let me mention a case which I attended, and which is reported in full in the Detroit Lancet for October, 1883. A patient, Mrs. H., who, messenger said, had rheumatism of the heart. Arrived within twenty minutes, and found twins had been born, one with membranes intact. There were but two pains, one immediately following the other, and with the second both children came, the labor lasting, as she said, only five minutes. After making her comfortable I discovered the child to be croupous pneumonia, who, after three months pregnant, and labor was brought on by the condition of the lungs. The mother made a splendid recovery and the children lived three months, when they succumbed to enteritis.

THE TREATMENT OF TAPEWORM.—Dr. Thomas Wilde, of Brooklyn, sends in the following item: "On April 26th, I presented to the members of the New York Pathological Society a complete tapeworm removed the day before. My desire was to inform the members of the condition of the profession at large, how the dreaded parasites could be easily removed and with trifling inconvenience to patients. In the report of proceedings published in The Medical Record, May 31, 1884, the most important part of the treatment is not mentioned. I refer to the preparatory treatment. Administer fluid extract of male fern three times daily, after meals, for one week. Dose: Make a thick gruel from diet. Pay no attention to the bowels. At expiration of the week order two ounces of the fresh bark of pomegranate root made into infusion or decoction to one pint. Commence in the morning and take a wineglassful every half hour or hour, dependent upon its effect on the stomach, until all has been taken. Then follow, about 11 A.M., with the following laxative:

B. Olei ricini. ............. 3 ij j.

Olei terebinth. Fl. ext. filix mas. ............. 4 ij j.

M.

The above is my treatment for tapeworm in adults. I have always used the fluid extract of male fern, though many prefer the etereal extract. In one of my cases the worm was expelled in one piece before the hour arrived for taking the castor-oil mixture, but as the patient considered it part of the treatment it was taken on time. The first tapeworm I ever saw, was in 1866. The fight lasted over two years. I had been made aware of the importance of starving the worm before attempting its removal. The patient was a lady, and heroically starved and starved until she was unable to fast any longer, but all to no purpose. I concluded the starvation treatment was a delusion and abandoned it. The above treatment was adopted and the worm was easily destroyed. I have followed the same plan in five other cases, and in each the worm was easily expelled."

A CASE OF ADIPOCRINE.—Dr. George A. Harding, of Sault Ste. Marie, Mich., writes: "A case of interest in the way of post-mortem change of the human body has recently come to my notice. Mrs. C.—died in the fall of 1876, aged fifty-six years, after an illness of some years' duration caused by (as reported) diabetes mellitus. She was buried in a sandy elevation of land that rose from a marshy tract; and was not disturbed till a few days since, when her faithful friends thought they observed a movement in the ground, and disinterred them for that purpose. They were much surprised when, on trying to lift the coffin in which she was buried, they discovered that it was very heavy, and this led them to open the box. They found the remains apparently little changed, and after the removal of a thin covering of earthy material from the face, and, indeed, the whole body, looked so natural that it was easily recognized by those who knew her during life, and as the flesh seemed hard, the report was soon circulated that she was petrified. Drs. Ennis and Gandy, in company with myself, made examination, and found the body, to all appearance, as reported, except, of course, the petrification. The ex- terior layer had crustaceous, and the sores that were on the body at death remained as left at burial. Her head was bald during life, but short hairs on the face still remained and were firm as in life; the nose was pliable in its lower portion, and the lips could easily be opened and closed. She was originally a very large woman, and fleshy, weighing nearly three hundred pounds, and the form of the body remained relatively the same; the abdomen was in a very much lower position than when alive, and the pericardium was in position and quite firm in consistency. I suppose there will be no hesitancy in pronouncing this adipocere, but the general firmness of parts, the natural appearance of the whole body, and the grey appearance, made it an exceptional case and one worth remem-bering. The grave was near a swamp, and at times full of water. The woman being very fat, the conditions were right for the formation of adipocere, which is simply an ammonial saponification of the body."

POISONING FROM HYDROCYANIC ACID—VERY SLOW ELIMINATION OF POISON.—Dr. G. W. Maser, of Parsons, Kan., sends us the history of a young man, aged twenty-seven years, who by mistake took a drink of a preparation of hydrocyanic acid (artificial bitter oil of almond). This was at 9 o'clock A.M. He drank the liquid and water, and vomited freely; became very weak. Dr. Maser saw him about two hours later, when he was retching, cyanotic, weak; pulse only 60; apparently becoming collapsed; pupils dilated. Stimulants and iron were given, and he improved, then sank again. From 1 to 8 P.M. was unconscious, and had at times tonic spasms of all the flexor muscles. Cold soaked cotton was employed as a respiratory measure. At 6 P.M. breathing was better and cyanosis less. Next day patient was up and dressed, but suffered from frequent and painful miscarriage, and complained of taste of bitter almonds in his mouth. Dr. Maser writes: "For several days I distinctly got the odor of the acid in the breath. But all the different books only say that it is very rapidly neutralized, i.e., in two or three hours. What I would like to understand is, whether the teaching as laid down in our text-books regarding the elimination of hydrocyanic acid is correct."

A RARE FORM OF LUXATION—DISLOCATION OF THE FIRST PHALANX OF THE THUMB FORWARD.—Dr. F. W. Putnam, of Binghamton, N. Y., writes: "T. J.—aged ten years, called at my office May 24, 1884, having a dislocation of the first phalanx of the left thumb forward. It was caused about half an hour previously by falling from a swing. I reduced it by grasping the thumb with my right hand, and the boy's left hand with my left hand, and making steady extension of the thumb, and counter-extension of the hand, and then firm and quite forcible flexion of the thumb. The luxation was thus readily reduced."

SIR WILLIAM SIMPSON.—The Edinburgh Ten-centen- nial has set afoot a world of personal gossip and anec- dotes regarding the older medical men in that school. So it is natural to meet a writer in The Cornhill, regarding Sir William Simpson: "His appearance was remarkable; Gerald Massey has
graphically described it in his dedication to one of his poems, 'Body of Bacchus with the head of Jove.' I remember no one in his profession who more impressed me as being a man of genius than he did. If not a wit himself, he was, at all events on one occasion, the cause of wit in another. He had, of course, an immense practice in Edinburgh, but it seemed to me a world too narrow for the exercise of his powers, and I often inquired of the doctors how it was that Simson had never come to London. 'My dear sir,' he replied, with a dry smile, 'he is quite right to stop where he is; there are no coroners' inquests in Scotland.' The Faculty has a large collection of professional jokes, but few, I think, better than this one.

DAMIANA AND HEMORRHoids.—Dr. H. Speier, of Belle Plaine, Minn., writes "that he recently prescribed extract of damiana in three-grain doses to two patients, men, who had sexual weakness, the result of excesses. After about two weeks they reported improvement in sexual power, but both suffered from bleeding piles. One patient had had piles slightly years before, the other never had had them. They were both soon relieved after stopping the damiana."

TWINS—THE SECOND Born in the Membranes.—Another case of this kind is reported by Dr. L. R. Dawson, of Seattle, Washington Territory. He writes: "I attended the birth of a native of Ireland, aged thirty, in her fourth confinement. The vertex was presenting in third position, and half an hour after my arrival she was delivered of a large male child, with slight talipes equinovarus of both feet. Ten minutes later, in two "pains," she expelled a medium-sized girl, with membranes entire and both placenta attached. The child was struggling vigorously within the membranes, which were unusually thick and resisting. The entire labor had lasted but three hours. The uterus did not contract very well, and there was some hemorrhage.

LIVING in the Fiftieth Century.—There were four ordinary meals, viz., breakfast at seven, dinner at ten, supper at four, and "liversets" at eight or nine at night. The latter, as well as breakfast, consisted of beef, mutton, fish, etc., with a few quarts of plain or mulled wine, and beer. Dinner and supper were heavy meals.

FOOD of the Ancients.—Camels and dromedaries' flesh, especially the hearts, were so prepared according to Pliny, delighted in donkey flesh; that of the wild ass was preferred to venison. The wild boar was called animal propert convivis naturum, and the classical portion of the sow was vulva nil dulcius amida. Plutarch says the gravid sow was actually trampled to death to make a delicious mass "fit for the gods." The Porcus trojanus was made by stuffing a pig with birds and various small animals. Fowls were drowned in Falernian wine. Peacocks raised in the island of Samos were sold to the value of £2,000 per year for food.

PRESERVATION of Dead Bodies.—Edward I., who died in 1307, was found not decayed 463 years subsequently. The flesh on the face was a little wasted, but not putrid. The body of Canute, who died in 1017, was found fresh in 1766. That of William the Conqueror and his wife Edith were found in 1720. In 1569 three Roman soldiers, in the dress of their country, fully equipped with arms, were dug out of a peat-moss near Aberdeen. They were quite fresh and plump after a lapse of about fifteen hundred years. In 1717 the bodies of Lady Kilsyth and her infant were embalmed and embalmed. In 1796 they were found as perfect as in the hour they were embalmed. The head of an infant's features were as composed as if he had only been asleep for eighty years. His color was as fresh and his flesh as plump and full as in the perfect glow of health; the smile of infancy and innocence was on his lips. At a little distance it was difficult to distinguish whether Lady Kilsyth was alive or dead, for her features and the very expression of her countenance were marked and distinct. The bodies seemed to have been preserved in some liquid, nearly of the color and appearance of brandy. The whole lead coffin was full of it, all its contents saturated with it, and the bodies were tinged with it. This unknown liquid was perfectly transparent, and its taste was quite rapid. The bodies were also filled with balm and juice, which were spread over the exterior of the bodies. The firm, compact, and elastic. When the flesh was cut into by the surgeon it was found quite firm. The writer does not say how much brandy he had imbibed. If he had been as blunt and truthful as Lady Hamilton, he possibly might have been speechless; or if as credulous as Sir John Fryse, he might have tried to raise the dead.

RAISING the DEAD.—Sir John Fryse, of Montgomeryshire, married three wives, and kept the bodies of the first two in his bedroom, one on each side of his bed. Finally his third wife died in 1748, and he applied to Bridget Bostock, of Cheshire, who healed all diseases by prayer, faith, and an embrocation of fasting-splinter, so that her salivary glands were always kept full to employ, to restore his last wife to life. He writes: "Madam, having heard by mouths after mouths that you have performed many wonderful cures, even where the best physicians have failed; that you restore sight to the blind; hearing to the deaf, and strength to the lame, I write to know whether you can restore the dead to life. Having lately lost a wife whom I tenderly loved, I entreat you to exert yourself in my behalf, that the deceased may be restored to me that I may enjoy your society.

SUPErNUMERARY TESTICLES AGAIN.—The letter which we have published upon this subject have brought out two interesting facts: one is that people with testicles are not so rare as has been supposed, the other, that the pleased owners of the triple apparatus are in the habit of winning money and other valuables by betting that they can show three testicles.

Dr. C. K. Kelley, of Plymouth, N. H., reports a case in an epileptic, a man whose intelligence was below the ordinary standard. "He had won a wager respecting his testicles, and was prepared to make a "wager" regarding them. The third testicle was small.

Dr. R. A. Woods, of Seymour, Ind., reports a case in a healthy man, eighty years of age at the time of examination. The third testicle was on the right side and was as large as the other two. The cords of the two right testicles united a short distance from the external opening of the inguinal canal, the cord formed by the union of the two being perceptibly thicker than the opposite one.

DR. ALLBUTT ON GYNECOLOGY.—Dr. Clifford Allbutt, in his lectures on Visceral Neuroses, hits off the gynecologist in a way that is hardly just, but is very amusing. He says: "A neuralgic woman is either told that she is hysterical, or that it is all uterus. In the first case she is comparatively fortunate, for she is only slighted; in the second she is entangled, or leading the dance of the gynecologist, who finds her uterus, like her nose, is a little on one side; or, again like that organ, is 'running a little, or is as flabby as her biceps, so the unhappy viscus is impaled upon a stem, or perched upon a prop, or is painted with carbolic acid every week in the year, except during the long vacation when the gynecologist is grouse-hunting, so that the limb was full and the limb of the inguinal canal, the cord formed by the union of the two being perceptibly thicker than the opposite one.

Dr. Clifford Allbutt, in his lectures on Visceral Neuroses, hits off the gynecologist in a way that is hardly just, but is very amusing. He says: "A neuralgic woman is either told that she is hysterical, or that it is all uterus. In the first case she is comparatively fortunate, for she is only slighted; in the second she is entangled, or leading the dance of the gynecologist, who finds her uterus, like her nose, is a little on one side; or, again like that organ, is 'running a little, or is as flabby as her biceps, so the unhappy viscus is impaled upon a stem, or perched upon a prop, or is painted with carbolic acid every week in the year, except during the long vacation when the gynecologist is grouse-hunting, so that the limb was full and the limb of the inguinal canal, the cord formed by the union of the two being perceptibly thicker than the opposite one.

ARRaign the uterus and you fix in woman the arrow of hypochondria, it may be for life."
PRACTICAL HINTS REGARDING THE METHODS OF EXAMINATION EMPLOYED AS AIDS IN THE DIAGNOSIS OF NERVOUS DISEASES.

By A. L. Ranney, M.D.,
Professor of Applied Anatomy in the New York Post-graduate Medical School and Hospital.

(Continued from page 651.)

THE CONDITION OF THE SENSORY NERVES.

Before completing a diagnosis of some forms of nervous disease, it is necessary to investigate the following functions: 1. The condition of the sensory nerves of the skin in respect to the sense of touch; 2, the appreciation by these nerves of varying degrees of temperature; 3, the appreciation by the patient of painful impressions transmitted to the brain by the nerves; and 4, the condition of the special senses of sight, smell, hearing, and taste.

Tests for Tactile Sensibility.—In this series of tests, as also in those employed to detect abnormalities of appreciation of different degrees of temperature, the following precautions must be taken against error in the results obtained:

1. The nature of the tests to be employed must be clearly explained to the patient, as well as the importance of accuracy in his decision respecting the sensations perceived. This insures his intelligent cooperation, and makes the patient more earnest in his endeavors to answer correctly.

2. The patient must be blindfolded, in order to avoid any information respecting the tests used reaching him by sight.

3. In order to make the patient keenly alert to avoid errors of statement, it is well to employ blank examinations. Thus, when the skin has not been touched with any instrument or foreign substance, it is well to ask "where the object is now felt," "how many points are now in contact with the skin," etc.

Having explained the objects of the tests about to be employed and then blindfolded the patient, the tactile sensibility of the skin should be first determined by the following methods:

1. Consciousness of simple contact impressions. When the skin is brushed by a hair or a fine feather, notice, first, if the patient perceives the contact immediately, and, secondly, if he can describe the sensation correctly.

2. The ability to locate contact-impressions. With tests of decreasing delicacy (the touch of a hair being the most delicate, and painful impressions the least so), notice to what extent the patient is able to correctly designate the point of contact of the body employed with the skin of different localities.

3. The degree of sensibility of different regions. This must be investigated with great care in some cases. Several methods are employed to determine it with accuracy. These are as follows:

(a) Objects of different shapes may be laid upon the skin and the patient requested to describe their form and character. Coins, keys, and weights may be employed for this purpose, as they are always to be had. This test should be used over many parts of the body and the results obtained compared with those of similar experiments made by the physician upon himself or some healthy person.

(b) The appreciation of pressure, as suggested by Weber, may be tested by placing weights of varying sizes upon the skin of some part, that has previously been supported in order to avoid the so-called "muscular sense" being a factor in the patient's decision. Dr. Beard has devised an instrument for this test that answers all purposes very well.

(c) Again, the various forms of aesthesiometers are used to detect the minimum distance which can exist between two points of simple contact with the skin without destroying the distinct perception of both points by the patient. This distance varies in health between extremely wide limits, because some regions are abundantly supplied with sensory nerves and tactile corpuscles while others are not. For this reason, the following measures can be used as the healthy standard for comparison in any given case. They are given in inches, lines, and millimetres so as to meet the requirements of any scale.

1. Point of tongue, 1/4 inch = 1 line = 1.1 mm.
2. Palmar surface of finger tips 1/2 " = 1 " = 2.2 "
3. Mucous surface of lips 1 " = 2 lines = 4.2 "
4. Palm of hand and tip of nose 1/2 " = 3 " = 6.3 "
5. White part of lips 1/2 " = 4 " = 8.4 "
6. Lower part of forehead 1/2 " = 5 " = 10.1 "
7. Back of hand, 1/2 " = 6 " = 10.7 "
8. Dorsum of foot 1/2 " = 7 " = 12.3 "
9. Forearm, 1/2 " = 8 " = 14.8 "
10. Sternum, 1/2 " = 9 " = 16.3 "
11. Middle of thigh 2 inches = 30 " = 76.2 "
12. Back, 2 inches = 31 " = 79.6 "

Various forms of aesthesiometers have been devised, but a simple pair of compasses, such as are used by ар-}
they will cause pain if so, and thus defeat the object of this test.

The suggestions previously made respecting the definite instructions to the patient, the use of blank experiments, and the employment of a bandage over the patient’s eyes apply to this test as well as to those previously described.

The following rules must be observed in case the aesthesiometer is to be used:

1. The two points of the instrument must be made to touch the skin simultaneously; otherwise the patient will detect the two points of contact more readily than if both meet the skin at the same moment.

2. The contact should be a gentle one; otherwise the impression upon the skin becomes a painful sensation.

3. The relative position of the two points should always bear the same relation to the axis of the limb or the median line of the body, because the sensibility of a part is affected differently when the points are directed transversely or longitudinally. This is essential to the accurate comparison of the sensibility of different regions of the body, or of corresponding regions of either side.

4. The table which has been previously given could be employed as a standard of comparison only when the sensory functions of the skin are impaired upon both sides. When the derangement is one-sided, the healthy side will be the safest guide for comparison.

5. Lesions of the cerebral hemispheres produce anesthesia when they involve the posterior one-third of the internal capsule. If the sensory cranial nerves are affected by such a lesion, the loss of sensation is commonly on the same side as the lesion, except in case of the optic nerve (the condition known as hemianopsia). The anesthesia of parts below the head, if due to cerebral causes, is confined to the side opposite to the hemisphere in which the lesion exists.

6. Anesthesia from lesions of one lateral half of the substance of the spinal cord exists, as a rule, on the side opposite to the spinal lesion.

7. Lesions which involve both lateral halves of the spinal cord create anesthesia on both sides of the body, provided the destructive process affects the so-called “sensory tract” of the cord, viz., the posterior columns, or the gray matter lying around them.

8. Anesthesia may exist in the same side as a spinal lesion, provided the posterior roots of the spinal nerves be pressed upon or destroyed by it, or in case the sensory nerves be affected by the spinal lesion before they cross to the opposite side of the cord.

9. Anesthesia, unlike motor paralysis, is not necessarily present in all parts of the body supplied by those nerves that are given off from the cord below the seat of the lesion. Anesthesia is often associated with a condition of increased sensibility or “hyperesthesia” of parts below the seat of the spinal lesion, and on the side opposite to it.

10. Anesthesia may often coexist with other sensory symptoms, such as pain, incoordination of movement, the peculiar sensation known as “formication,” numbness, tingling, and other subjective sensations.

11. Anesthesia of spinal origin is generally bilateral and symmetrical, because lesions of the cord commonly affect both lateral halves.

8. Tactile sensibility may be destroyed by spinal lesions, and yet the sensibility to pain and temperature may occasionally be retained. In rare cases, sensibility to temperature may be lost, and the sensibility to pain and touch may be normal. It is not infrequent for the neurologist to record an absence of sensibility to pain, when tactile sensibility remains unaffected, and accurate perceptions of temperature are still experienced by the patient. These subjects can detect a needle thrust into the muscles from a simple sensation of touch. These clinical facts seem to confirm the view that has been advanced by late physiologists, viz., that the paths of

\[1\] The lateral columns (Fig. 21) and the posterior columns are probably concerned (as well as the gray substance of the cord in general) in the transmission of sensory impressions to the brain.

\[2\] The column labeled “commissura posterior” in some animals, the lateral columns in the dorsal region of the spinal cord, is considered to be concerned in the transmission of sensations from the legs.

[FIG. 21] This is a side view, although it represents only the anterior half of the spinal cord. It shows the gray matter of the cord, and also the lateral columns (Golgi’s columns) and the white matter (the crossed pyramidal tract) (Fig. 21). Unfortunately, this view is not as clear as it should be, and this is a side view, although the column labeled “commissura posterior” is considered to be concerned in the transmission of sensations from the legs.

This view is directly opposed to the older one that has been generally accepted by standard authors, viz., that sensations of pain travel along the gray matter of the cord, and those of touch, and perhaps of temperature, pass up the posterior columns of the spinal cord.
conduction of sensations of touch, pain, and temperature probably lie in different parts of the spinal cord.

**Hyperesthesia.** The skin may be rendered extremely sensitive in certain diseased conditions. This abnormal state of the nerves is termed "hyperesthesia" in contradistinction to "anesthesia" or a loss of sensation.

When the "sensory tracts" of the spinal cord are involved by a localized lesion, the parts below the regions rendered anesthetic (by the cutting of the sensory nerves) are usually affected with hyperesthesia. The cause of this is not yet known.

A narrow band of hyperesthesia is also developed, as a rule, at the upper level of the spinal lesion. If in the dorsal region, this zone of hyperesthesia generally encircles the body. When in the lumbar region, it is more or less vertical over the limbs in accordance with the particular spinal segment which happens to be affected.

Hyperesthesia probably indicates, according to our present knowledge, some irritation of the nerve-fibres distributed to the regions so affected. The cut introduced is admirably adapted to illustrate the effects of a one-sided spinal lesion upon the sensory functions of the skin.

In the disease known as locomotor ataxia, after a paroxysm of "stabbing pains" has subsided, the seat of previous pain becomes markedly sensitive to the touch, while the rest of the body is not similarly affected.

Hyperesthesia may be of service in diagnosis. It may afford valuable information respecting the spinal segments that are irritated by some destructive process within adjacent regions of the spinal cord. Again, if limited to the area of distribution of some individual nerve, it may point most suggestively toward the existence of some local cause of irritation of that nerve itself. Finally, Valleeix has pointed out the situation of certain regions in the course of the more important nerves of the body where extreme sensitiveness to pressure or touch exists in connection with neuralgic attacks. These are known as the "puncta dolorosa."

They have been separately described by the author in his work, "The Applied Anatomy of the Nervous System."

Hyperesthesia may be functional or organic. If functional, it is often due to some form of general spinal irritation; if organic, it is commonly associated with more or less anesthesia. We meet the organic variety chiefly in connection with spinal meningitis, compression of the sensory nerve roots, and locomotor ataxia.

**Delayed sensations.** To the beginner in medicine as well as to the laity, nothing strikes the intelligence so forcibly as this symptom when well marked. Imagine a patient stuck with a pin, when unaware of its occurrence, and an interval of time (varying from one to thirty seconds) to elapse without any consciousness of the wound. Imagine the patient then suddenly becoming conscious of the injury with all the evidences of pain that should have occurred without any perceptible interval of time in a healthy subject. This is delayed sensation. It occurs chiefly in connection with the disease known as "locotomotor ataxia."

This symptom is to be interpreted as an evidence of imperfect conduction of sensation to the brain by means of the sensory nerves and the so-called "sensory tracts" of the spinal cord. The sensation is not arrested "in toto;" it is simply delayed. Complete abolition of sensation or "anesthesia" is liable to be developed later—when the nerves or sensory tracts are so extensively involved as to be no longer able to perform the functions.

**Sensibility to Temperature.** In testing this variety of sensibility, the precautionary steps previously mentioned in connection with sensory disturbances must be carefully observed.

Test-tubes holding water of different degrees of temperature are then applied to different regions of the body which have given previous evidences of sensory disturbances, and the patient's ability to discriminate between them with accuracy should be noted. The temperature of the test-tubes should be greater or less than that of the skin (98°), and of a uniform size. This prevents the confusion of simple "tactile" sensations with those of temperature. Breathing upon the surface of the patient answers as a rough test for the appreciation of heat.

**Sensibility to Pain.** The tests for this variety of sensibility comprise (1) pinching or pricking of the skin; (2) the application of extreme heat to the skin; and (3) the use of a powerful Faradic current upon the skin with dry electrodes. The patient should never be prepared for this test, as he may fail to give external evidences of pain from an assumed fortitude. Sensitiveness to pain and temperature may sometimes be affected when tactile sensations are not impaired.

**The Special Senses.** These comprise smell, sight, hearing, taste, and touch. The latter has already been discussed.

**FIG. 31.—Diagrammatic Representation of the Skin Symptoms in Unilateral Lesion of the Dorsal Portion of the Spinal Cord on the Left Side (Emb). The diagonal shading (a) signifies motor and vascular paralysis; the vertical shading (c and d) signifies anesthesia of the skin; the dotted shading (e) indicates hyperesthesia of the skin.**

**FIG. 32.—A Diagram designed to show some of the Relations of the Optic and Olfactory Nerve-fibres to Surrounding Parts. F, Frontal lobes of cerebrum; P, parietal lobe; J, temporal-occipital lobe; S, fissure of Sylvius; B, fissure of Rolando; O, occipital lobes; C, cerebellum; M, medulla oblongata; I, corpora quadrigemina; v, optic tracts; z, optic chiasma; 6, optic nerves; 3, olfactory nerve; 5, motor-ocular nerve; g, trigeminal nerve; a, basis crania; b, tegmentum crania. The circles at the parietal lobes represent the points where the olfactory tracts and the occipital:temporal:parietal and occipital:parietal:temporal:frontal fissures come to a point in the olfactory and occipital lobes.**

**The nerves of the first four are connected with the brain. We therefore are liable to encounter abnormalities of these senses in connection with brain diseases, but not with diseases of the spinal cord.**

**Smell.** The abolition of smell, or "anosmia," is to be
detected by the following methods: (1) Use the same test upon the nostrils alternately; (2) avoid all irritating substances, such as ammonia, acetic acid, snuff, etc.; (3) employ both agreeable and disagreeable odors (coffee, wine, cheese, etc.), so that the nose may perceive them by means of the throat, rather as imaginary taste-perceptions than as true olfactory impressions.

The abnor mal acuteness of smell, or "hyperosmia," may indicate brain disease that creates irritation of the olfactory nerve. Nauseating odors to the healthy subject may become agreeable to such patients. Pleasant odors, such as those of flowers, may cause nausea, headache, or possibly convulsions.

Paralysis of the eye-muscles. The attitudes assumed by the patient as a result of defective power in some of its muscles have been discussed in the second portion of this article. These are described more fully in the author's work previously referred to.

Hemianopsia. This condition is characterized by a blindness of one lateral half of each eye; the unaffected half of each eye retains its power of sight. The forms of this condition that are observed and the tests employed to detect it have been referred to already. A choked disk. This condition is also known as a "neuro-retinitis," because the optic nerve and retina both participate in the changes that ensue. It has been discussed already in this article, and more fully described in a paper on the corpora quadrigemina (see Medical Record, August 18, 1863).

Robinson's pupil. This condition is characterized by extremely small pupils that contract for the focusing of vision upon near objects (within a radius of twenty feet), but do not respond to varying degrees of light. The tests employed to determine this point have been previously mentioned in the second section of this article.

Amblyopia and amaurosis. These terms are usually employed to convey all the various conditions of blindness where no organic changes in the eye itself can be seen to account for them. The term "amblyopia" is frequently used to denote a mild degree of "amaurosis."

The more common causes of these two conditions comprise (1) poisons, such as lead, tobacco, and urea; (2) exposure to a prolonged glare, as in snow-blindness; (3) sleeping with the eyes open; (4) irritation of the fifth cranial nerve, as in severe neuralgia; (5) certain brain diseases. The latter are of special interest in this connection. The following diagrams may prove of aid in explaining certain anatomical points that bear directly upon the subject.

---

**Diagram 1:**
A diagram showing the General Course of Fibers in the Sensory and Motor Tracts, and their Relation to Certain Fasciculi of the Optic Nerve-trunks (modified from Segnis). The course of sensory fibers in the optic nerve, extending to the spinal cord, and the course of motor fibers passing through the central nervous system.

**Diagram 2:**
A diagram showing the visual fields of the brain. The visual areas are divided into the right and left hemispheres, and the upper and lower quadrants are indicated. The visual fields are shown to be symmetrical, with slight deviations on the temporal and nasal sides.

---

**Stover.**-In connection with vision, the neurologist is chiefly called upon to detect the following conditions: (1) Paralysis of the eye-muscles; (2) the Robertson pupil; (3) the condition known as "hemianopsia" or less correctly, "hemiplegia;" (4) the condition of the retina known as the "choked disk;" (5) the conditions known as "amblyopia" and "amaurosis."

The first diagram (Fig. 33) shows that the optic nerve-fibers eventually pass to those regions of the gray matter on the surface of the brain (the cerebral cortex) that are associated with the intelligent perception of the images focused upon the retina. But it will be observed that the optic nerve-fibers (a and b) first pass through certain collections of gray matter or "centres" within the optic thalami and the corpus quadrigemina before they radiate to the so-called "visual area" of the convolutions. Between the "visual area" and the "centres" designated in the diagram pertaining to sight-perceptions, the optic nerve-fibers traverse what is known as the "internal capsule" of the brain.
Let us now compare the preceding diagram with another which will make some of these statements more intelligible to the general reader. It will help to explain why it is that the two optic tracts are called, causes hemianopsia or blindness of one lateral half of each retina; while injury to or destruction of the visual area of the convolutions of the internal capsule of the brain causes ambylophia or amaurosis of the opposite eye.

Fig. 35.—A diagram designed to show the Course of Fibres within the Optic Nerves, and some of the more important Relations of the same. A, B, and C, fibres which do not cross at the chiasma, but probably do at the corpora quadrigemina; D, E, and F, fibres which do decussate at the chiasma. The relation of these fibres to the "internal capsule" of the cerebrum is also shown. This portion of the cerebral hemisphere is shown to be in relation with the fibres distributed to both eyes; hence, lesions within it tend to produce "crossed, hemianopsia." The relation of bundles within the chiasma is made apparent. The fibres of the chiasma which connect the two eyes directly (inter-renal fibres), are not shown, because they have no bearing upon symptoms, even if their existence is to be considered as demonstrated.

The author would refer those readers who are desirous of further information upon this subject to his article upon the "Corpora Quadrigemina" in The Medical Record of August 18, 1883.

Taste.—This special sense is presided over by the gustatory branch of the fifth cranial nerve, the glosso-pharyngeal nerve, and the chorda tympani branch of the facial nerve. Taste may be affected, therefore, by any diseased condition that can cause either a diminution or destruction of the fibres of these nerves. Certain functional diseases, in contradistinction to organic lesions of the brain, may also cause modifications of taste.

An abnormal sensitiveness of taste is known as "hypergeusia." It may be developed in connection with hysteria; with melancholia and some other types of insanity; and with facial paralysis of thumatic origin. Such subjects can often detect extremely small quantities of sapid substances in solution, which in health would be unperceived. They may perceive gustatory sensations when the electric current is applied over the spine in the region of the neck or upper dorsal vertebræ. They may develop a loathing of certain dishes which have previously been their delight, from some imaginary taste of a disagreeable character. Again, this condition may express itself in an unnatural enjoyment of food. Finally, sweetish, sapid, or sour tastes within the mouth may be constantly present.

A loss of the sense of taste is known as "ageusia." It may be complete or partial. Some regions of the tongue may be affected and others retain the sense of taste. In some instances, the tongue may be sensible to certain substances, and insensible to others. It may be associated with a sense of burning and bitterness within the mouth, as in a case reported by Böttcher, where a tumor at the base of the brain was its exciting cause.

This abnormal state has been observed to follow the development of tumors of the brain or its coverings; paralysis of the fifth cranial nerve; sclerosis of the medulla oblongata; injuries to the glosso-pharyngeal nerves; atrophy of the nerves associated with taste; and ear disease causing pressure upon the chorda tympani branch of the facial nerve.

Drinking.—The mechanism of the ear is so complicated that defects in hearing are commonly due to some abnormal condition of the apparatus itself, rather than of the nerve of hearing or the brain. Perhaps the most reliable test to determine the presence of the latter condition is the employment of the tuning-fork. If this instrument be set in vibration and applied to the teeth, or bones of the skull, the transmission of the sound-waves through the bones will enable them to reach the nerve-filaments of the internal ear and afford the patient perceptions of sound. If the patient is unable to perceive sound when thus conducted to the nerve-filaments, it is strongly suggestive of some diseased condition within the cavity of the skull.

In closing this article, the author feels that he has perhaps overstated the patience of his readers. If he has erred in this direction, it is because he has endeavored to cover a large field within the limited compass of a single article, and to so interpret the symptoms of nervous diseases as to bring them within the grasp of the general practitioner of medicine. It must not be inferred that all of the tests described are of necessity demanded in each individual case that is brought to the notice of the neurologist. As Gower happily remarks, "To know our enemy is, if not half the battle, at least an important part of it." When once the symptoms of nervous diseases have been thoroughly mastered, the special lines of investigation demanded in each case become as clearly defined as does the course of his vessel to the mariner, to reach the harbor for which he steers. This article gives but the rough outlines of a chart in which the short cuts to valuable information in diagnosis are imperfectly jotted. Arduous and persistent labor on the part of each of its followers can alone fill in its details and render it complete.

ON FOERSTER'S METHOD OF ARTIFICIALLY RIOPENING CATARACTS.

By WM. F. MITTENDORF, M.D.,
NEW YORK.

It is generally admitted that a cataract, in order to be successfully operated upon, must be mature or ripe. The connection of the lens and its capsule is very slight at this time, and its escape after the opening of the latter is more or less complete. If any cortical matter remains it will, being opaque and having undergone certain retrogressive changes, soften rapidly and become eventually entirely absorbed. The process is very different if parts of the lens are still clear or imperfectly opaque. These portions are not yet loosened from the capsule, and will remain adherent to it after the removal of the cataract. Shortly after the operation they undergo decided changes; they swell, and will not only interfere with vision if they are centrally located, but they exert pressure upon the iris and cause an inflammation of it, which may subsequently lead to the loss of the eye.

The rule is, therefore, not to operate unless the cataract is perfectly ripe. This is usually easily diagnosed by the absence of any clear portions of the lens, which would give the cataract a mottled or speckled appearance or show itself by a glistering mother-of-pearl-like look of it, or by a broad dark shadow between the pupillary edge of

---

1 Read before the Medical Society of the State of New York, February 6, 1884.
the iris and the lens; the latter indicating the presence of clear lens substance between the anterior capsule and the nucleus. If the lens is ripe it is uniformly opaque, and no red reflex of the fundus of the eye can be seen with the ophthalmoscope, even after the dilatation of the pupil by a mydriatic. If left to nature this process may be completed in four or eight months after the first sign of a lenticular opacity; but in some cases it may take many years. The hercules of the process may prevent years of blindness and relieve not only the patient, but also his family, from great distress.

If a perfectly healthy lens is injured it will, as a result of this accident, become opaque; a traumatic cataract will be the result. Acting upon this well-known fact, several operators have attempted to hasten the maturing of a cataract developing very slowly by the puncturing of the lens-sac with a needle. But unfortunately this is not devoid of danger; the lens may become dislocated, or swelling of the cataract and severe inflammation may be the result, or what is more frequently the case, the effect of the puncture is unimportant and evanescent; the ripening of the cataract is then slightly hastened. This operation is described in detail in the second edition of the Medical Record.

Another plan to accomplish the same purpose has lately been advocated by Professor Foerster, of Breslau, whose experience in this line has been very extensive. He had observed, like several other operators before him, that after a preliminary iridectomy the opacity of the lens developed rapidly in the case. He thought, therefore, to make a preliminary iridectomy in the direction in which we intend to extract the cataract, which is usually in an upwards curve. The lens will now, after the escape of the aqueous humor, fall forward and come in contact with the posterior surface of the cornea, a condition which must necessarily be associated with a certain amount of traction on the suspensory ligament of the lens and the ciliary body, and it has been inferred that this might be the cause of a more rapid increase of the cataract. If the cornea is rubbed with a hard but smooth substance, so as not to injure it, either in a circular manner or by stroking it from the centre towards the periphery, as Dr. Foerster recommends, great changes may be produced in the lens, and as the opacity, as long as the lens is in contact with the cornea any pressure exerted upon the latter must also be felt by the former, and may therefore lead to a certain amount of disturbance of its anatomical arrangement, especially if some opacity of the anterior cortical matter is already present.

The effect of this manipulation may be so decided that a partly opaque lens can be transformed into a ripe cataract within a few days. But such rapid changes are only exceptional; it takes usually more than four or six weeks to accomplish it. The cause of this change is supposed to be a disturbance of the anatomical arrangement of the lens-fibres, or as others have expressed it, a direct crushing of them. It strikes me, however, that pressure sufficient to do this would lead necessarily to a rupture of the delicate suspensory ligament. We might explain it, however, in the following way: Professor O. Becker, in his recent researches on the anatomy of the healthy and morbid lens, finds that the very first step in the development of a simple cataract is the formation of spaces or clefts between the lens-fibres. They are formed by the normal shrinking of the fibres and the collection of the nutrient fluid. The presence of the latter will now, by abnormal diffusion, lead to disturbance of nutrition, to swelling of the surrounding fibres, and to further cataractous changes. By pressure on the lens the fluid of these spaces will, acting as a wedge, be easily forced between the fibres of the surrounding clear portions of the lens and thus lead to an opacification of them. This explains why in the rubbing of a perfectly clear lens or of a cataract in which only the nucleus becomes opaque and hard, the cortical substance remaining perfectly clear, no effect whatever is produced. In very old people with hard lenses this manoeuvre is of course less effective than in younger ones without a great amount of lens.

This operation has also been called a trituration, or as Dr. Noyes prefers to call it, a massage of the lens. Foerster, who has done this operation more than two hundred times, considers it devoid of great danger; he does not even report any complications or inflammatory sequelae. If such a result could always be obtained, a very valuable operation would be added to ophthalmic praxis, especially as it tends to simplify the final extraction of the cataract by removing the source of great dangers to the ultimate success. By performing the iridectomy some time in advance of the extraction we are doing away with all annoying hemorrhage into the anterior chamber, and iritis is not so apt to occur in the course of the operation.

But the question is, Is this operation devoid of great danger, or must it be used only in certain exceptional cases and with great care? As this operation is comparatively new, the results which other surgeons have had with it are of the greatest importance. In a very able paper on this subject by Professor H. D. Noyes, which was published in the Medical Record August 4, 1883, he closes with the remark that the moderate experience thus far collected indicates that this operation merits further trial.

The object of my paper to-day is to give you the result of my experience, which is unfortunately not quite so fortunate as that of Professor Foerster. Nor is it as good as that of Dr. Noyes, who out of eight cases had twice severe iritis as a sequel to the operation. I have thus far made twenty operations of this kind during the last fifteen months, and have observed three times very serious complications, and in one of these I fear it led even to the loss of the eye, as purulent iritis and panophthalmitis developed (see Case 11). Even if we admit that very severe complications may follow a simple iridectomy, or that a perfectly normal cataract extraction may be followed by irido-cyclitis and loss of the eye, yet the large number of inflammatory conditions of the iris that have been observed by Dr. Noyes and myself indicates the dangerous nature of the operation. A mild form of iritis, the result of swelling due to the pressure of the lens, like posterior synechiae, was observed in eight eyes. In the remaining nine cases no bad effects of the operation were observed; the healing process was good and short, and some of the patients could leave the bed on the second, and the hospital on the third or fourth day; they required no after-treatment, except an application of a cold solution of atropine and warm compresses, one day as long as there was a ciliary injection; this disappeared entirely about the eighth or tenth day. Considering that the operation was always done very carefully, and that thorough disinfection of the instruments as well as of the eye was conscientiously observed, the great number of complications is very striking; but this has also been the experience of other operators besides Dr. Noyes and myself, and I know of the loss of two eyes after this operation, which had been done by very skilful and careful surgeons.

Why should there be so much danger to the iris and to the ciliary body in this procedure, so much more than in an iridectomy for corneal opacities, for instance? I think this depends partly upon the condition the eye is in at the time of a developing cataract, but especially upon the nature of the operation, namely, the rubbing of the cataract and the amount of pressure needed to affect the lens sufficiently. It is well known that with the formation of a cataract a certain amount of swelling of
Method of operating.—I would recommend that the following rules be observed as strictly as possible: The eye should be brought fully under the influence of a mydriatic before the operation. Ether must be given to produce profound narcosis. A narrow cataract-knife, which is not too thin or elastic, should be used to make the incision into the corneal section. The trichotomy must be moderately large and peripheral, but it must not encroach upon the ciliary region. The trituration of the lens should be confined as much as possible to the pupillary space, and is to be done with a smooth, unyielding instrument; the convex side of a strabismus hook is as good as anything. It must be done in a rotatory manner; it is not to be interrupted if possible, and should be completed in a minute or two.

After-treatment.—After a thorough cleansing and disinfecting of the wound and conjunctival sac by means of a concentrated solution of boric acid, atropine is to be instilled. Both eyes are to be bandaged, and the patient must be kept in bed for a few days until the wound is healed. If no pain or other signs of inflammation are present the bandage may be removed and the patient allowed to sit up. The last traces of injection around the wound will disappear in about ten to fourteen days.

Results.—The time intervening between this operation and the complete ripening varies considerably; it depends on the extent of the opacity, the nature of the cataract, and the amount of strabismus used, and the extent of the inflammation or cause a prolapse of the vitreous humor at the time of the final extraction of the lens. In order to avoid these dangers the pressure exerted upon the cornea should be moderate but permanent, thus preventing the lens from moving to and fro; this will also lessen the chances of injuring the iris. The trituration should be done by a rotatory movement only, and be limited to the space of the normal pupil and the newly made coloboma. A rubbing or stroking motion from the centre to the periphery of the lens, as Dr. Foerster recommends, appears to me very dangerous, because the pressure at the periphery is very apt to injure the suspensory ligament, and because this manoeuvre does not give us a steady pressure. This is especially the case if the instrument used for the trituration is elastic, as this would make it very difficult to judge about the amount of pressure made, and because the pressure cannot be a steady, uniform one. For these reasons a strabismus hook, using the back of it as originally recommended, is preferable. I use an elastic rubber spoon or spud. In order to enlarge the area for the movement of the instrument and to lessen the danger of iris, the iris may be brought under the influence of a mydriatic in order to dilate the pupil. The use of atropine is also necessary for some time after the operation.

The indications for the performance of this operation, as you will see by the following cases, have been, in the first place, simultaneous formation of cataracts in both eyes; both advancing very slowly, but at such an even pace that both eyes became useless for any practical purposes, and were likely to remain so for quite a length of time without any chance of maturing soon. This was the case in thirteen patients, of whom fifteen triturations of the immature cataracts were made.

The second indication was the loss of one eye, either the result of an injury or an unsuccessful operative interference, in two patients, the remaining eye showing lenticular opacities which progressed very slowly.

The third cause was in one patient an incurable disease of the retina, which could not be improved by treatment and left the patient with very poor vision, the other eye being affected with an old but not complete cataract.

To the fourth class belong two patients who came from a great distance and could not well afford to return, and if they had returned it would have been perhaps only to find that the cataracts were not yet ready for an operation.
latter appear semitransparent after the use of atropine. Trituration of lens with strabismus hook after iridectomy November 20, 1883; slight iritis and two fine posterior synechiae; leaves his bed on the fourth day after the operation and returns after five weeks, which he spent visiting; O. S. cataracta immatura. For more than ten months the sight became affected and has been getting poorer, but has changed only slightly in the last few months. Is very tired of his condition. Trituration of lens January 15, 1885; iridectomy small; used Dr. Wecker’s hard rubber spatula; marked iritis. Cataracta extracted March 29th; healing normal; V. = 2/3; pupillary exudation.

Case III.—Andrew H., aged forty-three years; American; farmer. O. U. cataracta immatura. Patient has been gradually losing his sight for the last five years; came to the city about a year ago, but the cataracts were not ripe; no sugar or albumin in urine; no family or specific history; has always been well. Both cataracts are opaque, with a yellowish colored portion of lens. V = fingers at 10. Trituration without ether, with hard rubber spatula. Patient feels perfectly well after operation and remains up the entire afternoon, and retires feeling splendidly. The next morning intense pain in eye, wound not closed; purulent infiltration of surrounding portion of cornea. The inflammation increasing steadily, I applied the second day six leeches to temporal region, but the process advances steadily, and after four weeks patient returns home with a subacute purulent irido-cyclitis, and has not been heard of since.

Case IV.—Captain C., aged fifty-five years; American. O. D. cataracta immatura. V. = finger 6; O. S. cataracta immatura. V. = finger 12. The right eye has been under observation for nearly two years, but the process has been advancing very slowly. Is in the liquid business, and has been using atropine for several months in order to be able to get around. Trituration of lens March 15, 1883; no ether; done at office; patient returns home and recovers entirely in three days without irido-cyclitis. Lens removed; and irido-cyclitis is made on May 3rd; no ether; no complications, and recovers without suffering any pains. Ultimate vision, 2/3 with + 10 D.

Case V.—Mary P., aged seventy years; Irish. O. D. cataracta immatura; O. S. cataracta incipiens centralis. Patient is very much depressed because the left eye begins to fail rapidly. V. = 1/20. The right eye has been blind for a long time, as she says. Is perfectly blind when she is exposed to sunlight. Trituration of right lens, which shows large, glistening sectors, June 6, 1883; slight iritis and several fine synechiae; operation August 2nd; normal; slight iritis sixth day; prompt use of a sixteen-grain solution of atropine relieving it, but recovery slow; no pupillary exudation and slight raising of pupillary space. V. = 1/16.

Case VI.—Frances M., aged sixty-one; Irish. O. U., cataracta immatura. The right eye is a little more advanced than the left; has been nearly blind for several months and had poor sight for nearly two years. Both eyes clear sectors. V. = finger at 8. Trituration of right lens June 26, 1883; no complication; recovers rapidly. Final extraction some time in August; entirely normal; slight capsular opacity. V. = 2/3 with 9 D.

Case VII.—Mrs. B., aged seventy-nine years; American. O. D., had an extraction, but vision is very poor—fingers at six feet. O. S. cataracta provecta—fingers at five feet. Some parts of lens less opaque than the rest. Patient has marked idiiosyncrasy for atropine, and only a drop applied to the eye sets up marked conjunctivitis and erythema of face resembling erysipelas. Trituration June 28, 1881; small iridectomy; atropine not tolerated; duboisin acts exactly like the former; very severe iritis. Extraction, October 2, 1883, is followed by very severe iritis; recovery very slow. Some pupillary exudation. V. = 2/3.

Case VIII.—Jos. C., aged thirty-five years; Italian. O. D., cataracta mollissima; O. S., cataracta incipiens centralis (well-marked shadow of iria). The right eye blind six months; the left eye very poor for four weeks, rapidly getting worse; has to be on the street all day, and is very much troubled about his eyes. No albumen or sugar in urine. Trituration very carefully O. D., no complications, July 5, 1883. Extraction September 6, 1883; soft cortical matter left in capsule after removing a good deal by rubbing eye with lids and thumb; some iritis on seventh day; pupillary exudation. Needled October 2d. V. = 2/3.

Case IX.—J. M. B., aged fifty-nine years; American. O. U., cataracta immatura; has not been able to work as an engineer for more than six months; is poor and cannot afford to lose more time. Slight began to fail in both eyes about the same time, but right eye is much better. Trituration of left lens July 12, 1883; iritis follows and several synechiae have formed. Extraction September 9th; recovery clear and rapid. V. = 2/3.

Case X.—Nicholas T., aged fifty-two years; Irish. O. D., cataracta immatura; O. S., cataracta incipiens centralis. Has been affected on right eye for more than three years; left eye only recently. Could not drive his cart on bright days. Trituration of right lens July 26, 1883; no complication. Cataract removed August 23d; normal; slight iritis the following week. V. = 2/3 with + 10 D.

Case XI.—Mary D., aged sixty-two years; Irish. O. D., cataracta immatura; O. S., cataracta incipiens centralis. The right eye has been blind since Christmas, 1882; the left one practically so; especially on bright days she cannot venture out of the house. She has always been a very busy woman and has to attend to the wants of a large family. Right eye has a very marked mother-of-pearl appearance; projection good. Foerster’s operation July 26, 1883, under ether; elastic hard rubber spatula is used, stroking the lens freely; moderate amount of iritis, lasting nearly two weeks. Extraction September 10th, nearly two months after the trituration. Lens perfectly opaque, cortical matter pretty soft; very slight iritis. The pupil small; irido-cyclitis is made on May 3rd; no ether; no complications, and recovers without suffering any pains. Ultimate vision, 2/3 with + 10 D.

Case XII.—Theodore C., aged fifty-seven years; German. O. D., cataracta immatura; O. S., cataracta immatura. Both eyes—became dim two years ago, and for the last two months the patient has not been able to go out alone. The right eye sees fingers at 8 feet, left eye at 12 feet. Patient is a grocer, and his business suffers so much that he is very depressed and anxious to take the chances of hastening the ripening process. Trituration of lens of right eye August 10, 1883; no iritis; rapid recovery and final operation four weeks later; no complications, healing process normal; slight capsular opacity in several places, which was not noticed before the operation; iritis may be the result of the pressure at the time of the trituration. V. = 2/3 with + 10 D.

Case XIII.—Theodore C., aged fifty-seven years; German. Same patient as Case XII. By request the left eye is subjected to Foerster’s operation September 28th, just three weeks after the extraction of the cataract of right eye. Trituration with iris forceps. Slight iritis follows, but in three weeks the eye is free of injection, and the final operation is made October 27th, one day less than four weeks after the first one. Large corneal section; slight iritis on seventh day, which is, however, promptly relieved by a sixteen-grain solution of atropine.
used morning and evening, and by the application on
two successive nights of two drops each time. Some fine
capsular striae. \( V. = \frac{1}{2} \) with +10 D.

CASE XIV.—Joseph M——, aged fifty-two years;
German. Patient has a pretty large posterior polar cata-
ratc on the right eye, which interferes with vision con-
siderably. The left eye has a traumatic anterior capsular
cataract, which makes the eye practically blind. Tritu-
ration of the left lens October 6, 1881. Recovery rapid
and without inflammation; is able to leave the infirmary
on the third day after the operation. No change in the
lens three months later.

CASE XV.—Joseph B——, aged thirty-four years;
Italian. Detachment of retina. O.S., field of vision very
small, down and outward. Has been under treatment for
four months but no permanent benefit has been gained.
Right eye shows an old but imperfect cataract, with
posterior synechiae; projection moderately good. No
albumen or sugar in urine. Trituration November 1,
1881, with hard rubber spoon in the usual manner.
Slight iritis. Final operation November 28th; normal;
nucleus small; much soft cortical matter remains in
capsule. Two small white spots in the right eye. January
4, 1884, \( V. = \frac{1}{2} \). Can be improved by another operation.

CASE XVI.—Captain C——, aged sixty years; Greek.
O. D., cataracta immatura; O. S., cataracta immatura.
The right lens is more opaque than the left one, but not
ready for an operation. He is very anxious to recover
his vision, and readily submits to Foerster's operation,
which was done November 1, 1883. Patient is hard to
get under ether, and struggled after the section had been
made, so that the operation had to be discontinued
til the ether took more effect. Some blood in anterior
chamber; trituration with a hard rubber spatula. On the
next day severe pain set in; wound had not healed by
first intention; its edges are infiltrated, bazy, and lens
removed almost immediately. Complete recovery, in
excellent condition and hemicranial pain. Leeches, atropine,
and quinine used freely. Patient very restless. Had chronic
dysentery two years ago for a long time, and is slightly
debilitated on account of it. Leaves hospital three weeks
after operation in a pretty comfortable condition, but
returns in about a week with a severe relapse of the
iritis. There is some cyclitis, and after several weeks
the patient leaves again with a mild form of irido-cyclitis.
Promises to return, but has gone to Europe since, so
that the final result cannot be given.

CASE XVII.—S. W. H——, aged seventy-three years;
American. The right eye is small, phthisical after a
cataract extraction performed in some place in New
Jersey three years ago; it is of course completely blind,
but not painful to the touch. The left eye has been
useless on account of a cataract for the last two years,
but it is not yet ready for an operation on account of
sectors in the lens. Patient says he could make a
good living if he could see, but is now dependent upon
the charity of others. Foerster's operation on Novem-
ber 1, 1883. No reaction of any consequence fol-
lowed, and the patient is able to leave the New York
Eye and Ear Infirmary on the fourth day after the opera-
tion. Extraction of the cataract on December 1, 1884.
No complication at the time of the operation nor during
the healing process, and patient leaves the hospital on
the twelfth day after the operation, and has now \( V. = \frac{1}{2} \)
with a sphero-cylindrical glass.

CASE XVIII.—Joseph M——, aged fifty-two years;
German. Patient had left eye trituated without much
benefit for a capsular opacity (see Case XIV.). The
right eye has a large posterior polar cataract and chro-
moidal changes, but both perception of light and pro-
jection of forms is good. Trituration in some place with hook November 7,
1883, about a month after the operation on left eye. No
complications at the time of operation, nor during the
healing of the wound. Eye soft, and corneal section
very difficult. January 15, 1884, no change in appear-
ance of lens.
of New York, moved that the resolutions be taken up as the first item of miscellaneous business to morrow. Carried.

Dr. G. M. Hammond then read a paper entitled

**CAN LOCOMOTOR ATAXIA BE CURED?**

The author of the paper had collected a few cases which showed that posterior spinal sclerosis has been cured, and presented a patient who had remained cured for nearly two years. There was a sphyphilitic history. Dr. Hammond reached the following conclusions:

1. That absence of the patellar tendon reflex in locomotor ataxia is not always caused by sclerosis of the posterior columns.

2. That sclerosis of the posterior columns may exist without being accompanied by the ordinarily prominent symptoms of ataxia.

3. That congestion of the posterior half of the spinal cord may give rise to most, if not all of the symptoms of locomotor ataxia.

4. That it is impossible during life to make a differential diagnosis between posterior spinal sclerosis and posterior congestion.

5. That posterior spinal congestion is curable.

6. That there is no evidence to show that sclerosis once existing in the spinal cord has ever been removed.

7. That those cases of so-called locomotor ataxia which have been cured were simply cases of spinal congestion more profound in the posterior half of the spinal cord.

Dr. Hammond thought the view, that the condition was congestion and not sclerosis in the cases in which it had been said that locomotor ataxia was cured, was probably correct. He then reported a case lately under his observation, in which a man with an apparently sphyphilitic history, exhibited all the symptoms of locomotor ataxia, which did not yield to iodide of potassium in very large doses with mercury, but promptly yielded to nitrate of silver, one-fourth grain t. i. d., with codeine to produce sleep. He could not account for such results, nearly complete disappearance of symptoms within two weeks, except upon the theory of congestion.

Dr. Bartholow, of Philadelphia, thought a distinction should be made in cases when drawing conclusions concerning the action of remedies; that is, between those due to gummatas and those due to sphyllis, when it acts secondarily as a cause. In that restricted sense he believed locomotor ataxia could be cured; that is, the gummatas may be removed and the symptoms relieved, besides in many other cases the progress of the disease can be arrested. He did not believe that any case of locomotor ataxia is curable in the sense of removing the status quo.

The paper was further discussed by Drs. Corning, of New York; Webber, of Boston; Rockwell, of New York; Massey and Mills, of Philadelphia; Bannister, of Chicago; Birdball, of New York, and Dr. G. M. Hammond.

Dr. S. G. Webber, of Boston, then read a paper on

**MULTIPLE NEURITIS,**

an affection which has lately assumed an importance not accorded to it formerly. It is only within a few years that general inflammation of the nerves has been recognized. Cases have been reported at intervals, but special attention was not directed to the subject until Jeffroy, in 1879, Leyden, in 1880, and Stewart, in 1881, described cases. Even then it was some months before the possibility of a general diffused neuritis was fully recognized, if, indeed, it is as yet.

Up to this time, Dr. Webber had found the records in the Boston City Hospital of six cases without and twelve cases with autopsy. He gave a summary of each of these, and exhibited microscopic sections of nerves removed from the bodies of the patients, which showed thinning of the medullary sheath at Ranvier's constrictions, without break in the axis cylinder, and without increase of nuclei; or in the fibres most altered, an increase of nuclei, granulated debris, and apparently small masses of protoplasm united in the midst of it. The distal ends of the nerves showed the changes of secondary degeneration after section of a nerve. Disturbances of sensation is one of the most constant and prominent symptoms. Sometimes the patient can mark the course of the nerve by the pain. General loss of flesh is a prominent symptom.

The disease is to be diagnosed from anterior poliomyelitis by pain and hyperesthesia, tenderness over nerve-trunks, etc. Differential diagnosis must also be made between it and progressive muscular atrophy—lead paralysis. Dr. Webber was not sure that any treatment shortened the attack. Salicylic acid seemed to cut short the pain in some cases. In most cases the patients recovered more or less completely, but in several cases much time and patience were required in straightening the contracted limbs, and strength was regained only very gradually.

The paper was discussed by Dr. Rockwell, of New York, who spoke of the good effects produced by touching the sensitive points with the actual cautery, and by Dr. Birdball, of New York, who was inclined to the opinion that the changes in the nerves in this class of cases are due to central lesions.

Dr. Webber had found blisters to be acceptable to patients, and they relieved the pain. He had been unable to induce his patients to submit to the use of the actual cautery.

Dr. R. W. Amidon presented a specimen which showed degeneration of gyrus angularis, the lesion found in

**A CASE OF WORD-DEAFNESS AND BLINDNESS, WITHOUT PARALYSIS.**

Dr. Roberts Bartholow, of Philadelphia, then read a paper on

**SOME OF THE USES OF CHLORIDE OF GOLD,**

in which it appeared that the compound of chloride of gold and sodium had proved serviceable in the treatment of a large number of affections, but especially sclerosis wherever developed.

The communication was discussed by Dr. Bannister, of Chicago, and Dr. Dana, of New York.

The Association then adjourned to meet at 2:30 P.M. Friday.

**FRIDAY, JUNE 29TH—THIRD DAY—AFTERNOON SESSION.**

The Association was called to order by the President. The Secretary acknowledged the receipt of letters of representation from Dr. Schmidt, of New Orleans; Eskridge and Weir Mitchell, of Philadelphia; Jewell and Clevenger, of Chicago, and Seguin, of New York. He also acknowledged the receipt of four monographs from Dr. Bernhardt, an associate member.

Dr. Danillo was elected associate member.

**PROPOSED AMENDMENTS TO THE CONSTITUTION AND BY-LAWS.**

Dr. W. A. Hammond offered the following:

To amend Article VI. of the Constitution by striking out the words, "third Wednesday in June," and inserting, "first Wednesday in May."

Dr. E. C. Spitzka offered the following amendment to the By-laws: "All business not of a scientific nature shall be transacted in executive session. An executive session shall be held after each regular session."

**ENCEPHALIC NOMENCLATURE.**

Dr. Wilder's resolutions were taken up and the one providing for the appointment of a committee of five by the President, to report next year, was adopted.

The President appointed Drs. Wilder, Spitzka, McBride, Birdball, and L. C. Gray.
On motion the other resolutions were referred to this committee.

The President called Dr. W. R. Birdsall, of New York, to the chair and then read a paper entitled 'The Effects of Injuries of the Spinal Cord Upon the Excretion of Carbonic Anhydride.'

The experiments were performed on rabbits and cats by means of Wordschlof's instrument. The apparatus was heated to 100° F., the rectal temperature was taken and the animal placed in a chamber. The reason for maintaining the calorimeter at so high a temperature was that he wished to see the effect on the rectal temperature. If the ambient air should be much lower than that of the animal, then so much heat would be dissipated through the vaso-motor paresis that no rise of rectal temperature would take place.

Dr. Walton read an experiment upon partial division of the spinal cord, an increase of carbonic acid was noted in all except two. It made no difference in a majority of them whether the white or gray matter was alone divided. In relation to temperature and partial section of the cord no rise of temperature was seen above that observed after the animal had been an hour in the calorimeter in the others fell below normal. The rise of temperature took place where little beyond the spinal gray matter was divided.

The paper was discussed by Drs. Bartholow, of Philadelphia, W. A. Hammond and E. C. Spitzka, of New York, and the discussion related to the effect produced on the temperature of rabbits merely by confinement and an analysis was given.

Dr. G. L. Walton, of Boston, then read a paper, entitled 'A Contribution to the Study of Hysteria as Bearing on the Question of Oophorectomy.'

When the hysterical symptoms occurring in persons possessing no hereditary nervous susceptibility date from the accession of a pelvic trouble, and disappear with its relief, the etiological connection between the local and general disturbance can hardly be doubted. It was to that class of cases, distinguished from those in which the local symptoms are secondary to the hysteria, that the question of oophorectomy should be narrowed. In certain cases of hysterical hemianesthesia and hystero-epileptics it is not improbable that the implication of the ovaries in an organic disease offers the starting-point for the irritation producing the hysterical condition, and in such cases the prospect of relief from operation is too good to be neglected, when milder measures have failed, and when the symptoms are severe enough to make life a burthen on account of pain.

Dr. Walton placed upon the anatomical connection between the ovaries and hysterical symptoms, and the relation which exists between them and the cortical cerebral nerve-cells. He also discussed the two theories, the dynamic and the vaso-motor, and gave his reasons for accepting the latter in explanation of the phenomena of hysteria.

Dr. Walton cited a case which illustrated the rôle which hysteria may play as an indication for the operation. The marked improvement which followed was with regard to the convulsive attacks, previously so severe and frequent, only two slight attacks having appeared since the operation.

On motion by Dr. Amidon, the courtesies of the Association were extended to Drs. Emily Blackwell, E. M. Cusher, and M. Putnam-Jacobi, and they were invited to participate in the discussion of Dr. Walton's paper.

The discussion was opened by Dr. E. C. Spitzka, of New York, who was far from being as clear in his mind as the author of the paper had expressed himself concerning the propriety of resorting to oophorectomy.

Dr. C. K. Mills, of Philadelphia, was of the opinion that, in certainly the vast majority of cases in which the operation had been performed, the patient might have been relieved by other measures.

Dr. J. J. Putnam, of Boston, thought that as the relief of eye-strain in a certain number of cases gave relief to other head symptoms, so oophorectomy, if performed with the patient's complete understanding of the possible results to be obtained, must necessarily remain as one of the means to be resorted to, at least when all other measures have failed.

Dr. Rockwell, of New York, had been impressed with the fact, based upon the records of cases seen at the Woman's Hospital, that in quite a minority of cases where various symptoms had been attributed to ovarian disease, they were really not dependent upon disease of the ovaries, but upon other conditions, and the patients had been relieved entirely while the ovarian disease remained unchanged.

Dr. Putnam-Jacobi referred to cases in which improvement followed the operation, and the discussion was closed by Dr. Walton.

Typical Hysterical Symptoms in Men Due to Injury, and Their Medical Legal Significance.

Dr. J. J. Putnam, of Boston, read a paper on the subject, in which he gave the history of a case, and some of the points brought out on the trial for damages for injuries alleged to have been produced by a railroad accident. It was the third case he had seen of more or less complete hemianesthesia in male patients, within a comparatively short time, as the result of concussion. It was well known that the general hysterical state, as well as a variety of marked hysterical symptoms, might make their appearance under certain circumstances in men.

A number of cases of this kind had been reported by Page ('Injuries to the Spine'), to whom justly belonged the credit of pointing out that Einichsen and his followers are on the wrong track in seeking to group the symptoms of railway concussion among the signs of spinal disease, instead of referring them to the functional central disorders where the majority of them unquestionably belong.

The only original observations which his paper sought to establish was, that even when all the prominent symptoms of hysteria, if any were present, have faded away, disorders of sensibility, mainly unilateral, may remain and serve as a welcome guide to the expert. It was past belief that a man, not previously under the training of a professional expert, should be shrewd enough to assert a set of symptoms which neither court nor jury could comprehend nor sympathize with.

Dr. Putnam thought it would conduct to the interest of justice and the credit of the profession, if the courts could be led to understand clearly that there is a hysteria which deserves something better than to be treated with a smile and a cold shoulder; that it is an affection which has its own pathology and its own symptoms, and is not a mere mirror of real disease.

The paper was discussed by Dr. C. L. Dana, of New York.

Dr. Sarah J. McNutt then presented a brain which showed atrophy with sclerosis of the region of the fissure of Rolando and read a paper entitled 'Double Infantile Spastic Hemiplegia' based upon the history of the case.

The Association then adjourned to meet at 8.30 p.m.

Third Day—Evening Session.

The Association was called to order by Dr. W. R. Birdsall, of New York, Vice-President.

Dr. Auguste Forel, of Zurich, was elected associate member.

Reading of papers being next in order, Dr. Birdsall called Dr. L. Weber, of New York, to the chair, and then read a paper on 'Ophthalmoplegia Externa Progressiva,' in which he reported two cases of slowly progressive
paresis of all the external muscles of both eyes, producing ptosis and nearly complete immobility of the eye-balls, with complete preservation of the functions of the internal ocular muscles, accommodation being normal, and reaction of the iris to light and accommodative movements also normal, without perceptible lesion of the fundus; vision normal in one case, defective from irregular astigmatism in the other; no evidence of disease in any other cranial nerve, or in any part of the body; no headache, nor sign or suspicion of syphilis; both male patients, aged respectively seventeen and twenty-nine years.

The paper was discussed by Dr. E. C. Spitzka, of New York, who spoke of the possible explanation of the paralysis from an anatomical standpoint, and the discussion was closed by Dr. Birdsall.

STATISTICS CONCERNING LOCOMOTOR ATAXIA AND SYPHILIS.

Dr. Birdsall also presented Dr. E. C. Seguin's statistics based on cases from private practice, with special reference to the efficiency of syphilis in the etiology of tabes dorsalis.

There were 72 cases, of which 22 gave a history of chancre alone, or 30 per cent.; 16 gave a history of chancre and secondary symptoms, or 22.2 per cent.; a total of 52.2 per cent. with syphilitic histories.

Of the 72 cases, there was no history of chancre or secondary symptoms, or 19.4 per cent.; in 10 cases no mention was made with regard to syphilis, or 28 per cent.; total, 48.4 per cent.

Of the 72 cases, therefore, there were 52.2 per cent. with syphilitic history, against 47.2 per cent. in which there was either no chancre or secondary symptoms, or no mention was made concerning syphilis.

Dr. Birdsall also added the statistics which he presented last year. Whole number of cases collected, 525; 225 with history of syphilis, or 43 per cent. Of his own cases there were 42, and of these 4 gave a history of syphilis, or 9.5 per cent.

Dr. Amidon presented Dr. Webber's (Boston) statistics; 62 cases, 33 hospital, 29 private; 20 had had syphilis, 54 per cent.; 17 had not, 46 per cent.; not mentioned in the other cases. Of the 37 cases 19 were hospital and 18 private patients; of the 19 hospital patients 13 had had syphilis; of the 18 private patients 7 had had syphilis.

Dr. E. C. Spitzka, of New York, had two sets of statistics; total 61 patients in dispensary practice, and 23 or 25 private patients. The proportion of well-established syphilitic cases was over eighty per cent. One case was a well-established cure effected by anti-syphilitic treatment.

Dr. Rockwell, of New York, had had 44 cases of locomotor ataxia, in 17 of which there was a distinct history of syphilis, or about forty per cent. Six of the patients were women, and two were syphilitic.

Dr. J. J. Putnam, of Boston, said that of the 34 cases which he sent to Dr. Seguin, forty-nine per cent. were syphilitic. There were two cases occurring in women, and neither of them was syphilitic.

Dr. E. C. Seguin remarked that of his sixty-one cases, two occurred in women, neither of whom was syphilitic.

Dr. L. Webber gave the statistics which he had already published (see The Medical Record, April 5, 1884).

The general subject elicited some discussion, after which Dr. C. L. Dana, of New York, read a paper entitled

FOLIE DU DOUTE AND MYOPIA

in which he referred to the history of folie du doute, or the "doubting madness," chiefly studied by the French. Griesinger and Berger had also described a psychopathic symptom which belonged to the same category, and had called it "doute KelsUCHT," or metaphysical mania. In folie du doute the patient is harassed with a constant desire to question, speculate, and refine over details. His mind is never settled, but is in a condition of "pruritus," it is a psychopathic symptom which indicates that the patient is a monomaniac, and truly insane, or only hypochondriacal, or profoundly neurasthenic and hysterical. It is the form in which primârè verrucktheit sometimes develops. Myopia, or fear of contamination, is a symptom indicating probably a similar condition.

Folie du doute has been divided into several varieties, such as the suspicious, the calculating, the timid, and, finally, the tactile, and myopia had been classed as the tactile form of folie du doute. This classification is open to criticism, but Dr. Dana was inclined to think it correct.

He then related two cases, one of typoid, folie du doute, as described by Falvet, Ball, and others; the other one of myopia, as first described by Dr. Hammond. The first patient was a married man, thirty years of age; the second was a single woman, twenty-eight years of age.

The paper was discussed by Drs. E. C. Spitzka and L. Weber, of New York; J. J. Putnam, of Boston, and the discussion was closed by Dr. Dana.

The following papers were read by title: "Mental Physics," by Dr. S. V. Cleveinger, of Chicago; "Note, with several photographs, on the Impossibility of Mistaking the Auditorium for the Trigeminal Region in the Medulla Oblongata of Reptiles," by Dr. John J. Mason, of New York, R. I.

Dr. G. Betton Massey, of Philadelphia, then read a paper, in which he reported

A CASE OF SUDDEN LOSS OF VISION, FOLLOWING ANESTHESIA OF THE FIFTH NERVE, WITH REMARKS ON THE MODIFYING EFFECTS OF ANESTHESIA ON THE CALYNO-REACTION OF THE SPINAL SENSES.

The paper was discussed by Dr. A. D. Rockwell, of New York.

Dr. George W. Jacoby read a paper on "CEREBRO-SPINAL SATURNISM, in which he reported two cases, one of saturnine paraplegia, and one of saturnine ataxia. The paper was discussed by Drs. Amidon, Birdsall, and Dana, of New York.

Dr. C. L. Dana, from the committee appointed to report a minute or letter on the death of Dr. George M. Beard, reported, and the report was accepted and ordered entered on the minutes.

The Association then adjourned, subject to the call of the Council as to time and place for 1885.

THE POWER OF LOCAL HEALTH BOARDS.—The United States Supreme Court has just decided an interesting case between two slaughter-house companies doing business in the city of New Orleans. One of these companies had some exclusive trade privileges granted to it by the Louisiana Legislature, which were afterward revoked by the Legislature. Subsequently health ordinances were passed by the city authorities of New Orleans which interfered with the business of the company to some degree. A suit was then brought to restrain any interference by the authorities, it being claimed that the original exclusive rights granted by the Legislature created a contract which could not be violated. The case came to the Supreme Court of the United States, which has just held that the regulation of unwholesome and dangerous trades is included in the general police powers of the State, which it has for its own preservation, and that nothing can interfere to prevent the execution of ordinances intended for the improvement of the general health or the well-being of society. This power to enforce health regulations cannot be bargained away, or legislated away under any circumstances, and consequently the Louisiana Legislature exceeded its powers in originally granting the exclusive privileges to the company, and it could afterward revoke them legally.
Progress of Medical Science.

PEDIATRIC APHRORISMS.—The following aphorisms of Professor Letamendi are quoted in El Diccion de May 10, 1884: 1. Malignant fever does not always come with the chill. 2. A grayish secretion is not always a sign of dysentery. 3. A patient who always asks for something is often sick. 4. A person who always wears the same clothes is often sick. 5. A person who always laughs is often sick. 6. A person who always cries is often sick. 7. A person who always sleeps is often sick. 8. A person who always walks is often sick. 9. A person who always sits is often sick. 10. A person who always stands is often sick. 11. A person who always talks is often sick. 12. A person who always reads is often sick. 13. A person who always writes is often sick. 14. A person who always draws is often sick. 15. A person who always paints is often sick. 16. A person who always plays is often sick. 17. A person who always works is often sick. 18. A person who always sleeps is often sick. 19. A person who always wakes is often sick. 20. A person who always dreams is often sick. 21. A person who always fears is often sick. 22. A person who always hopes is often sick. 23. A person who always regrets is often sick. 24. A person who always rejoices is often sick. 25. A person who always grieves is often sick. 26. A person who always rejoice is often sick. 27. A person who always grieves is often sick. 28. A person who always rejoices is often sick. 29. A person who always grieves is often sick. 30. A person who always rejoices is often sick. 31. A person who always grieves is often sick. 32. A person who always rejoices is often sick. 33. A person who always grieves is often sick. 34. A person who always rejoices is often sick. 35. A person who always grieves is often sick. 36. A person who always rejoices is often sick. 37. A person who always grieves is often sick. 38. A person who always rejoices is often sick. 39. A person who always grieves is often sick. 40. A person who always rejoices is often sick. 41. A person who always grieves is often sick. 42. A person who always rejoices is often sick. 43. A person who always grieves is often sick. 44. A person who always rejoices is often sick. 45. A person who always grieves is often sick. 46. A person who always rejoices is often sick. 47. A person who always grieves is often sick. 48. A person who always rejoices is often sick. 49. A person who always grieves is often sick. 50. A person who always rejoices is often sick. 51. A person who always grieves is often sick. 52. A person who always rejoices is often sick. 53. A person who always grieves is often sick. 54. A person who always rejoices is often sick. 55. A person who always grieves is often sick. 56. A person who always rejoices is often sick. 57. A person who always grieves is often sick. 58. A person who always rejoices is often sick. 59. A person who always grieves is often sick. 60. A person who always rejoices is often sick. 61. A person who always grieves is often sick. 62. A person who always rejoices is often sick. 63. A person who always grieves is often sick. 64. A person who always rejoices is often sick. 65. A person who always grieves is often sick. 66. A person who always rejoices is often sick. 67. A person who always grieves is often sick. 68. A person who always rejoices is often sick. 69. A person who always grieves is often sick. 70. A person who always rejoices is often sick. 71. A person who always grieves is often sick. 72. A person who always rejoices is often sick. 73. A person who always grieves is often sick. 74. A person who always rejoices is often sick. 75. A person who always grieves is often sick. 76. A person who always rejoices is often sick. 77. A person who always grieves is often sick. 78. A person who always rejoices is often sick. 79. A person who always grieves is often sick. 80. A person who always rejoices is often sick. 81. A person who always grieves is often sick. 82. A person who always rejoices is often sick. 83. A person who always grieves is often sick. 84. A person who always rejoices is often sick. 85. A person who always grieves is often sick. 86. A person who always rejoices is often sick. 87. A person who always grieves is often sick. 88. A person who always rejoices is often sick. 89. A person who always grieves is often sick. 90. A person who always rejoices is often sick. 91. A person who always grieves is often sick. 92. A person who always rejoices is often sick. 93. A person who always grieves is often sick. 94. A person who always rejoices is often sick. 95. A person who always grieves is often sick. 96. A person who always rejoices is often sick. 97. A person who always grieves is often sick. 98. A person who always rejoices is often sick. 99. A person who always grieves is often sick. 100. A person who always rejoices is often sick.
"A SOVEREIGN STATE."

An important conference of health officers of several of the Southern States was recently held at New Orleans for the purpose of considering rules for the uniform regulation of quarantine on the Gulf coast. During the conference a representative from Tennessee offered a resolution to memorialize Congress to invest the National Board of Health with authority and means as a medium of interstate quarantine. In the discussion which followed, the President of the Louisiana State Board of Health, with old-time assurance, informed the conference that Louisiana was "a sovereign State" and could take care of herself. The proposition was lost by the following vote, viz.: Ayes, Mississippi and Tennessee; noes, Louisiana, Texas, Alabama, and Florida. This action of the conference is a curious illustration of the influence which local quarantines have upon the opinion of health officers as to the sovereignty of the States which control them. On the contrary, States located in the interior and on the great lines of travel, and which must depend for their protection against foreign pestilences on the power of the seaboard States to prevent their invasion and spread, avail themselves of every possible means and aid to protect their people from the devastations of these epidemics. To the latter the sovereignty of the State is an idle and meaningless phrase in their organization against a common foe that knows no State lines in its triumphal march.

It is not surprising that the health officers of Tennessee feel deeply on the subject of protection from yellow fever. Situated as that great State is, in the very heart of the South, it is peculiarly subject to invasion by a contagious or infectious disease of foreign origin which passes the quarantine of the Gulf or South Atlantic coasts. And her experience proves that her health authorities are not too anxious nor too strenuous in their efforts to throw around the State impregnable defences against the further invasions of wide-spread epidemics, and especially of that most dreaded of all preventable plagues, yellow fever. Three times within a generation has this terrible scourge passed the quarantines of the Gulf and swept over the fairest portions of Tennessee like the besom of destruction. Within the last decade we have heard intelligent citizens of the Western part of that State discuss the question of the propriety of occupying their homes only during the winter months.

When it is remembered that this scourge of her people, this blight upon her material prosperity, has so many times and so recently reached Tennessee through the gateway of the Mississippi Valley—the Louisiana quarantine—it seems to us a matter of prudence and wise foresight on the part of her representatives in the conference, not only to invoke the co-operation of other States, but also of the general Government, in a common effort to prevent the spread of an epidemic from one State to another. And it is presumptuous on the part of the health authorities of the State of Louisiana to assert her sovereignty and her ability to take care of herself in the presence of that monarch pestilence of the tropics, yellow fever, which knows no metes or bounds of human empire and laughs to scorn the sovereignty of States. But even admitting the claim that Louisiana can take care of herself in the management of epidemics, why should she prevent another State from securing protection from the wide dissemination of the seeds of pestilence which have passed through her quarantine and been scattered broadcast through the Valley of the Mississippi? But the history of yellow fever gives multiplied proofs that the Louisiana State Board of Health never has been so powerful and so vigilant that either the people of that State or of the Valley States could rely implicitly upon its ability to protect them from that scourge of the tropics. If, indeed, we may trust the reports of the New Orleans Auxiliary Sanitary Association, we have grave doubts as to the ability of the State Board of Health to take care of the sanitary interests of New Orleans.

A citizen recently made an inspection of a small area of that city with his eyes open and nose well poised. He is a clergyman—therefore truthful, and has travelled much in oriental cities—and is familiar with the sight of filth and the odor of putrefaction. He declared at a recent meeting of the Association that, in all his experience at home and abroad, he never witnessed filth, nor about the houses of the people, greater in amount and more disgusting in quality, and that it exceeded by far anything he had known in any city on the globe. He proposed in future comparisons to substitute "more filthy than Clio Street" for any saying hitherto employed expressive of extreme filthiness.

New Orleans has much at stake during the coming season, and she cannot be too cautious about her public health and the healthfulness of the State and city. Let but the breath of rumor or suspicion that yellow fever is present or even threatens New Orleans get abroad, and her International Exhibition will be limited to that one "sovereign State."

AN OPPORTUNITY FOR AMERICAN PATHOLOGISTS.

At the banquet in Berlin, tendered to Dr. Koch on the return of the cholera commission, that eminent and successful investigator was called upon for a speech. In his response allusion was modestly made to the results of the commission's work, and the suggestion was put forth that, by a similar course of investigation, the germ of yellow fever and other infectious diseases might be found. It would be naturally inferred from the tenor of the remarks that Dr. Koch and his assistants held themselves ready to visit some part of the new world and hunt down, for example, the hypothetical parasite of yellow fever. If this duty should be assigned them, they
would, no doubt, be cordially welcomed and efficiently assisted. But it would be a little odd, with our National Board of Health, and our numerous State and municipal sanitary organizations, to see a few foreigners in our midst looking for, and perhaps discovering, the germs that have so far eluded us.

Yellow fever is the bane of American seaports in the summer. It interferes with our commerce, and at intervals spreads death and disaster among the people. As a country we are especially interested in finding the specific organism of this disease, if such exists. Are there no investigators among us competent, and no State or other organization willing to undertake a thorough study of the disease, using the methods adopted abroad? Or must we wait for Dr. Koch to come, capture the bacillus in a few months, and then return to be fitted and decorated with more medals at Berlin?

We write this while aware that reports (whose authenticity is, however, questionable) are published to the effect that the organism of yellow fever has already been discovered.

MICROCOCCI UNDER THE FLOOR.

We find it stated in the Medical Press and Circular that Dr. Rudolf Emmerich, assistant in the Hygienic Institution, Munich, some time ago discovered the encapsuled micrococci (Friedländer's) which are said to be characteristic of pneumonia under the flooring of a prison at Amberg. He subjected them to pure cultivation experiments, which gave the result that they really were Friedländer's cocci. He considers that the cause of an epidemic of pneumonia that ravaged the prison in 1880, and from which forty-six out of one hundred and sixty-one inmates succumbed, is now made plain. He examined the corresponding parts of houses that were free from disease, and in these failed to find a fungus similar to that discovered in the prison.

Such a discovery as this is somewhat startling, and, assuming the correctness of Dr. Emmerich's conclusions, may well tend to excite misgivings as to the possibility of ever thoroughly disinfecting a room or a house in which a person sick with contagious disease has been. But as regards Friedländer's diplococci, it is as yet by no means proven that they are characteristic of pneumonia. In a communication made to the recent German Surgical Congress, Dr. Schüller stated that he had found these identical organisms in a case of metastatic arthritis occurring in scarlet fever. Strange coincidences are constantly occurring and will continue to occur at the end of time, and the association of the micrococi of Friedländer with pneumonia may possibly be found to be but another illustration of this fact.

A WORD CONCERNING VACCINATION.

It does seem superfluous at this late day to bring forward any new facts in support of the value and necessity of vaccination. Still, the anti-vaccinationists are not all dead yet, and until they are it seems but an act of charity to adduce fresh proof from time to time in the hope, vain though it may be, of converting some of them. It is, of course, well understood, though our anti friends seem often to be unaware of it, that the protection afforded by vaccination may be weakened or entirely lost after a lapse of years, and hence arises the necessity of revaccination. An editorial in a recent number of the London Lancet on this subject has called forth a letter from Mr. Herbert Gonde, Resident Surgeon of the Small-pox Hospital, Highgate Hill, in which the most conclusive evidence of the prophylactic value of vaccination is adduced. It is the custom in this hospital to revaccinate all the employees as soon as they enter upon their duties, whether they show the marks of a previous vaccination or not. Mr. Gonde writes: "We have now an unbroken record of forty-eight years during which no nurse or servant of the hospital has contracted small-pox, even in a modified form. The only exception to this rule was in the case of an assistant gardener, who was hired in 1881; this man refused to be revaccinated, caught small-pox, and died." It seems incredible that any sane man can, in the face of such evidence as this, continue in the honest belief that vaccination does not protect against small-pox. Doubtless there are many facts which at first sight seem to justify the opponents of vaccination in the stand which they take. Cases are by no means rare of small-pox occurring in subjects who have been cut for the cowpox, but the fault lies not in the principle, but in an imperfect vaccination, or in a weakening of the protective influence through lapse of time. No doubt also accidents sometimes occur from the inoculation of impure virus, or even from the slight scratch of the skin by the lancet, just as grave accidents sometimes follow other trivial causes. But there surely are no arguments against the protective value of the operation. Possibly some of these evil effects might be obviated by following the method proposed by Dr. Bourgeois, of a subcutaneous introduction of the virus by means of a modified hypodermic syringe. There can be no question that many physicians are too careless about vaccination and do not take pains enough to assure themselves that the operation has been successful. In this they inflict a double wrong—on their patients by inspiring them with confidence in a fancied security which they do not possess, and on the cause by bringing discredit upon vaccination itself as a certain prophylactic against small-pox.

IS MORPHINE DANGEROUS IN CARDIAC DISEASE?

From time to time we are shocked to hear of the sudden death of a person, soon or immediately after the hypodermic use of morphine, given probably for the relief of severe pain. Subsequent autopsical examinations have then repeatedly shown the existence of grave organic lesions of some important organ or system, which was either overlooked by the physician in charge, or having been clearly recognized, was not held to contra-indicate the hypodermic use of morphine. Accidents of this kind would seem to be particularly frequent where renal disease is present. In chronic heart disease a disastrous result appears to be likewise a quite possible consequence of employing so potent and rapidly acting a drug.

In a recent number of the Centralblatt für Nervenheilkunde, Dr. Runeberg reports a case in which a calamity of this kind occurred. The patient was a strong man, forty years of age, to whom, during an attack of angina pectoris, an injection of one-fifth grain of morphia was given. About
two minutes later the man gave a sudden start, opened his eyes, and died. The autopsy revealed extensive sclerosis of the coronary arteries, with softening of a portion of the cardiac muscle. Although such a condition rendered the patient liable to sudden death at any moment, yet Dr. Runeberg wisely suggests that the lethal issue was at least hastened by the morphine administered. Dr. Israel has recorded a somewhat similar experience, where death followed the injection of only one-eighth of a grain. In this case the patient suffered from cardiac insufficiency, associated with renal disease. These and numerous other instances of the same kind, recorded and unrecorded, are so striking as to render the theory of a coincidence, to say the least, improbable. And it therefore behooves us to exercise the utmost caution in the administration of morphine to patients suffering from grave cardiac lesions.

And this particularly as morphine, in proper cases of heart disease, is an altogether invaluable remedy, that may be just as potent for good as it seems to be capable of effecting evil. The subject is well worthy further careful study, in order that we may learn with more accuracy just what constitutes the contra-indications for its employment.

WHAT CONSTITUTES "SOUND HEALTH." The term "in sound health," used in many life insurance policies, and which the companies often hold to be an absolute guaranty of freedom from all disease, is construed by the courts much less strictly.

In a recent case, in a Western State, it was held as follows: "It would be most unreasonable to interpret the term "in sound health," as used in contracts for life insurance, to mean that the insured is absolutely free from all bodily infirmities or from all tendencies to disease. If that were its meaning, we apprehend but few persons of middle age could truly say they were in sound health. Yet, to obtain a life insurance a person must say that or its equivalent. It is absurd to suppose that Mr. Morrisan intended to say in his application that he had no bodily infirmity, and was aware of no tendency to disease or that the company so understood him. Many cases have been adjudicated, which give construction to the term "good health" or "sound health" (which means the same thing), as those terms are used in contracts for life insurance. Some of these cases are referred to in May, Insurance, § 295. They all seem to sustain the conclusion we have reached, that "a touch of dyspepsia coming on," which manifests itself only after long intervals, which yields readily to medical treatment, and which is not shown to have been (as some of the cases put it) organic and excessive, is not inconsistent with a representation that the person so affected is in sound health, as that term is employed in contracts for life insurance."

TROUBLE IN HOSPITAL MANAGEMENT IN FRANCE. We had occasion several months ago to comment upon the expulsion of the Sisters from the Paris hospitals, and we then predicted that it would not be long before the unwisdom of such a step would be made manifest. But the hour of retribution has come even sooner than we anticipated. M. Charles Quentin, the director of the Conseil de l'Assistance Publique, recently addressed a confidential circular to the officers, lay and medical, of the different hospitals, wherein he complains of the lax discipline which now prevails in these institutions, and especially bewails the frightful increase in expenditures. With a degree of coolness that would make a Laplander shiver, he throws the entire responsibility for this changed condition of affairs upon the attending physicians and surgeons. In order to give greater weight to his accusations he cites two cases. One patient was receiving soup, meat, and vegetables twice a day, with a pint of vin ordinaire as his regular diet, and in addition was said to be taking as extra diet three pints of wine, three eggs, coffee, and about eight ounces of rum. Another was down on the extra diet list for over six pounds of meat per diem, in addition to a liberal supply of eggs and milk. But M. Quentin proves too much with his examples of wasteful extravagance. For no one can imagine a medical man ordering over six pounds of meat in addition to a quantity of other food for one patient; but it is very possible for one of the subordinates into whose hands the diet list is given to add a cipher, and thus convert an order for 300 grammes (about three-fourths of a pound) into one for 3,000 grammes (nearly seven pounds). The circular having in some way been made public, M. Després has taken up the cudgels in behalf of the medical staffs, and tells M. Quentin very plainly where the fault lies. The over-zealous gentlemen who drove the Sisters out of the hospitals are now, he says, beginning to reap what they have sown. And instead of a body of religious women who served without pay and asked only for the necessities of life, they have now to deal with a set of unscrupulous nurses who are "on the make" purely and simply, and have no interest in their work except for what it will bring them in the way of salary and perquisites. It must be remembered that these people are of a very different stamp from the professional nurses in this country, who as a class are capable, conscientious in the discharge of their duties, and kind to the patients under their charge. The French lay-nurses were recruited at short notice in large numbers to supply the places of the expelled Sisters, and naturally were ignorant of the duties required of them, and in general possessed of none of the qualifications necessary for filling so responsible a position. M. Després, who can hardly be accused of clericalism, took but little pains to conceal his disgust for the whole proceeding, and one need not be a prophet, nor the son of a prophet, to foresee that the general dissatisfaction with the present hospital management will in time compel a return to the old order of things. And the return of the good Sisters will be hailed with joy by the poor patients even more than by the doctors.

DEATH OF DR. A. BLONDEAU.—The death of Dr. Blondeau, member of the editorial staff of Le Progrès Médical is announced.

FRENCH CONGRESS OF SURGERY.—The Paris Surgical Society has voted to arrange for an Annual Congress of French Surgeons. America, Germany, and Italy, now have such organizations.
News of the Week.

The Health Exhibition in London is a decided success. Over 50,000 visitors are present on some days.

Medical Paris.—At the meeting of the Académie de Médecine, May 27, 1884, M. Luys took up again the subject of the "Movements of the Brain." His conclusions were: 1. That there is a free space between the brain and the skull which is filled with cephalo-rachidian fluid. 2. The brain moves in this space in accordance with the attitudes of the body. M. Verneuil read a paper upon "Pleurale Effusion in Consequence of Removal of Tumor of the Breast." Two patients with scirrhus of the breast were operated upon and both died. Autopsy showed pleural effusion on the affected side and renal disease. The relation of the effusion to the renal disease and the operation were discussed. M. Verneuil thought that the operation excited the pleurisy. In the Société Medecale des Hôpitaux the discussion on the treatment of diphtheria with vapor of turpentine and eucalyptus was continued at its session May 23d. Nothing very positive seems to be developed. M. Graucher made a report upon the micro-organisms of ulcerative endocarditis which he has isolated and cultivated.

The Death of Dr. J. G. Adams, of New York.—The profession will be pleased to hear of the death of Dr. J. G. Adams, which occurred in Liverpool last week. Dr. Adams was born in New York, August 12, 1807. John Adams, his father, was for many years the president of the Fulton Bank and a prominent business man. Dr. Adams was at one time a physician in the New York Hospital, but was never in general practice. He contributed extensively to medical journals and was once the editor of one of them. He also wrote the biographies of a number of eminent medical men, among them those of Dr. Jacob Harson, Dr. Alexander H. Stevens, his preceptor in surgery in the College of Physicians and Surgeons of the City of New York, and of Dr. Edward Langdon Beadie. Dr. Adams was an extensive traveller, especially in Egypt. He sailed for Liverpool on May 24th, in the Servia, and on the passage was taken ill. On his arrival in Liverpool he was carried to the Adelphi Hotel, where he died. In the earlier days of his life he was a student at Columbia College, and left Columbia for Yale, where he was graduated a B.A. in 1826, and in 1829 took the degree of A.M. In 1832-3 he graduated from the College of Physicians and Surgeons. He was in 1836 the president of the Medical and Surgical Society of New York. At one time he was the vice-president of the New York Academy of Medicine. In 1873 he was the vice-president of the New York Society for the Relief of the Widows and Orphans of Medical Men. He was a trustee of the New York Dispensary in 1874, and at the time of his death was a member of the Medical Society of the State of New York.

The late Dr. Willard Parker.—At the adjourned quarterly meeting of the Trustees of the College of Physicians and Surgeons, New York, held June 13, 1884, the following preamble and resolutions were unanimously adopted, and the Registrar was directed to send a copy thereof to The Medical Record:

Whereas, Dr. Willard Parker, a late member of this Board, has been recently removed by death, after a long life of usefulness, both as Professor and practitioner of Surgery, and as Trustee and Vice-President of the College; therefore,

Resolved, That this Board do now express its high appreciation of the ability, energy, and untiring faithfulness of Dr. Parker in the performance of his duties as teacher; of his earnest devotion to the interest and prosperity of the institution, and of his valuable services as adviser and manager in the administration of its affairs; also,

Resolved, That in Dr. Parker the College of Physicians and Surgeons has lost a firm and constant supporter of its professional reputation; a most efficient aid in the formation and execution of plans for its improvement, and a teacher and colleague of unsurpassed merit, of acknowledged eminence, and well-deserved popularity.

John C. Dalton, M.D., President.
Ellsworth Eliot, M.D., Registrar.

The Appearance of Cholera in France and China.—A week ago (June 21st) it was announced that cholera had appeared at Toulon, France. The first death occurred, it is believed, on June 4th, and from that time till the 22d seventeen deaths had taken place. Fourteen new cases and eighteen deaths were reported on the 23d. It is supposed that the disease was brought to France by troops returning from Egypt. All the European governments have taken steps to prevent the introduction of cholera into other ports. Cholera is also reported to have broken out in the neighborhood of Fekin, and at Tokio.

The Umbrellas of Lulu Hurst.—Our esteemed correspondent, Dr. Jordan, of Columbus, Ga., writes that he does not think the criticism made upon Lulu Hurst's peculiar force correct. He writes: "When the girl catches the handle of an umbrella, and holds it for five to twenty seconds—the scientific investigators twenty feet away—until it is torn to pieces, tell me, I pray, who is hypnotized, the girl or the umbrella? A chair is also caused to move when no one but the girl is in contact with it. In order to assert your theory you utterly ignore these facts." We shall be glad to see a careful record of the exercise of Lulu Hurst's force upon isolated umbrellas and chairs, with tests to show that no human muscles contract when the phenomena are exhibited.

Conviction for Abortion Possible in Ohio.—The editor of the Cincinnati Lancet and Clinic, referring to this subject as raised by the Columbus Medical Journal, says: "All of which reminds us of the ways of the courts in Cincinnati, until a little reflex back-action business was instituted on the part of the people that has had a wonderful result in its effect on our legal tribunals, so that we are at this time justified in saying to the Columbus Medical Journal that a doctor of the baser sort has recently been convicted in Cincinnati of the crime of committing abortion, and has actually been sentenced to a long term of imprisonment in the penitentiary, where he is now doing the State service."
Army Items.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 15 to June 21, 1884.

Haffesert, J. C. G., Major and Surgeon. Granted leave of absence for four months. S. O. 141, par. 5, A. G. O., June 18, 1884.

Power, J. Y., Captain and Assistant Surgeon. From Fort Ringgold, Tex., to Fort Brown, Tex., as Post Surgeon. S. O. 73, Headquarters Department of Texas, June 9, 1884.

Maddox, T. J. C., First Lieutenant and Assistant Surgeon. From Fort Clark, Tex., to Fort Ringgold, Tex., as Post Surgeon. S. O. 73, Headquarters Department of Texas, June 9, 1884.

Black, C. S., First Lieutenant and Assistant Surgeon. From Fort Concho, Tex., to Fort Clark, Tex. S. O. 73, Headquarters Department of Texas, June 9, 1884.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 21, 1884:

The report of the Section on Surgery, Nebraska State Medical Society, has just been received. The report was made at the Society’s session in May last. It is an unusually full one, and the Western enterprise which gets it out so soon is entitled to recognition.

An Unjust Spite Against Pigs.—A board of health in an English town had a spite against pigs, and not long since passed an ordinance that no animal of that kind should be kept within fifty feet of a dwelling-house. This ordinance at once created great opposition, and in a suit to test its legality the court held that the board of health had exceeded its authority.

The New French Codex, of French National Pharmacopœia, is said to be full of errors and is being severely criticised. A supplement will probably be issued containing corrections. The fact is of interest in view of the recent unsuccessful attempt to “boom” a national governmental pharmacopœia for this country. In France it is necessary by law that physicians prescribe according to the last adopted pharmacopœia.

To Prevent Conception.—The Australian Medical Gazette gives some of the methods employed by the aborigines of Central Australia to prevent conception. One mode is to make an opening into the male urethra just anterior to the scrotum; another is to split up the entire urethra, so as to entirely destroy the urethral canal from the scrotum to the base of the glans penis.

To Prevent Sore Throat.—A gargar of strong black tea and used cold, night and morning, is now the fashionable preventative in London against falling a victim to sore throat during the cold winds of the spring.

Chloroform Narcosis During Sleep.—Dr. C. B. Taylor writes to the British Medical Journal: “Some years ago I was consulted by the parents of an exceedingly nervous girl, seven years of age, who was suffering from hypermetropia and double convergent squint. The agitation of the child and consequent distress of the parents at the idea of any surgical interference were so great, that they thought it would be better to employ chloroform, and, after dismissing the patient with some reassuring remarks, arranged that this should be done the same night. Accordingly, about ten o’clock, when the child was fast asleep, I administered chloroform without disturbing her, and performed the operation on both eyes, replacing her in bed while still insensible. The anesthetic was gradually worn out without any secon,” which had never been broken; there was no vomiting, and the child did not wake until the following morning at the usual hour. There was no pain; and her alarm on finding that her eyelids were bloodshot when looking in the glass, was allayed by suggesting that she had caught cold. She made an excellent recovery. The deformity was quite removed, and she was suspected that she had undergone any operation at all.”

The Skriljevo.—Under this fearful name syphilis has existed as an endemic since the end of the last century along the coast of Croatia and Dalmatia. It is supposed to have been introduced there by sailors. All efforts looking to the extermination of the disease have hitherto been unavailing, owing to the scarcity of physicians and the want of money and poverty of the people. A new law, proposed in the Reichsrath to appropriate 30,000 florins to defray the expense of transportation and board in hospital for three months of some five hundred syphilitic patients. A clause in the bill provides for the compulsory incarceration in hospital of all those affected, and this, says the Weiner Medizinische Wochenschrift, is the most important part of the bill, and if it be carried, the appropriation would remain unexpended, owing to the repugnance of the sufferers to undergo hospital treatment. One would imagine that anybody afflicted with skriljevo would seek to be rid of it as soon as possible, and it is only to be hoped that those suffering from the laryngeal manifestations of the disease are not compelled to demonstrate the name—such an effort would certainly increase their misery.

Rectal Etherization.—The New York correspondent of The Weekly Medical Review writes concerning rectal etherization as follows: “An adult patient in one of the largest hospitals in this city died two hours after the etherization. On examination the gut was found ruptured at the site of an ulcer, showing that the rapid distention which often occurs is dangerous, especially in a weakened condition of the intestinal canal. Another patient presented alarming symptoms on the operating table, as cyanosis, feeble heart-action, pallor, etc., after the ether-tube had been removed after ten minutes trial, with no anesthesia produced in that time, indicating that the ether in the intestine was absorbed suddenly and rapidly. This patient lingered long with diarrhea, bloody stools, etc., and died at the end of three weeks from new haemorrhage. Other cases have presented alarming symptoms of exhaustion and bloody diarrhea, and had the operations been grave, these, added to the shock of the operation, would undoubtedly have proved fatal in many of the cases. It is a noteworthy fact that those who have had the most experience of all in this country is but limited, are the most cautious and guarded in its praise or approval, and while recognizing its usefulness in operations about the face, still consider it of limited range of application and attended with considerable danger.”
